Hydrogen peroxide (35% PEROX-AID®)	Salmon, trout, and esocid eggs	Control fungi of the family saprolegniaceae
	Freshwater-reared finfish eggs	Control mortality due to saprolegniasis
	Freshwater-reared salmonids	Control mortality due to bacterial gill disease (<i>Flavobacterium branchiophilum</i>)
	Freshwater-reared coolwater finfish and channel catfish	Control mortality due to external columnaris disease (<i>Flavobacterium columnare</i>)
Oxytetracycline hydrochloride (OxyMarine, Oxytetracycline HCl Soluble Powder-343®, Terramycin-343 Soluble Powder, PENNOX 343, TETROXY Aquatic)	Finfish fry and fingerlings	Mark skeletal tissues, most often otoliths, of finfish fry and fingerlings for identification purposes
Tricaine methanesulfonate (Tricaine-S®)	Fish, amphibians, and other aquatic poikilotherms	Temporary immobilization

TABLE 7 FDA-APPROVED DRUGS FOR AQUACULTURE USE IN THE USA (2014) (*continued*)

Dosage Regimen	Comments
IMMERSION	
Tanks and raceways: salmon and trout: above 50°F: up to 170 µL/L for up to 1 hr; below 50°F: up to 250 µL/L for up to 1 hr. All other finfish: up to 250 µL/L for up to 1 hr Earthen ponds: 15–25 µL/L indefinitely	Drug must not be subjected to temperature <40°F. Do not apply to ponds when water is warmer than 80°F, there is a heavy phytoplankton bloom, or dissolved oxygen is <5 mg/L. Ponds may be re-treated in 5–10 days if needed. Do not treat ponds containing striped bass. Test on a small number from each lot to check for any unusual sensitivity to formalin before proceeding.
All finfish eggs: 1,000–2,000 ppm for 15 min; <i>Acipenseriformes</i> : up to 1,500 ppm for 15 min	Preliminary bioassay should be conducted to determine species sensitivity.
Tanks and raceways: 50–100 µL/L for up to 4 hr daily Earthen ponds: 25 µL/L as single treatment	Drug must not be subjected to temperature <40°F. Do not apply to ponds when water is warmer than 80°F, when there is a heavy phytoplankton bloom, or when dissolved oxygen is <5 mg/L. Ponds may be re-treated in 5–10 days if needed.
1,000–2,000 ppm for 15 min	Preliminary bioassay should be conducted to determine species sensitivity.
Coldwater and coolwater: 500–1,000 mg/L for 15 min in a continuous flow system daily on consecutive or alternate days until hatch Warmwater: 750–1,000 mg/L for 15 min in a continuous flow system daily on consecutive or alternative days until hatch	Initial bioassay on a small number is recommended before treating entire group.
100 mg/L (30 min) or 50–100 mg/L (60 min) daily on alternate days for 3 treatments	Initial bioassay on a small number is recommended before treating entire group.
Fingerling and adults (except northern pike and paddlefish): 50–75 mg/L (60 min) daily on alternate days for 3 treatments Fry (except northern pike, pallid sturgeon, and paddlefish): 50 mg/L (60 min) daily on alternate days for 3 treatments	Use with caution on walleye. Initial bioassay on a small number is recommended before treating entire group.
200–700 mg oxytetracycline hydrochloride (buffered) per liter of water for 2–6 hr	
15–330 mg/L (fish) 1:1,000 to 1:20,000 (other poikilotherms)	Powder is added to water; concentration depends on desired degree of anesthesia, species, size, water temperature and softness, stage of development. Preliminary tests of solution should be made with a few fish; 21-day withdrawal time (fish); laboratory or hatchery use only in other poikilotherms; water temperature >50°F (10°C)

TABLE 7

FDA-APPROVED DRUGS FOR AQUACULTURE USE IN THE USA (2014) (continued)

Drug	Species	Indications
INJECTABLE		
Chorionic gonadotropin (Chorulon®)	Male and female brood finfish	Help improve spawning function
MEDICATED ARTICLE/FEED		
Florfenicol (Aquaflor®)	Freshwater-reared finfish	Control of mortality due to enteric septicemia of catfish associated with <i>Edwardsiella ictaluri</i> , streptococcal septicemia in freshwater-reared warmwater finfish, columnaris disease in freshwater-reared finfish
Oxytetracycline dihydrate (Terramycin-200® for Fish)	Pacific salmon	Mark skeletal tissue, most often otoliths, of finfish fry and fingerlings for identification purposes
	Freshwater-reared salmonids	Bacterial coldwater disease (<i>Flavobacterium psychrophilum</i>)
	Scaled warm freshwater-reared finfish	Control bacterial hemorrhagic septicemia (<i>Aeromonas liquefaciens</i>) and pseudomonas disease (<i>Pseudomonas</i>)
	Cool freshwater-reared finfish	Control bacterial hemorrhagic septicemia (<i>Aeromonas liquefaciens</i> , furunculosis (<i>Aeromonas salmonicida</i>), and pseudomonas disease (<i>Pseudomonas</i>)
	Lobster	Control gaffkemia (<i>Aerococcus viridans</i>)
Sulfadimethoxine-ormetoprim (Romet-30®)	Salmonids	Control furunculosis (<i>Aeromonas salmonicida</i>)
	Catfish	Control enteric septicemia (<i>Edwardsiella ictaluri</i>)
Sulfamerazine	Rainbow, brook, and brown trout	Control furunculosis (<i>Aeromonas salmonicida</i>)

Note: This is an abbreviated summary. For complete labeling, see the package insert. Approval applies only to the specific drug that is the subject of a new animal drug application (NADA); active ingredients from other sources (eg, a bulk drug from a chemical company or similar compounds made by companies other than those specified in the NADA) are not approved new animal drugs. Approval applies only to use of the drug for the indications and manner specified on the label.

TABLE 7

FDA-APPROVED DRUGS FOR AQUACULTURE USE IN THE USA (2014) (continued)

Dosage Regimen	Comments
INJECTABLE	
50–510 IU/lb males; 67–1,816 IU/lb females	IM injection up to 3 doses; total dose not to exceed 25,000 IU in fish intended for human consumption; restricted to use by or on the order of a licensed veterinarian
MEDICATED ARTICLE/FEED	
10 mg/kg/day for 10 consecutive days	Veterinary Feed Directive drug; 12-day withdrawal time
250 mg/kg/day for 4 days	Salmon <30 g; in feed as sole ration; 7-day withdrawal time
2.5–3.75 g/100 lb/day for 10 days	In mixed ration; water temperature not <48.2°F; 21-day withdrawal time
2.5–3.75 g/100 lb/day for 10 days	In mixed ration; water temperature not <62°F; 21-day withdrawal time
1 g/lb medicated feed for 5 days	In feed as sole ration; 30-day withdrawal time
50 mg/kg/day for 5 days	In feed; 42-day withdrawal time
50 mg/kg/day for 5 days	In feed; 3-day withdrawal time
10 g/100 lb/day for up to 14 days	In feed; 21-day withdrawal time; not currently available

Antibiotics: Antibiotics can be delivered to pet fish through any of the treatment routes listed; however, medicated food is most common and usually most effective. Common antibiotics used in pet or ornamental fish include oxytetracycline, potentiated sulfa drugs, and enrofloxacin

(in koi and exhibit fish). For approved dosages and withdrawal times, see TABLE 7. Oxytetracycline (Terramycin® 200) can be fed at a dosage of 55–83 mg/kg/day for 10 days to control many gram-negative bacterial infections, including columnaris disease. Because oxytetracycline has been

on the market for many years, there may be significant resistance to it in some bacterial isolates. Romet®-30 (sulfadimethoxine and ormetoprim) also is effective against many gram-negative organisms, with less resistance. Palatability can be a problem when feeding medicated food to sick fish, which may have a poor appetite.

Florfenicol is available as Aquaflor® for use in medicated feed (see AQUACULTURE, p 1743).

Erythromycin is not FDA approved for use in fish but is an excellent antibiotic for fish infected with gram-positive bacteria, particularly *Streptococcus*. Erythromycin can be fed at a dosage of 100 mg/kg/day, for 14 days. Palatability may be a concern with erythromycin-medicated feed. Erythromycin has been used in management of bacterial kidney disease of salmonids and streptococcal infections in food and nonfood species. FDA permission is required for use in food animals.

Delivery of antibiotics in a bath treatment is not generally recommended because of unknown or limited efficacy and damaging environmental effects (ie, antibiotics tend to kill the biofilter). Oxytetracycline (100–400 mg/L for 1 hr, daily for 10 days) has some efficacy when delivered in a bath. Oxytetracycline in a bath treatment is chelated by hard water and is therefore ineffective in marine systems. Enrofloxacin has been used as a bath at 2.5–5 mg/L for 5 hr, daily for 7 days. Water changes are recommended after the 5-hr contact time, and the drug may be chelated by hard water. Kanamycin has also been used as a bath treatment at dosages of 50–100 mg/L for 5 hr, repeated every 3 days for three treatments, with water changes recommended after the 5-hr contact time. Nephrotoxicity is a concern in fish treated with aminoglycosides. Many other options are discussed in the literature.

Injection is the most effective way to control the amount of antibiotic delivered to a fish. Enrofloxacin can be delivered IC at a dosage of 5–10 mg/kg, and the higher dosage can be repeated every third day, minimizing handling. Three treatments are generally recommended. When using enrofloxacin, the less concentrated dose (22.7 mg/mL) is recommended, even for use in large fish, because of adverse tissue reactions with the concentrated dose. If injection volume is excessive, more than one injection site can be used. Other injectable antibiotics include amikacin (5 mg/kg, IM, every 3 days for a total of three treatments). As with other aminoglycosides, nephrotoxicity may be a concern. Erythromycin (10 mg/kg/day, IM, for 3 days) can be used to treat gram-positive infections in large fish.

Use of topical ointments containing antibiotics can be practical in pet fish. Some seem to absorb fairly quickly, but if treating a substantial wound, it may be appropriate to cover it with a waterproof compound. Frequent application of antibiotic ointment (eg, twice a day) can work well to treat superficial ulcers in pet fish.

Parasiticides: Several brands of formalin (37% formaldehyde in aqueous solution, not 10% formalin used for fixation of tissues for histology) are FDA approved as parasiticides for use in finfish and penaeid (saltwater) shrimp (see TABLE 7). These products are usually used as a prolonged bath at concentrations of 15–25 mg/L. Vigorous aeration during formalin treatment is essential. A concentration of 25 mg/L is equal to 2 drops/gal. or 1 mL/10 gal. (useful for delivering formalin to aquarium fish).

Salt is categorized as of “low regulatory concern” by the FDA and has many uses in fish medicine, including destruction of single-celled protozoans and management of osmoregulation. Salinity is typically measured as parts per thousand (ppt) or g/L (1 ppt = 1 g/L). Seawater is typically 32–37 ppt salt. By increasing or decreasing the amount of salt to which a freshwater or marine fish is exposed, osmoregulatory stress can be minimized and many parasites eliminated. For freshwater fish, a 30 ppt dip for 0.5–10 min, depending on species, is an effective ectoparasiticide and is strongly recommended when moving fish. When fish show signs of distress, commonly manifested by rolling on their side, they should be removed from the bath. The use of salt is a quick and effective way to minimize the introduction of some protistans into a system with new fish. A solution of 5–10 ppt salt is recommended for transportation of freshwater fish; most species will tolerate this concentration for several hours or days. Permanently increasing salinity to 2–3 ppt in a freshwater system can minimize some parasitic protistans. Salt is not generally practical for use in production ponds, except for control or prevention of nitrite toxicity, because of their large volume, but it can be used in ornamental ponds that are not more than several thousand gal. Less information is available on lowering salinity for marine fish; however, freshwater dips adjusted for temperature and pH are often recommended when moving animals. Lowering salinity to 16–18 ppt can be very useful when treating some parasitic diseases, particularly *Cryptocaryon*.

In saltwater systems, copper is sometimes applied in a chelated form, because

it stays in concentration longer. Chelated compounds may be difficult to use safely and require careful monitoring. Copper sulfate (CuSO_4) can be used to treat marine fishes, but the concentration of active copper (Cu^{2+}) must be closely monitored (test kits are available) and should be maintained at 0.18–0.2 mg/L for up to 3 wk. When using over-the-counter products in marine aquaria, label directions should be followed. Cu^{2+} concentrations should be tested at least once a day.

Copper is extremely toxic to invertebrates and plants, which must be removed before the water is treated. Finally, copper will adversely impact the nitrifying bacteria in biofilters, and a transient increase in ammonia and nitrite should be expected for weeks to months after treatment. Monitoring of ammonia and nitrite until measurable concentrations subside is recommended.

Organophosphates have been used in nonfood fish practice for decades to control monogenea, parasitic crustaceans, and leeches. Organophosphates can be used in freshwater systems, for ornamental fishes only, at concentrations of 0.25 mg/L as an indefinite bath. Most compounds are sold as 37.3% active ingredient liquid. Toxicity and efficacy are affected by pH, with more acidic pH resulting in increased toxicity. For this reason, an increased dosage may be necessary in marine systems (pH 8–8.3), with concentrations up to 1 mg/L used by some facilities. Some veterinarians add atropine (0.1 mg/kg, PO, IM, or IC) to the food of sensitive freshwater fishes and marine exhibit fish before treatment with organophosphates. Because of environmental concerns, organophosphates should not be used in outdoor ponds, unless specific provisions for such use exist in state law and are followed by the veterinarian. After treatment with organophosphates, most facilities hold water for up to 96 hr before allowing any discharge, and divers are usually restricted from entering exhibit tanks for at least 48 hr. Organophosphates may not be used in food fish in the USA.

Diflubenzuron is a chitin synthesis inhibitor effective against anchor worms (*Lernaea*), fish lice (*Argulus*), and other crustacean parasites in aquarium fish only. It is used as a prolonged bath at concentrations of 0.03 mg/L. It has a fairly long half-life (>1 wk), and treated water should be retained for 28 days and then run through a carbon filter before discharge.

Metronidazole is used to control intestinal protozoans and can be delivered in a medicated food or as a bath when fish are anorectic. Although very effective against

Spirotrunculus spp, metronidazole does not seem to be effective against gastric infections with *Cryptobia iubilans*. A concentration of ~7 mg/L (~250 mg metronidazole dissolved in 10 gal. of water) can be administered daily for 5 days. A daily water change a few hours after treatment is recommended. Metronidazole can be administered in medicated feed at 50 mg/kg, PO, for 5 days. Metronidazole may not be used in food fish in the USA.

Fenbendazole has been used to control intestinal helminths in fish. A dosage of 25 mg/kg, delivered in food for 3–5 days, has been commonly recommended, but efficacy has not been evaluated in controlled trials. When fenbendazole has been used in a bath treatment, high mortality has occurred. Consequently, this use is not recommended. Levamisole administered in a bath treatment at a concentration of 2 mg/L is also used by some clinicians. These compounds may not be used in food fish in the USA.

Praziquantel is selective for flatworms, so consequently is used to control cestodes and external monogeneans. The most common use of praziquantel is as a prolonged bath in large marine aquaria for control of capsid monogeneans. It is applied at a concentration of 5 mg/L and may remain active for several weeks. Treated water should be run through an activated carbon filter before discharge. Praziquantel can also be administered PO at a dosage of 35–125 mg/kg for up to 3 days or as a short-term bath treatment at a concentration of 10 mg/L for 3 hr. Efficacy has been demonstrated in yellowtail kingfish fed praziquantel at a dosage of 50 mg/kg/day, for 7 days. Use of praziquantel is not permitted in food fish in the USA.

Chloroquine has been used to control *Amyloodinium* spp in ornamental marine fish. It is applied as a prolonged bath at concentrations of 10 mg/L. Efficacy in recirculating systems seems to be very good; however, there are essentially no data on treatment intervals, effects on biofilters, or other basic husbandry effects. Weekly examination of fish, including biopsy of infected tissue, is recommended to assess treatment efficacy. Some aquarists have used chloroquine (10–15 mg/L for 7 days; follow-up with 10 mg/L may be required) coupled with decreased salinity (16–18 ppt) as a treatment for *Cryptocaryon* in marine fish. Results are mixed, but advantages include decreased labor, because intensive water testing is not required (as is the case for Cu^{2+}). Use of chloroquine is not permitted in food fish in the USA. Treated water should be run through a carbon filter before discharge.

Anesthetics: Tricaine methanesulfonate (MS-222) is the most commonly used anesthetic for fish. An FDA-approved product is available. MS-222 is used to sedate, anesthetize, or euthanize fish. It should always be buffered with baking soda (sodium bicarbonate) at a ratio of 2 parts baking soda to 1 part MS-222. *See also* p 1753.

Eugenol and clove oil (an over-the-counter product, usually 84% eugenol) have become popular with pet fish enthusiasts as anesthetics. These products are not FDA approved for use in fish in the USA, and use in food animals is prohibited. When eugenol at concentrations of 50, 100, and 200 mg/L was compared with MS-222 in red pacu, it resulted in effective immobilization of fish; however, there was concern about analgesia, prolonged recovery, and a narrow margin of safety, especially at higher concentrations. Use of both MS-222 and eugenol resulted in hypoxemia, hypercapnia, respiratory acidosis, and hyperglycemia in red pacu. Aquí-S® is a product approved for sedation of fish in other countries, and it is currently being investigated in the USA as an anesthetic for non-food fish. The active ingredient is isoeugenol, but evidence of carcinogenicity in laboratory animals has caused the use of this product in any food fish to be strictly prohibited. The US Fish and Wildlife Service has an active INAD program assessing the potential use of Aquí-S in non-food fish.

Euthanasia: Veterinarians should follow the AVMA Guidelines for Euthanasia of Animals (*see* p 1641). When using overdoses of MS-222 for euthanasia, the pH should be carefully ascertained before use; the sodium bicarbonate buffering can be variable because of the type of water used to make up the euthanasia solution.

Surgical Considerations

Increasingly, surgery is an option for management of some medical problems in pet or exhibit fish, including neoplastic disease, failure to ovulate (ie, "egg bound" fish), and gas bladder repair for buoyancy problems. Fish skin does not have the subcutaneous tissue that provides flexibility to domesticated animal tissue; therefore, wounds are not usually treated by surgical closure but instead allowed to heal by second intention. The clinical evaluation before surgery is similar to that in other species, although there may be more emphasis on imaging and less on blood work. Radiology and ultrasound work very well in fish, and use of these techniques

before an invasive surgical procedure is recommended.

Descriptions in the literature show how a fish may be positioned for a surgical procedure. For smaller animals, such as koi, a foam "bed" is easily constructed and can be covered with something as simple as clear plastic wrap so that the fish does not lose skin, scales, or mucus from direct contact with the foam. The "bed" can be positioned over an aquarium using a plastic tray with holes to allow water drainage. A pump can move water containing an anesthetic solution (usually MS-222) from the aquarium through a small tube or catheter and across the fish's gills. Ideally, dissolved oxygen, ammonia, and pH should be monitored in the anesthetic solution. The fish can be covered with a clear plastic surgical drape (avian drapes work well), followed by fairly minimal preparation of the incision site. Plucking scales along the incision line and carefully cleaning the area with a sterile swab soaked in sterile saline may be all that is required. Very dilute disinfectants such as povidone-iodine or chlorhexidine can be used, but if the fish is clean this is probably not necessary (or recommended) because the normal mucus has significant antibacterial properties.

Absorbable sutures are generally not recommended in fish, because they may persist for significant periods of time (>1 yr in some cases). Monofilament material and a needle with a cutting edge generally work well. The simple interrupted suture pattern works well to close fish skin, but other techniques can be used successfully. Skin sutures should be removed when the incision site has healed, generally at 3–4 wk. Surgical staples have been used successfully in fish. Results using cyanoacrylate tissue adhesive have been mixed because of a significant inflammatory reaction seen in some species. If postoperative antibiotics are used, enrofloxacin delivered via IC injection at a dosage of 5 mg/kg is a good option but can only be given to non-food fish. Butorphanol given at 0.1–0.4 mg/kg, IM, and meloxicam at 0.15 mg/kg, IM, have been used for postoperative pain control in non-food fish. Increasing the salinity in freshwater systems to 1–3 ppt (g/L) is strongly recommended during the recovery and healing periods. Most freshwater fish should be able to tolerate a salinity of 3 ppt (3 g/L) on an almost indefinite basis.

Quarantine and Biosecurity

Quarantine is strongly recommended for pet fish and certainly for animals intended

for display in public aquaria. A 30-day period is the minimum time for quarantine, but longer periods may be necessary. Quarantined animals should be handled only when contact with all other animals is finished for the day. Quarantined animals should have their own designated equipment (ie, nets, buckets, siphons, etc) and be kept separate from other animals. Disinfectant should be used on equipment and in footbaths at entry points to the quarantine area.

When receiving fish, a thorough history should be obtained regarding previous treatment or disease outbreaks. Fish should be examined early in the quarantine period; a visual examination may suffice, but for valuable specimens a full clinical examination, including recording the weight of the animal and completing gill, skin, and fin biopsies, is recommended. Moribund fish should be examined, and dead fish necropsied. Prophylactic use of antibiotics may be warranted in some shipments, especially recently imported marine specimens. Treatment with praziquantel for monogeneans is often prudent with marine fish as well. Goldfish commonly have significant monogenean infestations, and treatment with formalin or praziquantel may be appropriate. Koi should be quarantined to prevent introduction of koi herpesvirus (KHV), a serious and reportable disease, to established populations. Koi should be quarantined for a minimum of 30 days at a temperature of 75°F (24°C). Fish that become ill during quarantine should be tested for KHV (*see* p 1812).

Quarantine is not useful for some pathogens, but that does not mean it should not be done. Examples are mycobacteria, which at this time cannot be detected with nonlethal tests, and many viruses, microsporidia, and myxozoans. These diseases are usually detectable using necropsy techniques if quarantined animals that die are thoroughly examined. Quarantine is most useful for detection of external parasites and some internal parasites that can be detected by examination of feces.

Biosecurity for the Home Aquarium:

For a modest investment, a hobbyist can set up a quarantine tank using an inexpensive 10-gal. tank, sponge filter, small aeration pump, and heater. Once fishes have cleared quarantine, the tank and equipment should be disinfected and stored dry until needed again. During the quarantine period, separate nets and siphon hoses should be used exclusively for the quarantine tank.

Before purchasing new fish, the hobbyist can run the previously disinfected sponge filter in an established tank that is free of disease to inoculate the sponge with nitrifying bacteria. This practice will help avoid the common water quality problems that occur in newly set up aquaria.

Common Water Quality Problems in Hobbyist Aquaria

New tank syndrome (*see* p 1775) usually occurs within the first 6 wk after a new fish hobbyist sets up a tank. Owners may report everything was fine for several weeks, and then the fishes suddenly become lethargic, anorectic, and frequently die. Although parasites may be present in newly purchased fishes, it is critical to perform a complete analysis on a water sample from the affected tank. Often total ammonia nitrogen (TAN) or nitrite, or both, are high enough to result in toxicity. Treatment should include decrease in feeding, water changes, the addition of chloride for nitrite toxicity, and evaluation of adequate biofiltration. It can take up to 8 wk for a biofilter in a tropical fish tank to become established. New tank syndrome can be avoided by several methods. One method, known as fishless cycling, is to completely set up the tank but with no fish addition; ammonia is added to achieve a concentration of at least 1–5 mg/L. This will initiate the “cycling” process, which should be monitored by regular testing for ammonia, nitrite, and nitrate. Once no ammonia or nitrite is present, fish can be added safely. Another method is to slowly add several fish to the tank over several months, although this can result in high ammonia or nitrite levels if not done carefully.

Old tank syndrome (*see* p 1775) can occur when water changes are small and infrequent. In some cases, no water is exchanged, and the practice of “topping off” is done by adding water to the tank to replace what has evaporated. Although this can occur in any tank, it is more frequent in tanks that are inhabited by large, carnivorous fishes. These fishes eat large, high-protein meals, frequently in the form of other fish, and consequently excrete large amounts of TAN. Consequently, the biofilter uses up bicarbonate to transform TAN to nitrite and nitrate, and the bicarbonate depletion decreases total alkalinity. This results in either a gradual or dramatic drop in pH. If the former, the fishes will adapt to the slow change often with no outward sign of distress. If the pH decline is rapid, the result could be death for the resident fishes.

The water quality parameters of total hardness, nitrate, total alkalinity, and pH are often abnormal. Total hardness (TH) and nitrate are usually significantly higher than normal. TH of the tank water should be compared with TH of the water used for water changes. Total alkalinity and pH are usually significantly lower. Often TAN will be high because of inadequate bicarbonate for the nitrogen cycle. If the fish are still alive, the water quality parameters should be returned to normal by performing daily small water changes to avoid pH shock. From that point on, the tank should receive regular, large water changes to prevent a recurrence of the problem.

NUTRITIONAL DISEASES

With so many species of fishes kept in home and public aquaria, providing good nutrition is a challenge. (See also p 2307.) A major hurdle is that nutritional requirements are known for only a handful of fish species. Given the vast diversity in fishes, it is dangerous to assume what is good for one type of fish will be good for a similar but unrelated fish. At the basic level, it can at least be determined whether the fish is carnivorous, omnivorous, or herbivorous. However, beyond that, the amount of protein and lipids required is unknown. In general, many fishes have a higher requirement for protein than other vertebrates.

Inadequate nutrition can result in poor growth, deformities, a depressed immune system, hepatic lipidosis, and impaired metabolism. Iodine deficiency can result in

thyroid hyperplasia, which has been seen in both elasmobranchs and teleosts. The condition may be caused by an overt nutritional deficiency or may be associated with chronic nitrate exposure and/or the application of ozone (see AQUATIC SYSTEMS, p 1766).

Hepatic lipidosis is a common problem seen in captive fishes and can occur for multiple reasons. Examples include starvation, a high percentage of carbohydrates in the diet, a high amount of lipids, and rancidity.

Fish require ascorbic acid, delivered in the feed. Most foodstuffs for fish should be supplemented with a stabilized form of ascorbic acid. Inadequate dietary vitamin C can result in a condition called "broken back disease" by some farmers and hobbyists. Severely affected fish exhibit extreme scoliosis. Less obvious, but detectable on wet mount examination (100×) of gill tissue, is "bent" or deformed cartilage, which may also indicate a history of ascorbic acid deficiency.

Feeding a wide variety of feeds is one way to try to meet the nutritional requirements. Live feeds can be varied with diverse commercially prepared feeds. This practice will also help prevent animals from eating only one type of feed. Fishes that feed at the surface should be fed feeds that float, whereas bottom-dwellers should be fed items that rapidly sink. The feed should be in particles easily ingested by the fish. Flaked feeds may be too large for a small-mouthed fish to easily ingest. Such feeds can be crushed to enable easy ingestion. In contrast, feeding

TABLE 8 PROTISTAN PARASITES OF FISHES

	Parasites	Tissue	Susceptible Species
External ciliates (motile)	<i>Ichthyophthirius</i> (FW), <i>Cryptocaryon</i> (SW)	Gills, skin, fins	All
	<i>Trichodina</i> (FW, SW), <i>Chilodonella</i> (FW), <i>Brooklynella</i> (SW)	Gills, skin, fins	All
	<i>Tetrahymena</i> (FW), <i>Uronema</i> (SW)	Skin, eye, muscle	All ("guppy killer")
External (sessile)	<i>Ambiphyra</i> , <i>Apiosoma</i> , <i>Epistylus</i>	Gills, skin, fins	Primarily pond fish
External flagellates	<i>Ichthyobodo</i> , <i>Cryptobia</i> (see also Internal flagellates)	Gills, skin, fins	All

flaked feed to a large fish like an oscar or other cichlid will result in a messy tank, because larger fish cannot easily ingest enough flaked feed to meet their requirements.

When feeding a mixed population of fishes, as is typical in hobbyist tanks, several types of feed items may be required to meet the needs of the fishes. Often, popular bottom-dwelling fishes such as loricariids and *Corydoras* catfish are expected to survive on the leftovers from the other fish. This is not an acceptable practice, and these fish should receive targeted feeding.

Another consideration is quantity of feed fed. Ideally, adult fishes should be fed 3% of their body weight daily for maintenance. Fry and fingerlings can be fed up to 5% of their body weight daily. Various types of feeds have dramatically different weights. For example, flaked feeds tend to be much lighter than pelleted feeds. Pelleted feeds come in different sizes and can be floating or sinking.

Most aquarium fishes should be fed at least daily, except for carnivorous fish that ingest large meals. These may be fed once or twice a week.

Careful attention must be paid to storage of feeds. Fish feeds usually have a high protein and oil content, which can deteriorate rapidly. Dry feeds should be kept in a pest-proof container and in an area of low humidity and temperature. High humidity and high temperature result in degradation of the diet, promotion of mold growth and potential mycotoxin produc-

tion, and rancidity. Many feeds can be frozen, which will prolong their shelf-life. A feed container kept at room temperature should be discarded after 2 mo of opening. Commercial feeds stored in the freezer should be discarded after 6 mo. Commercial frozen feeds such as brine shrimp, bloodworms, mysids, glassworms, etc, should be discarded after 1 yr. If thawed, these feeds should not be refrozen.

PARASITIC DISEASES

All of the major groups of animal parasites are found in fish, and apparently healthy wild fish often carry heavy parasite burdens. Parasites with direct life cycles can be important pathogens of cultured fish; parasites with indirect life cycles frequently use fish as intermediate hosts. Knowledge of specific fish hosts greatly facilitates identification of parasites with marked host and tissue specificity, whereas others are recognized because of their common occurrence and lack of host specificity. Examination of fresh smears that contain living parasites is often diagnostic.

The most common parasites of fish are protistans (see TABLE 8). These include species found on external surfaces and species found in specific organs. Most protistans have direct life cycles.

Protistans Infecting Gills and Skin

Ciliates: Ciliated protozoa are among the most common external parasites of fish. Most ciliates have a simple life cycle and

TABLE 8 PROTISTAN PARASITES OF FISHES (continued)

Signs	Diagnosis	Treatment
White spot disease; no spots visible if on gills only	Wet mount	FW—formalin, CuSO ₄ ; SW—formalin, Cu ²⁺ , decreased salinity, chloroquine (efficacy not completely demonstrated)
High respiration rate, piping, excess mucus, flashing, loss of condition	Wet mount	FW—formalin, CuSO ₄ ; SW—formalin, Cu ²⁺
Mucus, flashing, intra-ocular lesions, popeye	Wet mount	External as above; improve sanitation Internal: no treatment
Excess mucus, flashing, piping, loss of condition	Wet mount	Formalin, KMnO ₄ , CuSO ₄ , Management—decrease crowding, correct sanitation
Blue slime, flashing, piping, excess mucus, loss of condition	Wet mount	Formalin, CuSO ₄ , KMnO ₄ , salt

TABLE 8 PROTISTAN PARASITES OF FISHES (*continued*)

	Parasites	Tissue	Susceptible Species
External dinoflagellates	<i>Piscinoodinium</i> (FW), <i>Amyloodinium</i> (SW)	Gills, skin	Tiger barbs, many marine fishes, including clownfish and red drum
Internal flagellates	<i>Spiromucleus</i>	Intestine	All cichlids, bettas, gouramis, other aquarium fishes
	<i>Cryptobia iubilans</i>	Stomach	African cichlids
	<i>Trypanosoma</i>	Blood	Wild-caught Ioricariids
Coccidia	Various genera	Intestine	Multiple

Note: FW = freshwater; SW = saltwater

divide by binary fission. Ciliates can be motile, attached, or found within the epithelium. The most well-known organism in the latter group is *Ichthyophthirius multifiliis*, which has a more complex life cycle than the other ciliates.

The infection caused by *I. multifiliis* is referred to as "ich" or "white spot disease." *I. multifiliis* is an obligate pathogen that cannot survive without the presence of living fish. All fish are susceptible, and a similar appearing parasite, *Cryptocaryon irritans*, is seen in marine species. *I. multifiliis* is readily transmitted horizontally via direct exposure to infected fish or via fomites (nets, etc). Fish that survive an outbreak may be refractory in future outbreaks but may also serve as a source of infection to previously unexposed individuals. The parasite invades epithelial tissue of gills, skin, or fins, leaving a small wound and visible white spot or nodule where each parasite encysts. The organism causes substantial damage because of its unique life cycle (*see below*), which allows

a rapid intensification of infection. Infected fish are extremely lethargic and covered with visible white dots. Mortality can be rapid and catastrophic. Infections confined to gill tissue may not be recognized by nonprofessionals (because white spots are not grossly visible) but are easily diagnosed using gill biopsy techniques. The organism is identified using a light microscope at magnification of 40 $\times$ or 100 $\times$. It is large (0.5–1 mm), round, covered with cilia, and has a characteristic horseshoe-shaped macronucleus. Its characteristic movement varies from constantly rotating to ameboid-like.

Ich infections require immediate and thorough medical treatment. Formalin or copper are often drugs of choice. Over-the-counter medications for pet fish often contain formalin and malachite green and are effective but, because of regulatory concerns regarding the use of malachite green, should not be dispensed by the veterinarian. Multiple chemical treatments (with intervals determined by water temperature) are required for successful treatment of *I. multifiliis*. At warm temperatures typical of home aquaria (eg, >26°C), infected fish should be treated every 2–3 days. Constant chemical exposure for at least 3 wk is generally recommended to control *Cryptocaryon* in marine systems; lowering salinity to 16–18 ppt is often helpful.

I. multifiliis has a direct life cycle but has massive reproductive potential from each adult parasite. Adults leave the fish host and encyst in the environment, releasing hundreds of immature parasites (tomites) that must find a host within a specific time frame (days for warmwater fish, weeks for

Typical white spots characteristic of "ich" on gold sevrums. Courtesy of Dr. Ruth Francis-Floyd.

TABLE 8 PROTISTAN PARASITES OF FISHES (continued)

Signs	Diagnosis	Treatment
Mortality, lethargy, piping; "velvet" (if on skin)	Wet mount	Copper sulfate, chloroquine (nonfood fish only); freshwater dips for marine food fish
Weight loss (anorexia), mortality of fry and juveniles	Wet mount	Metronidazole (nonfood fish only)
Extreme weight loss, anorexia	Wet mount, histology	None; management—correct sanitation, feeding, stocking density, cull affected fish
Anemia, mortality	Wet mount	
Weight loss, mortality	Histology	Sulfamethazine (efficacy questionable)

coldwater fish), determined by water temperature. For this reason, leaving a system fallow is one way to prevent reinfection. While encysted, parasitic life stages are refractory to chemical treatment, but cysts can be removed by thorough cleaning and removal of debris from gravel substrates.

Two important groups of ciliates are motile and move on the surface of skin and gills of fish: *Chilodonella* spp (which has a marine counterpart, *Brooklynella* spp) and the trichodinids, which are found on both freshwater and marine fish. Fish with chilodonelliasis typically lose condition, and copious mucous secretions may be noticed in areas where infestation is most severe. If gills are heavily infested, the fish may show signs of respiratory distress, including rapid breathing and coughing. The gills may be visibly swollen and mucoid. Infected fish may be irritated as evidenced by flashing (scratching) and decreased appetite. *Chilodonella* can be easily identified from fresh biopsies of infected tissues. They are 0.5–0.7 mm, are somewhat heart-shaped with parallel bands of cilia, and move in a characteristic slow spiral. See TABLE 8 for treatment.

Several genera of peritrichous ciliates have been grouped together and are collectively referred to as the trichodinids. These include *Trichodina*, *Trichodinella*, *Tripartiella*, and *Vauchomia* spp. Clinical signs associated with trichodinid infestation are similar to those of chilodonelliasis, although secretion of mucus is not usually as noticeable. Trichodinids are easily identified from biopsies of infected gill or skin tissue. They are readily visible using a light microscope at 40×–100×. Trichodinids move along the surface of infected

tissue and appear as little saucers or, from a lateral view, as little bubbles. The body of the organism may be cylindrical, hemispherical, or discoid. Trichodinids are characterized by an attaching disc with a corona of denticles on the adoral sucker surface. For treatment of trichodinids, see TABLE 8. Infestations of *Trichodina* often indicate poor sanitation and/or overcrowding, so chemical treatment alone may not be adequate for complete control.

Tetrahymena corlissi, another ciliate, may be motile and surface dwelling but is also occasionally found within tissue, including skeletal muscle and ocular fluids. Somewhat similar to *Tetrahymena* are the scuticociliates that affect marine fishes. *Uronema* and *Miamiensis*, like *Tetrahymena*, are teardrop-shaped ciliates that, although primarily found on external tissues, can be very invasive. *Tetrahymena* spp are pear shaped and 10–20 µm long, with longitudinal rows of cilia and inconspicuous cytostomes. External infestations of *Tetrahymena* spp are not uncommon on moribund fish removed from the bottom of a tank or aquarium and are often associated with an environment rich in organic material. As long as *Tetrahymena* spp are restricted to the external surface of the fish, they are easily eliminated with chemical treatment and sanitation. When they become established internally, they are not treatable and can cause significant mortality. Fish with intraocular infections of *Tetrahymena* spp develop extreme exophthalmos. The parasite is readily identified by examining ocular fluids with a light microscope.

Ambiphysa, *Apiosoma*, and *Epistylis* spp are sessile peritrichs that do not feed on the fish host; instead, they attach to the

fish, which is often debilitated, and use their cilia to filter and ingest bacteria and small microorganisms in the water column. When seen in low numbers, they cause little harm; however, in high numbers they can cause irritation. Their presence on a fish usually indicates a rich, organic environment. Often, just performing large water changes will diminish the population. Salt can also be used to help control the numbers. *Ambiphyra* and *Apiosoma* are solitary but can be seen in large groups on a heavily infested fish. *Epistylis*, *Vorticella*, and *Carchesium* are colonial stalked peritrichs.

Flagellates: *Ichthyobodo* spp are some of the most common and smallest ($\sim 15 \times 5 \mu\text{m}$) flagellated protistan parasites of the skin and gills. A kinetoplastid protist, they are flattened, pear shaped organisms with two flagella of unequal lengths. These parasites can be found on freshwater or marine fish from a broad geographic range. *Ichthyobodo* move in a jerky, spiral pattern, and free-swimming organisms are fairly easy to identify in direct smear preparations. Once attached, the organism can be difficult to see, but movement typical of a flickering flame may be seen under $400\times$ and is characteristic. Affected skin often has a steel-gray discoloration due to copious mucus production ("blue slime disease"), and gills may appear swollen. Behavioral signs of infestation include lethargy, anorexia, piping, and flashing. *Ichthyobodo* is readily controlled with salt, formalin,

copper sulfate, or potassium permanganate baths. Because the parasite has a direct life cycle, a single treatment should be adequate. If reinfestation occurs, sanitation and quarantine practices should be evaluated.

One of the most serious health problems of captive marine fish is the parasitic dinoflagellate *Amyloodinium* spp. Its freshwater counterpart, *Piscinoodinium* spp, is less common but can also result in high mortality. These parasites produce a disease that has been called "velvet," "rust," "gold-dust," and "coral disease" because of the brownish gold color they impart to infected fish. The pathogenic stages of the organism are pigmented, photosynthetic, nonflagellated, nonmotile algae that attach to and invade the skin and gills during their parasitic existence. When mature, these parasites give rise to cysts that contain numerous flagellated, small, free-swimming stages that can initiate new infections. Control of *Amyloodinium* is challenging, and the prognosis is guarded. Copper sulfate is the only therapeutic option for food animals in the USA, and repeated treatments are necessary to break the life cycle. The disease is particularly problematic in clownfish. The treatment of choice in ornamental fish is chloroquine, delivered at 10 mg/L as an indefinite bath.

Oomycota: Although the oomycetes (water molds) share some morphologic traits with the true fungi, they are more closely related to diatoms, opalinids, and

TABLE 9 COMMON METAZOAN PARASITES OF FISHES

	Parasites	Tissue	Susceptible Species
Myxozoans (IH)	<i>Myxosoma cerebralis</i> (whirling disease)	Head, cartilage, backbone	Rainbow trout, salmonids
	<i>Ceratomyxa shasta</i>	Posterior intestine	Salmonids (Pacific NW)
	<i>Aurantiactinomyxon ictaluri</i> (PGD, HG)	Gill	Channel catfish
	<i>Henneguya</i>	Gill	Channel catfish, other
	<i>Sphaerospora auratus</i> (renal dropsy)	Kidney	Goldfish (pond-reared)
	Proliferative kidney disease	Kidney	Rainbow trout, all salmonids
Monogeneans	<i>Gyrodactylus</i> (live bearer, except in Loricaridae)	Skin, fins	Goldfish, koi (predisposed)

labyrinthulomycetes. Of the many genera of water molds, *Saprolegnia* and *Aphanomyces* are the most frequently associated with disease in freshwater fishes. These primarily saprophytic organisms are common to freshwater fish around the world. *Saprolegnia* commonly infects fish eggs and traumatized external tissues of live fishes. Gross signs are grayish white, cotton-like growths on the skin, gills, eyes, or fins that may invade deeper tissues of the body. Fishes exposed to water temperatures below their optimal range are especially susceptible to *Saprolegnia* infection. Microscopically, saprolegniasis can be recognized by making direct smears from the infected tissues and observing the large nonseptate filaments. The sexual stages of the organism can be seen only in cultures of the organism and are required for specific identification. Sabaroud's dextrose agar is acceptable for primary isolation of oomycetes, including the genus *Saprolegnia*. Preventive measures include removal of predisposing causes, eg, improper temperature, inadequate sanitation, excessive chemical treatment, or the presence of dead, infected fish and decaying organic material. If the environment is clean, the temperature is appropriate for the species, and skin pathogens have been eliminated, a single treatment with potassium permanganate, formalin, or hydrogen peroxide is often adequate to control external saprolegniasis. There are some effective over-the-counter products sold through the pet trade that contain mala-

chite green. These dilute solutions should be effective in the home aquarium but should not be dispensed by the veterinarian and should never be used on food animals. Use in zoologic collections is also discouraged.

Epizootic ulcerative syndrome (EUS), caused by *Aphanomyces invadans*, is a reportable disease and endemic to much of the USA.

Internal Protistan Parasites

Flagellates: *Spironucleus* spp are common, small (~9 μm), bilaterally symmetric, flagellated (four pairs) diplomonad protists most frequently found in the intestinal tract of finfish. Among ornamental fishes, the cichlids are highly susceptible. However, they are also frequently seen in the intestinal tract of gourami and some catfishes. Pathogenicity of these organisms is variable and correlated with the number present. If there is a loss of condition, or >15 organisms are seen per low-power field on wet mounts of intestinal tissue or contents, then treatment is strongly recommended. The only treatment available for spironucleosis is metronidazole (use only in ornamental species), which should be given orally but can be administered as a bath if fish are anorectic. Chronic infections have been seen in fish maintained in unsanitary or crowded conditions.

Cryptobia and *Trypanosoma* spp are slender, elongated (6–20 μm), actively

TABLE 9 COMMON METAZOAN PARASITES OF FISHES (continued)

Signs	Diagnosis	Treatment
Blacktail, skeletal deformity	Histology, isolation of parasite	None; regulatory concern
Weight loss, distended and hemorrhagic vent	Wet mount, histology	None; regulatory concern
Mortality, piping	Wet mount, histology	None
None, severe hypoxia	Wet mount	None
Mortality, severely enlarged and cystic kidney	Histology	None
Lethargy, darkening, fluid accumulation, exophthalmia	Wet mount, histology	None
Excess mucus, flashing, weight loss	Wet mount	Praziquantel in nonfood fishes, formalin

TABLE 9 COMMON METAZOAN PARASITES OF FISHES (*continued*)

	Parasites	Tissue	Susceptible Species
	Family: Ancyrocephalidae Family: Dactylogyridae (egg layers)	Gills	Goldfish, koi, angelfish, discus (predisposed), channel catfish
	Capsalids; <i>Benedenia</i> , <i>Neobenedenia</i> (egg layer)	Cornea, gills, skin	Marine tropicals, other marine species, marine angelfish (predisposed)
	Polyopisthocotylea	Gill	Striped bass
Trematodes (IH usually mollusc)	Heterophyidae	Gill	Redtail shark, black shark, rainbow shark, angelfish (FW), other pond-reared fish, aquarium fish
	<i>Clinostomum</i>	Skeletal muscle	Largemouth bass, centrarchids, hybrid striped bass
	<i>Bolbophorus confusus</i>	Skeletal muscle, viscera	Channel catfish
	<i>Posthodiplostomum</i>	Viscera, heart, posterior kidney	Largemouth bass, bluegill, centrarchids, salmonids, other fish
	<i>Diplostomum</i>	Eye (lens)	Fish are IH (unspecified species)
Cestodes	<i>Diphyllobothrium latum</i>	Viscera, musculature	Salmonids, other FW species
	<i>Corallobothrium</i>	Intestine (adult)	Channel catfish
	<i>Proteocephalus ambloplitis</i>	Ovary (larval stage)	Largemouth bass
	<i>Bothriocephalus acheilognathi</i>	Intestine (adult)	Carp, aquarium fish
Acanthocephalids	<i>Acanthocephalus</i>	Intestine	Wild-caught salmonids, wild-caught marine fish
Nematodes (fish as DH)	<i>Capillaria</i>	Intestine	Angelfish, discus, other aquarium fish
	<i>Camillanus</i>	Posterior intestine	Largemouth bass, other centrarchids
	<i>Philometra</i>	Posterior intestine	Aquarium fish
Nematodes (fish as IH)	<i>Eustrongylides</i>	Encysted in coelom	Angelfish, other aquarium species
	<i>Contracaecum</i>	Encysted in viscera	Largemouth bass, centrarchids
Leeches	Leech	Skin	FW game fish, aquarium fish

Often none	Direct visualization	
Anemia, weight loss	Direct visualization	None

motile, biflagellated kinetoplastid protistans easily detected in fresh blood and tissue smears of both marine and freshwater finfish. Hematozoic forms are generally described as *Trypanosoma* and have a well-developed undulating membrane. Trypanosomes can be transmitted by leeches and have been associated with anemia in blue-eyed plecostomus *Panaque suttoni* and other wild-caught loriciariids. *Cryptobia iubilans* has been associated with granulomatous disease in African cichlids and discus. Clinical disease is manifest by severe weight loss and cachexia. Clinically affected fish should be culled. Presumptive diagnosis can be made from microscopic examination of fresh tissue. Typically, granulomas will be found in the stomach, which may be visibly thickened. Acid-fast positive material will not be found in granulomas caused by *Cryptobia*. Motile flagellates may be visible using magnification of 400× or greater.

Sporozoans: Coccidiosis, although common in freshwater or marine finfish, is rarely diagnosed in live fish. Many species of finfish are affected. Species of the genera *Cryptosporidium*, *Eimeria*, and *Goussia* have been frequently reported in both freshwater and marine fishes. The life cycles of many fish coccidia are unknown, and some involve more than one host to complete their development. In addition to intestinal infection, the internal organs may be affected; sporulated *Eimeria*-like oocysts and sexual and asexual stages can be found in direct smears and histologic sections of the internal organs.

A number of *Eimeria* species are found in skates and rays. Of these, *E. southwelli* has caused high mortality in cownose rays (*Rhinoptera bonasus*), although it has been reported in other species of rays. Infected cownose rays often present with pale skin and loss of weight despite normal appetite. Fluid obtained by aspiration of the coelomic cavity should be examined for presence of coccidia. Treatment with toltrazuril 10 mg/kg/day, PO, for 5 days may help control but not eliminate infection. This parasite is highly prevalent in wild-caught cownose rays.

Heavy intestinal infection of *Goussia* spp has been associated with high mortality in comet goldfish (*Carassius auratus*). Affected fish are lethargic, frequently lay on their side, and have pale feces. Clumps of cells in the intestine can be visualized on a wet mount, but histopathology is required for diagnosis.

Sulfamethazine, at 22–24 g/100 kg of fish wt/day in the feed for 50 days at 50°F (10°C),

is used to treat food fish (21-day withdrawal time) in some countries. An FDA-approved form of this drug is not currently available in the USA. For aquarium fish, 10 ppm sulfamethazine in the aquarium water once a week for 2–3 wk has been reported to be preventive, but safety and efficacy data are sparse.

Metazoan Parasites

Metazoan parasites include the myxozoans, helminths, and crustaceans, and are common in both wild and cultured fish (see TABLE 9). Fish frequently serve as intermediate or transport hosts for larval parasites of many animals, including people. Helminths with direct life cycles are most important in dense populations, and heavy parasite burdens are sometimes found. In general, heavy parasite burdens seem to be more common in fish originating from wild sources.

Myxozoans: Although originally thought to be single-celled organisms, myxozoans are multicellular and closely related to Cnidaria. They are common fish parasites and have life cycles that use invertebrates as definitive hosts and fishes for multiplication. Hence, myxozoan infections are often more common in wild fish or fish reared intensively in outdoor fish ponds. The organisms tend to be host- and tissue-specific. Accordingly, expression of the disease is related to the specific pathogen and host and location within the host. For example, coelozoic myxozoans that reside in cavities typically cause little pathology, unlike the histozoic forms that reside in tissues. Myxozoan-infected fish in captive display aquaria are not able to transmit the infection unless the necessary intermediate hosts are present.

Myxozoans are divided into two groups, Myxosporea and Malacosporea, and members of both groups are infective to fishes. Although a few cases of direct life cycle have been reported, myxosporeans usually have an indirect life cycle, with oligochaete or polychaete worms used as a definitive host. In contrast, bryozoans are used as a definitive host by the malacosporeans.

There are two important myxosporean infections of ornamental fish. “Renal dropsy of goldfish” is caused by the myxosporean *Sphaerospora auratus*. The disease is characterized by renal degeneration and ascites and is usually diagnosed by identification of spores in histologic sections of the kidney. Affected fish present with extreme abdominal distention but may have few other clinical signs. Radiographs may reveal a mass in the area of the

posterior kidney; definitive diagnosis is made at necropsy and confirmed histologically. No practical treatment is available. *Henneguya*, a myxosporean occasionally found in ornamental fish, causes white nodular lesions that are usually found in gill tissue and may be grossly visible. *Henneguya* is easily identified by the forked-tail appendage of the spore, seen microscopically. If ponds are dried and limed heavily, infection can be eliminated, apparently by reduction of the intermediate hosts. Aquarium infection can be self-limiting in the absence of intermediate hosts. Although an occasional cyst may be considered an incidental finding, severe damage has been associated with diffuse distribution of interlamellar cysts.

Myxosporean diseases significant in aquaculture include whirling disease and proliferative kidney disease of salmonids and proliferative gill disease ("hamburger gill disease") of channel catfish. Whirling disease is caused by *Myxobolus cerebralis*. Fish are infected as fingerlings when the parasite infects cartilage in the vertebral column and skull, resulting in visible skeletal deformities. Affected fingerlings typically show rapid tail-chasing behavior (whirling) when startled. The disease is also sometimes called "blacktail," because the peduncle and tail may darken significantly. Recovered fish remain carriers. Adults do not show behavioral signs, but skeletal deformities associated with infection do not resolve. Whirling disease can be prevented by purchasing uninfected breeding stock and maintaining them in an environment free of the definitive hosts (tubeficid worms). A presumptive diagnosis of whirling disease is made by detection of spores from skulls of infected fish. Diagnosis may be confirmed histologically or serologically. Whirling disease is of regulatory concern in some states.

Monogeneans: Monogeneans have direct life cycles and are common, highly pathogenic, and obligatory parasites most commonly seen on skin and gills. The preferential location of some species is in internal organs such as the esophagus, stomach, posterior kidney, or urinary bladder. Freshwater parasites tend to be ~0.1–0.8 mm long and are best seen microscopically; however, several important species parasitizing marine fish are significantly larger and may be visible grossly. The worms can be identified by their characteristic hold-fast organ, the haptor, which is armed with large and small hooks. Aquarium and cultured fish are

subject to a rapid buildup of parasites by continual infection and worm transfer to other fish in the tank or pond. Although many species are host specific, the more common types seen in aquaria are less selective. The two most common monogeneans in freshwater aquaria are gyrodactylids and ancyrocephalids. *Gyrodactylus*, a common parasite of many ornamental fishes, primarily gives birth to live young and is usually found on skin; the ancyrocephalids lay eggs and parasitize the gills. Dactylogyrids are egg-laying gill monogeneans commonly seen in cyprinid fishes, especially goldfish and koi. High numbers of any of these monogeneans can result in catastrophic mortality of infested fishes.

The capsalids are a large group of monogeneans that affect brackish and marine fishes and include the genera *Neobenedenia* and *Benedenia*, which are important monogeneans in marine fishes. They attach and graze on skin and gill and the cornea. The capsalids lay sticky eggs easily transmitted via fomites. Monogenean-infected fish may show behavioral signs of irritation, including flashing and rubbing the sides of their bodies against objects in the aquarium. Fish become pale as colors fade. They breathe rapidly and distend their gill covers, exposing swollen, pale gills. Localized skin lesions appear with scattered hemorrhages and ulcerations. Ulceration of the cornea may become evident if the eyes are involved. Mortality may be high or chronic.

Praziquantel (5 mg/L, prolonged bath) is the treatment of choice for monogenean infection in freshwater and marine ornamental fish. Formalin is the only treatment option for food fish. When using formalin, multiple treatments at weekly intervals are recommended for egg-laying monogeneans, because eggs are resistant to chemical treatment. Organophosphates (0.25 mg/L, prolonged bath) have been used successfully in ornamental fish in the past, but treatment with praziquantel is considered more effective. Organophosphates should be avoided in systems containing elasmobranchs and some characins and cichlids. Many monogeneans on marine fish can be partially removed using freshwater dips for 1–5 min, depending on the tolerance of the species; however, eggs will not be damaged or removed. To prevent the disease, introduction of infected fish should be avoided.

Trematodes: Trematodes belong to the phylum Platyhelminthes, and this class contains two subclasses, Aspidogastrea and Digenea, both of which contain members that infect fishes. Also known as flukes, this

group of flatworms has a complex life cycle that includes a variety of host animals, typically beginning with a mollusc. Fishes can be a second intermediate or final host, depending on the requirements of the trematode species. Although adults may be found in the intestine of infected fish, it is more common to see the metacercarial stage in fishes. This stage is usually considered to cause little harm to the host but much depends on the site of encystment. For example, large numbers of metacercariae encysted in gill tissue can be detrimental to normal function.

Nematodes: Nematodes are common in wild fish exposed to the intermediate hosts. Fish may be definitive hosts for adult nematodes, or they may act as transport or intermediate hosts for larval nematode forms (anisakids, eustrongylids, and others) that infect higher vertebrate predators, including people. Encysted or free nematodes can be found in almost any tissue or body cavity of fish. Aquarium and cultured pond fish may be heavily infected if crustacean intermediate hosts are present. *Cyclops* and *Daphnia* spp are common intermediate hosts for *Philometra* sp, a nematode that is pathogenic for guppies and other aquarium fish. These blood-red worms can be seen in the swollen abdominal cavity and protruding from the anus of affected fish (red worm disease). *Capillaria* spp are commonly found in aquarium fish, particularly freshwater angelfish. Heavy infections in juvenile angelfish have been associated with poor growth rates and an inability to withstand shipping and handling. Treatment with fenbendazole (25 mg/kg for 3 days) is recommended, but efficacy has not been firmly established. Levamisole (10 mg/L) administered as a bath treatment for 3 days has also been recommended.

Small, gray speckled fish louse (*Argulus* spp) attached to the tail fin of a fancy goldfish.

Courtesy of Dr Louise Bauck.

Ivermectin can be highly toxic to aquarium fish, particularly cichlids, and its use is discouraged.

Leeches: Leeches are parasitic blood-suckers of fish and also serve as vectors for blood parasites offish (eg, *Trypanosoma*, *Cryptobia*, and haemogregarines). They can produce a debilitating anemia due to chronic blood loss and disease. Leech infestations are most common in wild fish, but aquarium and pond infestations can occur by introduction of infested fish, plants, etc. Heavily infested fishes have been observed to swim primarily at the water surface, often with their dorsum exposed. Fishes exhibiting this behavior also suffer from ulcerative lesions of the exposed skin. ●rganophosphates (0.25 mg/L, prolonged bath) are somewhat effective but not approved for use in food fish. Further, environmental regulations may restrict use in outdoor ponds. Multiple treatments may be required to control leeches, because eggs are resilient and juveniles may continue to hatch. Preventive measures include avoiding leeches (ie, effective quarantine). Infestations in recreational fishing ponds are often self-limiting.

Crustaceans: Parasitic crustaceans include copepods and branchiurans. Some copepods, such as the anchor worm, are obligatory parasites of finfish during specific stages of their complicated life cycle. They lose their copepod form, including their appendages, and become rod- or sac-like structures specifically adapted for piercing, holding, feeding, and reproducing. Grossly, they appear as barb like attachments to the skin or gills, where they feed on blood and tissue fluids. They can cause hemorrhage, anemia, and tissue destruction, as well as provide a portal of entry for other pathogens. Many different species of these parasites can be found on freshwater and marine fish. The anchor worms, *Lernaea* spp, are commonly found in a wide variety of aquarium- and pond-reared fish, including goldfish and other cyprinids. *Ergasilus* spp infest the gills.

The branchiurans, often called lice, have flattened bodies adapted for rapid movement over the skin surface. By means of hooks and suckers, they periodically attach for feeding by inserting the piercing mouth part (stylet) into the skin. Sea lice (*Lepeophtheirus salmonis*) are a significant disease problem of pen-reared salmonids. Consultation with a salmonid health specialist is suggested if these parasites are encountered, because treatment options are limited and environmental concerns are significant. *Argulus*

spp are commonly found on aquarium, pond-reared, and wild freshwater fish.

As a chitin synthesis inhibitor, diflubenzuron is the most effective treatment for crustacean parasites. It is applied once at the rate of 0.03 mg/L and has a long half-life. Because of this and the toxicity of diflubenzuron to all crustaceans, treated water must be retained for 28 days before release. Organophosphates are somewhat effective in controlling crustacean parasites, but legal restrictions constrain clinical use (see p 3064). Some success has been achieved in treating freshwater fish for parasitic copepods by giving infected fish a 3% (30 ppt = 30 g/L) salt dip (<10 min, remove fish when it rolls) followed by 5 ppt (5 g/L) salt added to the affected tank for 3 wk. The increased salinity kills immature forms as they hatch. Diflubenzuron and organophosphates are not approved for use in food fishes.

BACTERIAL DISEASES

Epidemics of bacterial diseases are common in dense populations of cultured food or aquarium fish. Predisposition to such outbreaks frequently is associated with poor water quality, organic loading of the aquatic environment, handling and transport of fish, marked temperature changes, hypoxia, or other stressful conditions. Most bacterial pathogens of fish are aerobic, gram-negative rods. Diagnosis is by isolation of the organism in pure culture from infected tissues and identification of the bacterial agent. Sensitivity testing before antibiotic use is recommended.

Aeromonas, *Pseudomonas*, and *Vibriosis*:

A number of bacteria produce a similar syndrome, generically referred to as **hemorrhagic septicemia** and characterized by external reddening and hemorrhage in the peritoneum, body wall, and viscera. Morbidity and mortality are highly variable, depending on predisposing conditions such as low dissolved oxygen, other water quality problems, handling stress, or trauma. Ulcerative lesions are common as disease progresses, and mortality can be significant if stress is not controlled. Antibiotic therapy is recommended if fish are dying. Common bacterial isolates from affected fish include *Aeromonas* and *Pseudomonas* spp, which are more common in freshwater animals, and *Vibrio* spp, more commonly isolated from marine fishes. Control is based on removal of predisposing factors. If antibiotic therapy is warranted, drug selection should be based on sensitivity testing when possible.

Aeromonas salmonicida, a gram-negative, nonmotile rod, is the causative agent of **goldfish ulcer disease** and **furunculosis** in salmonids and is a very important disease of koi and goldfish. The disease also occurs in freshwater and marine species other than the groups mentioned above. In the acute form, hemorrhages are found in the fins, tail, muscles, gills, and internal organs. In more chronic forms, focal areas of swelling, hemorrhage, and tissue necrosis develop in the muscles. These lesions progress to deep crateriform abscesses that discharge from the skin surface. Liquefactive necrosis develops in the spleen and kidney. Diagnosis is made by isolating and identifying a pure culture of the organism from infected tissue. Avoidance through use of good quarantine practices, and vaccination when appropriate, is preferable to treatment. Successful treatment is possible, based on appropriate antibiotic therapy. Blood culture is an effective and nonlethal method for effective identification and sensitivity testing of *A. salmonicida* isolates from valuable koi. Commercial vaccines are available for prevention of *A. salmonicida* in salmonids and koi, but information on efficacy in koi is limited.

Vibriosis is a potentially serious, common systemic disease of many cultured, aquarium, and wild marine and estuarine fishes; it is less common in freshwater fish. Three genera of the family Vibrionaceae are frequently associated with infection in fishes: *Vibrio*, *Listonella*, and *Photobacterium*. These genera can result in hemorrhages and ulcerations of the skin, fin, and tail; hemorrhagic and degenerative changes of internal organs; and other systemic changes. Diagnosis requires identification of pure isolates from infected tissues. Isolation of *V. cholerae* from fish is not uncommon and should not cause alarm as long as the isolate is the non-O type. Preventive measures include minimizing stress and crowding. Coldwater vibriosis (Hitra disease), a serious problem in sea farming of salmonids, is characterized by high mortality, resistance to drug therapy, and stress mediation. The etiologic agent is *Aliivibrio salmonicida*. Because members of this family are ubiquitous in marine environments, avoidance is difficult. Preventive vaccination with formalin-killed *Vibrio* is used in the salmonid industry. Antibiotic therapy should be based on results of sensitivity testing.

Edwardsiella: *Edwardsiella ictaluri* is commonly associated with disease in channel catfish; however, it is also

responsible for high mortality in zebrafish, both in research laboratories and aquarium fish. It is an obligate pathogen and can be transmitted by direct contact with infected fish, water, and feces. Clinical signs of disease in infected zebrafish include hemorrhaging in the skin, pale gills, lethargy, and splenomegaly. On histopathology, bacteria frequently can be found in high numbers in spleen, anterior and posterior kidneys, nares, and forebrain. It can be isolated on standard culture media, but it is slow-growing. Coinfections with *Aeromonas* spp are common; *Aeromonas* spp are fast growers and can easily overgrow *E. ictaluri*.

Although more commonly reported in aquacultured fish species, **epitheliocystis** is seen in aquarium fishes and is frequently seen in discus (*Symphysodon* spp), oscar (*Astronotus ocellatus*), and occasionally other pet fishes. Epitheliocystis is caused by an obligate intracellular bacteria in the order Chlamydiales. Infection most frequently involves the gills and occasionally the skin. Infections are more common in freshwater-reared fish species. Epitheliocystis should be suspected if colorless spherical structures (infected, hypertrophied cells) that have granular contents are seen on gill biopsy or skin scraping. Histopathologic examination typically reveals basophilic hypertrophied cells. Clinical signs are variable and depend on severity of infection. Heavily infected fish may be lethargic and dyspneic. Oral oxytetracycline has been used to successfully control infections.

Flavobacterium: *Flavobacterium columnare*, the member of this group responsible for **columnaris disease**, is most common in warmwater species of fish. A presumptive diagnosis can be made from visualization of typical organisms on wet mounts of infected skin or gill tissue. There are several strains of this bacterium, which range from low to high virulence. As yet unidentified water quality conditions predispose susceptible fishes to infection with the virulent strain. Mortality can be acute, and by the time the condition is seen it may be difficult to control.

Gram-positive Bacterial Infections:

These infections of concern to fish culturists and aquarists may be caused by *Streptococcus* and related genera *Lactococcus*, *Enterococcus*, and *Vagococcus*. Infections are uncommon but can cause significant mortality (>50%) when they do occur. Chronic infections may continue for

weeks, with only a few fish dying each day. Species known to be susceptible include salmonids, assorted marine fish (eg, mullet, sea bass), tilapia, sturgeon, and striped bass. Susceptible aquarium species include rainbow sharks, red-tailed black sharks, rosy barbs, danios, and some tetras and cichlids. In general, all fish should be considered susceptible. A characteristic manifestation of *Streptococcus* infection is neurologic disease, often manifest by spinning or spiraling in the water column. Brain and kidney cultures from suspect fish should be incubated on blood agar at 25°C for 24–48 hr. Gram stains of pinpoint bacterial colonies reveal typical chains of gram-positive cocci, which allow a presumptive diagnosis. Confirmation requires definitive identification of the organism. Antibiotic therapy should be based on sensitivity testing. Erythromycin is often the drug of choice, but it is not FDA approved for this use. Sources of infection may be environmental or include live foods, such as tubefed worms, amphibians, or previously infected fish. Future epizootics can be prevented if the source of infection is identified and eliminated. *Streptococcus iniae* has been isolated from tilapia and aquarium fish and has zoonotic potential. Autogenous vaccines are available for use in aquaculture facilities.

The zoonotic gram-positive bacterium *Erysipelothrix rhusiopathiae* is frequently associated with rostral ulceration in cyprinids such as tiger barbs (*Puntigrus tetrazona*) and rosy barbs (*Pethia conchonius*). It usually responds well to treatment.

Mycobacteria: Mycobacteriosis is a chronic or acute, systemic, granulomatous disease of aquarium fish and cultured food fish, particularly those reared under intensive conditions. Predisposing environmental factors include low dissolved oxygen, low pH, and high organic load, all found in recirculating aquaculture systems. Correct use of ultraviolet light as a way to disinfect system water reduces bacterial counts and can be a useful tool to control infection in exhibit animals. The causative bacteria can be any number of species of *Mycobacterium*, including *M. chelonae*, *M. marinum*, and *M. fortuitum*. Syngnathids (sea horses) are particularly susceptible, but the disease can be seen in any fish. These weakly gram-positive, acid-fast, nonmotile bacteria are difficult to grow but can be isolated using Löwenstein-Jensen or Middlebrook media after incubation at 25°C for 3–4 wk. Signs

Granulomatous lesions typical of *Mycobacterium* in a fancy goldfish. Courtesy of Dr. Ruth Francis-Floyd.

are variable and nonspecific; they can include emaciation, ascites, skin ulceration and hemorrhages, exophthalmos, paleness, and skeletal deformities. On necropsy, gross lesions of viscera consist of grayish white, necrotic foci that sometimes coalesce to form tumor-like masses. Granulomas may not be grossly visible and are often found first on wet mounts, especially of anterior kidney and spleen, or other viscera from infected fish. A presumptive diagnosis is based on visualization of acid-fast rods in granulomatous material from suspect lesions. Definitive diagnosis requires isolating and identifying the bacteria. There are no effective treatments that eliminate mycobacteria in fish. Mycobacteria can cause zoonotic infections, and aquarists should be informed of potential risks if handling or cleaning contaminated fish or exhibits. An infected aquarium should be disinfected before other fish are added. Bleach is not an effective disinfectant against mycobacteria; disinfection with alcohol or phenolic compounds is recommended.

MYCOTIC DISEASES

Aquatic fungi often are considered secondary tissue invaders that follow traumatic injuries, infectious agents, or environmental insults such as poor water quality or low water temperatures. Because many fungi grow on decaying organic matter, they are especially common in the aquatic environment.

For more information on *Saprolegnia* and other members of the Oomycota, which are fungus-like protists, see p 1761.

Fusarium solani is emerging as an important cause of disease in captive marine fish, particularly elasmobranchs. This organism is found in aquatic plants and soils in tropical and subtropical regions. Clinical disease has been reported in bonnethead and scalloped hammerhead sharks, as well

as several species of marine fish, including angelfish and parrotfish. Disease is associated with low water temperatures ($<80^{\circ}\text{F}$ or 27°C). Bonnethead sharks are particularly susceptible and develop erosions and granulomatous lesions along the head. Resolution of lesions requires warming the affected animals to a more appropriate temperature for the species.

Closely related to true fungi, **microsporidia** are tiny, obligate intracellular, spore-forming parasites with single polar filaments. They are common parasites of finfish and are host- and tissue-specific; they can also infect helminth parasites of fish. The spores are extremely resistant, and microsporidia are considered nontreatable. Microsporidia have a direct life cycle; therefore, horizontal transmission in an aquarium is likely. Some species of microsporidia cause the formation of xenomas; a xenoma results in the hypertrophy of an infected cell and its nucleus and is often surrounded by fibrous connective tissue by the host.

The spores are very hardy and can remain infective in water for many months. Ingestion of the spores is the primary route of infection, but entry through other portals, eg, damaged skin or gills, and transovarial transmission are possible.

Recommendations for management of microsporidian disease include removal of older and moribund animals from a population, ultraviolet sterilization, and strict biosecurity. Depopulation and disinfection are recommended for elimination of microsporidian infections.

Ovipleistophora ovariae infects ovarian tissue of golden shiners (bait fish), resulting in sterility. The organism has no intermediate host and is transmitted horizontally (through ingestion of infective spores) or vertically (through infected ova). Fertility declines as fish age, eventually resulting in sterility. Grossly, infected ovarian tissue appears marbled. Diagnosis is confirmed by examination of a wet mount of suspect tissue, revealing presence of microsporidian spores.

Neon tetra disease is caused by *Pleistophora hyphessobryconis*, which infects the skeletal musculature of a number of species of aquarium fish, including tetras, angelfish, rasboras, barbs, and zebrafish. Infected fish may exhibit abnormal locomotion caused by muscle damage, and muscle tissue may appear marbled or necrotic at necropsy. The spores are readily visualized in wet mounts of infected tissue.

The microsporidia *Pseudoloma neurophilia* infects zebrafish and can

be problematic in research facilities and the pet industry. The nervous system and skeletal muscles are the most common sites of infections, but occasionally other organs such as gonads are affected. A common presentation is lordosis, but some fish may present with a grossly distended body with pale epaxial musculature caused by a massive number of parasites. Often, fish may be heavily infected yet show no clinical signs of disease. Xenomas are not formed with this microsporidia. Fish are infected by ingesting spores from an infected fish or during spawning activity, when spores may be released from an infected ovary. It is unknown whether this parasite can be transmitted vertically. An important source of infective spores is tank debris.

A number of microsporidia belonging to the genus *Glugea* are associated with disease in a disparate group of host fishes, including seahorses, flounder, and sticklebacks. Infection with the members of this genus results in xenoma formation.

VIRAL DISEASES

Descriptions of viral diseases of fish are rapidly expanding. Viruses are being reported in new species, and interpretation of the significance of findings is also changing. Several viral diseases of ornamental fish are reportable (see TABLE 6, p 1787).

Although viruses of homeothermic animals are cultured at uniform temperatures, fish viruses have wider, but specific, temperature tolerances in fish cell cultures at lower temperatures. Because of this relatively defined temperature range, variation in temperature may enable control, although often it merely induces latency. Because many viral diseases of fish are geographically limited, regulatory agencies and fish farms in disease-free areas consider them exotic diseases and require certification of introduced stocks. Many result in high mortality in young fish and little or no losses in adults, which may become carriers. For these reasons, avoidance of carriers and certification of SPF replacement stocks are frequently required. Specific testing procedures are available. Most vaccines used for control of fish diseases are for bacterial agents; however, use of vaccines to control some viral diseases is being introduced. Drugs are not effective; however, antibiotics and other drugs may be used to control secondary bacterial infections. Management techniques that minimize stress and crowding, biosecurity measures, and temperature manipulation hold the greatest promise for control of piscine viral diseases.

Herpesviruses

Carp Pox: One of the oldest recognized fish diseases, carp pox is caused by Cyprinid herpesvirus-1 (CyHV-1). Pox lesions may be seen on other species of fish and are sometimes referred to as fish pox. Lesions typically are smooth and raised and may have a milky appearance. They are benign, non-necrotizing areas of epidermal hyperplasia. Severe cases may result in development of papillomatous growths, which may be a site of complicating bacterial infection. Generally, lesions are self-limiting and of minimal clinical significance. Carp pox can be a significant problem in koi because their aesthetic quality, and hence market value, is severely compromised. For the serious koi enthusiast, fish affected with carp pox should be culled, preferably during quarantine. Surgical removal of the lesions has not been rewarding.

Koi Herpesvirus: Koi herpesvirus (KHV), caused by Cyprinid herpesvirus-3 (CyHV-3), was first recognized in 1996. It is widespread in the USA and considered endemic. Confirmed cases must be reported to the State Veterinarian and the USDA Area Veterinarian in Charge. Because the disease is endemic, regulating bodies report its occurrence to the OIE, but they do not require specific action, such as depopulation, when the disease is reported.

KHV causes clinical disease in koi and common carp. Goldfish and grass carp are refractory to clinical disease but may serve as carriers. Koi that are exposed, but survive, may also serve as carriers. Clinical disease is seen at water temperatures of 72°–81°F (22°–27°C), with maximal mortality at temperatures of 72°–78°F (22°–25.5°C). Mortality rates can reach 80%–100%. Fish of any age are susceptible, but mortality rates may be higher in younger fish, especially fry. The most obvious lesions are seen on gill tissues, which are severely affected and develop a mottled red and white appearance with obvious hemorrhage in some cases. Affected fish are lethargic, swim at the surface, and may show behavioral signs of respiratory distress. The presence of severe bacterial or parasitic disease may mask the fact that KHV is the primary cause of gill lesions. The disease is transmitted horizontally by exposure to sick or carrier fish and also by exposure to contaminated water, substrate, or equipment.

When KHV is suspected, affected fish can be shipped to a laboratory for confirmation. Freshly dead specimens shipped on ice and received within 24 hr should be adequate.

PCR or virus isolation and identification can be used to confirm the infection in dead animals. Because of the value of koi, there is significant demand for nonlethal testing protocols. Blood, gill tissue from biopsy, feces, or mucus may be used to assess the status of moribund fish. It is important to note these tests can result in false-negatives if performed on clinically normal fish. Indirect tests using blood samples, including ELISA or virus neutralization, are less straightforward. Negative test results could indicate a true negative or, alternatively, that the infection is in its early stages and the fish has not yet developed a measurable antibody response. A negative test result could potentially be obtained from a previously infected fish that has had a decrease in circulating antibody; however, such a fish could still function as a carrier. There is a misconception among some hobbyists that a negative blood test is an adequate screening test to exclude carrier status. Practitioners should communicate this clearly to owners, because it is easily misunderstood.

If KHV infection is confirmed in a population of koi, depopulation is strongly recommended. Surviving fish are carriers and can serve as a source of infection for naive fish. Although mortality decreases or stops as water temperature approaches 86°F (30°C), survivors will retain carrier status and therefore put other populations at risk.

Prevention of KHV is best accomplished with careful quarantine protocols. A minimum quarantine of 30 days at 75°F (24°C) is recommended to minimize the chance of introducing KHV to an established population of koi. If disease develops during the quarantine period, fish should be evaluated with special consideration for excluding KHV. After quarantine, a new fish may be placed in an isolated area with a few fish from the established population and monitored for signs of disease for at least 2 wk as an added precaution. If koi are taken to shows, quarantine protocols should be followed every time they return. Koi enthusiasts should be strongly encouraged to attend English-style shows (versus Japanese-style shows), where competing fish are not placed in a common container.

Herpesviral Hematopoietic Necrosis:

This condition of goldfish is caused by Cyprinid herpesvirus-2 (CyHV-2). It is probably widespread throughout the USA, but it is not a reportable disease. Clinically ill goldfish often are anorectic and exhibit pale gills and ascites. At necropsy, the spleen and kidneys (anterior and posterior) are often enlarged. As is typical for herpesviruses, survivors can be carriers and

exhibit clinical signs of disease if subjected to stressors. Water temperatures between 10° and 22°C will result in replication of the virus that can be detected with quantitative PCR. There is no treatment.

Herpesvirus of Angelfish: A herpesvirus of angelfish (*Pterophyllum* spp) has been detected by electron microscopy of skin from moribund angelfish. Affected fish produce copious amounts of skin mucus that gives affected fish a grey sheen. Often, these fish have multiple parasitic infestations and bacterial infections, similar to that of KHV in koi. It is suspected that survivors are carriers.

Rhabdoviruses

Viral Hemorrhagic Septicemia (VHS):

This reportable disease is caused by a *Novirhabdovirus* and is a member of the family Rhabdoviridae. This disease is listed by OIE as notifiable. Most of the reported hosts are not ornamental fishes, but koi were shown to be susceptible experimentally to genotype IVb. This genotype affects a diverse group of fishes in the Great Lakes region of North America.

Spring Viremia of Carp (SVC): This acute, virulent, usually hemorrhagic disease of cultured carp is caused by a *Vesiculovirus* that, like VHS, is a member of the Rhabdoviridae family. The disease is listed as notifiable by the OIE. Historically, it was reported in Europe and the former USSR; however, several outbreaks have been reported in the USA between 2002–2007, in both wild fish and cultured ornamental koi. SVC is considered a foreign animal disease in the USA and must be reported. It causes disease in common carp, including koi, as well as grass, bighead, silver, and crucian carp. Limited experience suggests that common goldfish may be susceptible.

Clinical signs are nonspecific and may include darkening of the skin, exophthalmia, ascites, pale gills, hemorrhage, and a protruding vent with thick mucoid fecal casts. Pinpoint hemorrhage in the swim bladder is indicative of SVC, if present. Coinfection with *Aeromonas* or other systemic bacteria may obscure the presence of the virus. The bacterial component of the infection can be controlled with antibiotics; however, depopulation of affected or exposed fish is required in the USA. The disease causes death in both adult and young fish. Clinical disease occurs at cool temperatures, 54°–72°F (12°–22°C), an important distinction from KHV. The virus is readily isolated in common fish cell lines and identified by serum neutralization and fluorescent antibody tests.

Iridoviruses

Lymphocystis Disease: This typically chronic, viral infection of wild or captive marine and freshwater fish is caused by an icosahedral DNA virus of the Iridoviridae family. Infection may be manifest by benign, cauliflower-like lesions typically located on fins. The disease affects a wide range of fish and is generally considered to have a global distribution. Within the aquarium trade, painted glass fish and marine tropical fishes such as the anemonefishes (Pomacentridae), marine angels (Pomacanthidae), and butterflyfishes (Chaetodontidae) are susceptible. Presumptive diagnosis is based on the presence of enlarged fibroblasts (up to 1 mm), which are easily visualized with a light microscope. Microscopic examination typically reveals the appearance of grape-like clusters of virus-laden cells. Diagnosis is confirmed histologically. Feulgen-positive cytoplasmic inclusions and a hypertrophied nucleus are pathognomonic. The disease is usually self-limiting but is of aesthetic concern.

Megalocytiviruses: Several other iridoviruses have been described in ornamental fish. Megalocytiviruses consist of two major groupings, red sea bream iridovirus (RSIV) and infectious spleen and kidney necrosis virus (ISKNV). RSIV has been found in >30 other marine fishes so far; many of the affected species include some tropical fishes kept in aquaria. RSIV is a reportable disease. ISKNV includes megalocytiviruses that primarily affect ornamental freshwater fishes. ISKNV is not currently reportable.

A megalocytivirus has been described in freshwater angelfish (*Pterophyllum scalare*), but the agent has not been isolated. It can result in high mortality. An iridovirus has also been isolated in the USA from gourami in the genus *Trichogaster* using a tilapia heart cell line. This virus does not grow on FHM cells or other common cell lines used for isolation of fish viruses. The gourami virus has been associated with systemic disease and mortality of *T. trichopterus* and *T. leeri* gourami. Efforts to fulfill River's postulates were supportive although not conclusive. Clinical disease with the USA gourami megalocytivirus appears to be more severe at water temperatures $\geq 30^{\circ}\text{C}$, based on very limited information. A megalocytivirus is known from dwarf gourami *Trichogaster* spp, but it is not known whether it is the same virus that affects gourami in the USA.

Other Viruses:

Koi sleepy disease is also known as carp edema virus. Caused by a poxvirus, it was first seen in Japan in 1974 and has since occurred in other countries, including the USA. Affected fishes appear lethargic, lay on their sides, and have thin body condition. Mortality is usually low but can be variable. Gill hyperplasia is a common histopathologic finding. Infected koi can recover, but it is unknown whether they retain a carrier state.

NEOPLASIA

Neoplastic diseases similar to those found in other animals are found in fish. Their incidence frequently is higher in some geographic areas and in certain species. Some tumors are genetically mediated, such as the malignant melanoma of the platy-swordtail cross, and possibly the pseudobranch tumor of cod, thyroid tumors, malignant lymphosarcoma of northern pike, and fibromas or sarcomas of goldfish. Liposarcomas have been reported in captive-bred clownfish, and pigmented tumors of unknown origin have been seen in wild Hawaiian marine butterflyfishes, *Chaetodon miliaris* and *C. multicinctus*. Both species are popular in the marine aquarium hobby. Although the reported incidence of tumors in sharks, skates, and rays is low, neoplasia does occur.

Gonadal tumors are important neoplastic disorders of fishes and have been reported in koi and northern pike. Typically, fish present with a swollen abdomen, and, depending on the severity of disease, there may be significant loss of condition. The presence of a mass can be confirmed with ultrasound. Biopsy of tissue may not offer a clear diagnosis. Laparotomy of affected fish often reveals a circumscribed mass of gonadal tissue. Fish that are not excessively debilitated are excellent surgical candidates for removal of the mass.

Viruses, especially retroviruses, have been associated with neoplasia in fishes. Two examples of viral-induced neoplasia have occurred in tropical fishes. Viral particles have been found in fibromas on the lips of freshwater angelfish. Debulking the tumor can allow affected fish to feed normally. Bicolor damselfish neurofibromatosis, a fatal disease, was reported in 1991 in wild *Stegastes partitus* found on the reefs of south Florida; it is believed to be a viral-induced tumor. Although not reported in captive bicolor damselfish, it has the potential to occur.

BACKYARD POULTRY

Raising backyard poultry (*Gallus domesticus*) in urban environments is a growing trend in the USA. In developing countries, backyard poultry represent ~80% of poultry stock, often consisting of indigenous unselected breeds of various ages, with various species mixed in the same flock. This serves to meet household food demands and is an additional source of income. Modern day USA backyard poultry owners often view their birds as companion animals, in contrast to poultry raised for commercial production. A 2010 USDA study in four cities (Los Angeles, Denver, Miami, New York) found that 0.8% of all households owned chickens, and nearly 4% of households without chickens planned to have chickens in the next 5 yr. As backyard poultry ownership becomes increasingly popular, owners must be properly educated about how to keep their flocks healthy; thus, more veterinarians must be capable of providing this education.

All commercial and domestic chickens originate from the red jungle fowl (*Gallus gallus*), which was domesticated in Southeast Asia many centuries ago. Today, hundreds of different chicken breeds are bred for different purposes and are characterized by meat-type, egg-laying type, and dual purpose. Meat-type chickens are characterized by rapid growth rate and good meat yield, versus egg-laying chickens, which are selected for good egg production. Dual purpose chickens, such as Plymouth Rock, New Hampshire, Rhode Island Red, Wyandotte, and Orpington, are reasonably good for both egg and meat production, making them a suitable choice for backyard chickens for most owners. Purchasing chicks and other poultry from a reputable hatchery or breeder is recommended to get off to a good start and prevent future problems. Purchasing from hatcheries or breeders that participate in the National Poultry Improvement Plan (NPIP) is recommended, because these flocks are routinely tested for diseases such as *Salmonella Pullorum* and *S Gallinarum* (see p 2865). A list of certified hatcheries and breeders can be found by contacting official state poultry associations. In addition, prospective owners are encouraged to physically visit the breeder flock or hatchery of purchase to ensure only healthy birds are brought into the backyard flock.

Many backyard flock owners have multiple ages and/or species of birds.

Mixing birds of different species and from different sources increases the risk of introducing disease, and it is preferable to keep only birds of similar ages and species together ("all in/all out"). If multiple ages and/or species are kept on a property, efforts should be made to minimize contact between groups by keeping them in separate locations. Separating new or returning birds for at least 4–6 wk is necessary to monitor for signs of illness. Practicing good biosecurity (see p 2068) is also key for good poultry health.

PHYSICAL EXAMINATION

Before conducting a physical examination, the bird's appearance and behavior should be observed from a distance and within the flock. A healthy bird should be bright, alert, and interacting with the flock, with good appetite and free of abnormal behavior. Chickens and other domestic fowl can be restrained for examination by reaching over the back and holding the wings down. Then, the bird should be picked up and the fingers inserted between the legs while supporting the breast with the other hand. Restraining the bird upside down is not ideal, because it may increase its stress level and also cause regurgitation, as well as result in broken

Open mouth of a healthy chicken. Courtesy of Dr. Patricia Wakenell.

bones if bones are brittle from low calcium. The bird should be kept as calm as possible to prevent injury to both the bird and the handler. A chicken catcher, which is a wire hook used to grab birds by the legs, can also be used. For larger birds such as turkeys, the handler can fold his or her arms and upper body over the wings and back of the bird, hug firmly, and lift. It is important to remain low to the ground when handling bigger birds; grabbing these birds by their wings or legs can be dangerous and easily cause injury during struggling. For waterfowl such as ducks and geese, it is easiest to use the neck as a catching handle; however, once the bird is caught, it should be picked up by grabbing the wings together behind the back and using the other hand to support the abdomen. Smaller flight birds, such as quail, chukar partridges, and pheasants, can first be restrained by careful use of a net or towel and then holding the wings or legs. Catching birds on the first attempt minimizes stress.

Physical examinations should be performed using a systematic approach.

1) Examine the head and neck. The comb should be bright red, slightly warm, turgid, and free of scabs and lesions. The bird should hold its head high and have good muscle tone.

2) Observe the eyes, and check for any discharge or cloudiness that may indicate illness. The eyes of a healthy adult bird should be clear and bright and have a copper-red iris and a round pupil with well-defined margins. Young chicks generally have a blue-gray iris. The eyelids should be free of swelling and opened wide.

3) Check external nares for discharge, crusts, and scratches. The beak should be

smooth and free of cracks, and the tips should come to a point.

4) Open the mouth and check for ulcers and mucosal lesions on the tongue and mucosal membranes at the commissures of the beak.

5) Check the color of the earlobes to predict the color of the eggs the hens will produce. Hens that have white earlobes generally produce white eggs, and hens that have red earlobes generally produce brown or other pigmented eggs.

6) Evaluate the feathers to check for feather loss and how they are distributed. Loss of feathers around the back and back of the neck may indicate mating behavior by roosters. Check feathers at the base of the feather shaft to look for parasites such as lice, mites, and nits (lice egg packets). Feathers around the vent should be clear and free of blood or feces. Pasting of the vent with loose feces may indicate enteric disease. Check for scabs and blood around the vent, which are evidence of vent pecking and cannibalism.

7) The two small bones at the sides of the vent are the pubic bones. They should be flexible and have space in between. If hens are in lay, this distance should be the width of three or four fingers. When the hen is not laying, the pubic bones are usually stiff and close together (distance between is one finger width or less).

8) Check the legs and feet. The scales should be smooth and closely adhered to each other. If scales are raised and crusty, there may be a scaly leg mite infestation. Check the footpads for scratches, swellings, or ulcers caused by footpad dermatitis or pododermatitis (bumblefoot).

MANAGEMENT

Environment: Backyard poultry ownership laws and regulations vary by city, county, and neighborhood. Some cities and homeowner's associations have specific rules about chicken ownership, whereas other cities permit chicken ownership with no limitations on the number or type of chickens. It is important to know the regulations and to keep peace with the neighborhood about owning poultry.

It is crucial to fence in backyard poultry to keep them at home and to protect them. Domestic chickens are easy prey for predators such as cats, dogs, skunks, hawks, and foxes. The fencing should extend into the ground at least a foot to prevent predators such as raccoons and foxes from digging under the fencing. Water holes and vegetation should be avoided around the coop, because they encourage waterfowl, insects, rodents,

Subacute pododermatitis (bumblefoot) in a chicken with swelling of the footpads.

Courtesy of Dr. Patricia Wakenell.

and other vermin to the area, which can harm poultry and spread disease. It is wise to cover the top of the enclosure to protect the birds from predators that fly or climb, as well as to prevent exposure to wild fowl that may transmit disease.

Overcrowding should be avoided; space allocation must consider and allow for growth of the birds. Enough indoor space should be available to prevent overcrowding during inclement weather. The type of bird will help determine the type of housing. Most breeds of chickens are hardy, although meat-type birds are usually sturdier than egg layers. Show breeds often do not have hybrid vigor and require heated or cooled housing. Minimum space requirements should be determined not only by size of bird but also for activity levels. However, in general, laying hens and larger chickens need a minimum of 1.5–2 sq ft of space inside and 8–10 sq ft in outside runs. Ducks and geese need much more space, 3–6 sq ft inside and 15–18 in outside runs.

Floor type is an important consideration in building a coop, and owners need to be cognizant about how to work with various materials. Putting the birds on dirt is cheap and easy, but manure is hard to remove and can become a muddy mess without proper maintenance. When the soil gets wet or contaminated, the dirt must be tilled and new soil added after topdressing the old dirt with lime or bleach to prevent parasite and microbial overgrowth. Wood is another option, but it must be in good condition, because old wood may rot and harbor pathogens, and exposed splinters can result in injuries. In addition, wood should not be treated, because chemicals such as lead can be harmful to birds. Concrete flooring is the best for permanent coops, because it is easy to clean, impervious to vermin, and a good barrier to predators. However, it is the most expensive and takes the most effort to maintain. It is also important to use good, absorbent litter material for bedding in the houses. The litter should be clean, dry, and free of mold. Good litter choices include pine shavings, rice and nut hulls, chopped straw, and ground corncobs. Litter can get very wet around the drinkers, and proper removal of caked litter is necessary. Wet litter encourages growth of pathogens, such as bacteria, fungi, and parasites, as well as leads to problems such as footpad dermatitis. Dry litter creates a dusty environment and may cause tracheal irritation. Ideally, litter should contain 20%–25% moisture; a quick test is to grab a handful of litter and see whether the litter clumps briefly and then crumbles apart.

Wet litter and high ammonia levels can lead to serious welfare issues, including ammonia burns of the cornea, footpad dermatitis, breast blisters, and skin burns. The US Environmental Protection Agency (EPA) recommends that people and animals not be exposed to 25 ppm of ammonia for 28 hr. Adequate ventilation allows for moisture to be properly removed from the bedding.

Chickens have a body temperature of 105°–109°F (40°–43°C) and start to feel heat stress at environmental temperatures >75°F. In temperature extremes, poultry will modify their behavior to stay in their thermoneutral zone (55°–75°F). The ideal temperature range for poultry is 65°–75°F, with a relative humidity of up to 40%. To encourage good air circulation, windows should be put up on the south or east side of the barn, with a narrow ledge on the windows to prevent birds from roosting and defecating in the area. Using misters and fans will help keep the poultry cool during the hot summer months, and a well-insulated barn will keep birds warm during the winter.

Nutrition: The biggest expense in raising poultry is the cost of feed. However, good feed is a sound investment, because unbalanced diets will reduce performance levels and may result in nutritional diseases. Common issues in backyard flocks are insufficient water quality or amount, prolonged storage and degradation of vitamins and minerals, dilution of balanced and complete nutrition with scratch or supplemental feed, and feeding diets for the wrong life stage. Poultry require 1.5–3.5 parts water for every 1 part of feed consumed (up to 5–6 times for waterfowl) and require more in hot weather. Poultry will not consume feed if the amount of water is inadequate, which can lead to serious health problems. Poultry owners also have to consider the possibility of bacteria (eg, coliforms) and other contaminants in the water, including arsenic, calcium, chlorine, copper, fluorine, iron, lead, magnesium, mercury, nitrates, nitrites, sodium, sulfate, and zinc.

Vitamin and mineral deficiencies seen in poultry are discussed in more detail in the poultry section (see p 2936 and p 2930). The most common vitamin deficiency problems in backyard flocks are caused either by not using a vitamin premix in the diet or by using a vitamin premix beyond its shelf-life, resulting in loss of efficacy. Typically, fat-soluble vitamin deficiencies, especially vitamin D₃, will become clinically evident before water-soluble vitamin deficiencies. The most common presentation of birds with vitamin D₃ deficiency is skeletal

abnormalities (rickets) that can present in a flock as mortality, loss of condition, and birds that are lame or reluctant to move because of scoliosis, soft and pliable bones, or lack of bone strength. Owners should be advised to purchase quality feed, store it correctly (avoid temperature extremes to prevent vitamins and minerals from denaturing), and use it within the expiration date. Feed should be stored in a dry, cool area to avoid vitamins from breaking down and to prevent mold/fungal growth. Using a black light to check for fluorescence in corn grains is a quick way to screen for harmful mycotoxins. If poultry owners wish to mix their own feed, the most common range of inclusion for a vitamin/mineral premix would be 3–10 pounds of premix per ton of feed. Most feed and premixes are available in large quantities and expire in 3–6 mo (as short as 2 mo in the summer), and poultry owners need to be aware of the dangers of feeding old and improperly stored feed.

Backyard poultry owners need to know how much feed each bird will consume a day to predict when to order the next batch of feed. A day-old chick will eat approximately the amount of feed that can fit on the surface of a US quarter, and an adult laying hen should eat no more than a quarter of pound of feed per day. In contrast, a meat-type bird may consume close to twice as much feed as an adult layer. However, overfeeding or giving feed ad lib can result in musculoskeletal disorders. Using commercial broiler breeds in a backyard setting is strongly discouraged, because these birds need to be on very strict feed restriction to avoid metabolic disease. Birds with access to outdoors will supplement their diet by foraging and eating insects. In addition, many poultry owners choose to supplement their birds' diet with table scraps and scratch grains. Scratch should not be overfed, because it may cause the birds not to eat a balanced diet. Fat scraps should be avoided also, because they promote fatty liver and acute death from liver rupture. Signs of low or inadequate nutrient density include slow growth, slow or lack of egg production, and feather loss. Although foraging behavior may be desired, the birds should still receive most of their diet from a balanced, complete ration.

The type of feed recommended varies with the species, age, and use of the bird. For some species of birds, finding the appropriate feed ingredients can be difficult. In general, gamebird owners who cannot find the appropriate gamebird starter feed can substitute a turkey poul starter feed, which is typically high in protein (25%–28% crude

protein). It is critical to not feed layer diets to nonlaying, growing birds, because the inadequate protein levels and high calcium content (3.5%–6%) may result in irreversible renal damage. Thus, one of the most common problems seen in mixed-age flocks is urolithiasis (gout). Causes of gout include infectious bronchitis virus, feeding excessive levels of sodium bicarbonate, mycotoxins, and more often, feeding a high-calcium (adult layer) diet to an immature bird. Diets for growing birds (pre-lay) are typically 0.8%–1.2% calcium, whereas laying birds require 3.5%–6% calcium because of the nutritional demand for laying eggs (a typical egg requires ~2 g of calcium). However, it is important for adult layers to have adequate calcium to avoid osteoporosis (cage-layer fatigue) and thin-shelled eggs.

LAYING AND REPRODUCTION

For laying hens, nest boxes just large enough to fit one “seated” hen are desirable. If eggs are to be collected for consumption, efforts need to be made to decrease broodiness in the hens. The term “broody” refers to a hen that stops laying eggs in order to sit on the eggs, even when no eggs are present. As soon as this behavior is noticed, the hen should be moved to a wire cage. Broody hens can have an aggressive temperament, and caution must be taken during handling. Most hens put into cages become less broody in 2–3 days. Without intervention, hens may remain broody for 3–4 wk.

Backyard flocks raised under natural light will stop laying once hours of daylight become shorter and undergo a molt period lasting 3–4 mo or longer. Artificial lighting may be used for layers to lay eggs during the winter months, which will increase the number of eggs laid during that period but not the total number of eggs laid by the hen. Light schedules are usually 13-hr days, or lights on all night. Hens will be stimulated to start laying again as hours of daylight increase, not with continuous lighting. Supplemented lighting increases the risk of cannibalism in birds not individually caged. Chickens will lay eggs for ~1 yr before going into a molt. As long as feather loss is not associated with insect infestation, reddened or abraded skin, poor nutrition, or open wounds, an “unusual molt” can be assumed for lengthy or bizarre-appearing feather loss. If desired, this is also the time hens can be culled from the flock. In general, even the best hens will approach only ~70% of their former production level in their subsequent production period. All hens should molt at least once a year. If the hens do not naturally

molt, molt can be induced by decreasing hours of light.

Incubation and Hatching of Eggs:

Probably the largest determinant in deciding whether to buy hatched chicks or hatch within the backyard flock is the desired size of the flock. For small flocks, inexpensive, easy-to-operate incubators/hatchers are available at farm stores or through mail order catalogs. When first starting out, as many as 50% of the eggs may not hatch, thus making egg space a concern if a large hatch is needed. Most home incubators have good temperature control but inadequate humidity control. Chicken eggs can withstand changes in humidity during incubation; however, other species such as turkeys are much more sensitive to poor humidity control. With home incubators, temperature should be regulated for at least 2–3 days before the eggs are placed. During incubation, the temperature should be checked twice daily (fluctuations between 98°F and 101°F are fine for chicken eggs; temperature requirements for other species should be researched before incubation) and the water pan kept full. Eggs (except dark shelled) should be candled at least once during incubation, typically after the first mortality peak at 7–10 days of embryonation. Candling consists of shining a light through the egg to determine embryo viability by detecting movement of the embryo and presence of blood vessels. Fertile eggs will candle dark except for the air cell (air sac) with visible blood vessels and a live embryo. Infertile or “yolker” eggs will candle through with only a slight shadow for the yolk and have no internal structures and no embryonic development. Embryos that died with no positive development can also candle this way. Dead or nonviable embryos may have a blood ring around the embryo, caused by the movement of blood away from the embryo after death.

Dead eggs can be removed before possibly exploding. Eggs need to be turned ~4 times/day until the last few days before hatch (embryonation day 18 for chicken eggs). It helps to know approximate incubation periods of the poultry of interest to gauge when to provide adequate interference for a successful hatch. For example, the incubation period for chickens is 21 days, for Bobwhite quail 23–24 days, for guinea fowl 27–28 days, for ducks 28 days, and for geese 28–33 days. If eggs do not hatch, examination of the dead embryos can yield some clues as to the cause.

Common problems include early deaths (infertile eggs, too long or improper storage of eggs before incubation, extreme

temperature fluctuation), late deaths but not pipped (extreme temperature fluctuation, poor humidity), pipped but dried and stuck to the egg shell (generally poor humidity in late incubation, hatching period, weakened embryos from temperature fluctuations), and pipped but drowned in egg fluids or malpositioned embryos (turning malfunction during incubation). Once the chicks are hatched, they should not be moved until dry and fluffed. Occasionally, chicks will hatch that have not completely absorbed their yolk sac and/or intestines. These chicks have a poor chance of survival, and euthanasia is warranted. If possible, all chicken chicks should be vaccinated for Marek's disease (*see* p 2849).

VACCINATION

For the small flock owner, vaccination is generally necessary only if the birds have had disease problems in the past, may possibly be exposed to other birds (eg, at poultry shows, meat swaps, or wild bird access), or if new birds are introduced to the flock (open flock). Birds should not be vaccinated for a disease not present in their local area, because this will only introduce new organisms into the flock. Also, a sick bird's immune system is compromised and unable to withstand the stress of vaccination.

If certain diseases are a problem in a backyard flock, vaccination may be recommended after veterinary consultation. Marek's disease is present in almost every flock, and vaccination of chickens is strongly recommended in all cases; vaccination is key for control and is inexpensive. Backyard poultry owners may purchase chicks from hatcheries and request their chicks be vaccinated at hatch with serotype 3, or they can vaccinate their own chicks if hatched onsite. Because the virus is ubiquitous and spreads through feather dander, vaccinating birds at hatch before they are most susceptible (2–7 mo) is critical to establish early immunity. There are three serotypes of Marek's disease: 1, 2, and 3. Because most backyard chickens are vaccinated only for serotype 3, they may not be fully protected. Vaccination does not prevent infection or shedding of the field virus.

COMMON MANAGEMENT-RELATED DISEASES

Birds are prey animals, so early signs of illness may be subtle and difficult to discern. Some early signs of illness include changes in eating and drinking habits; dull feathers; soiling of the feathers around nares, vent,

shoulders, or eyes; swelling around or discharge around the eyes; discharge from the eyes or nares; abnormal feces; favoring or lameness in limbs; or decrease in activity.

Cannibalism: Pecking or cannibalism (*see* p 2873) is one of the most frustrating and common problems to control in floor-reared birds. Certain species such as pheasants and quail are notorious for cannibalism, often leading to individual cages as the only housing option. Certain breeds can be more aggressive than others within specific species. Cannibalism usually does not begin in chicks <2–3 wk old, although in young chicks, it is generally the result of insufficient feed or diarrhea (soiled or pasty vents). In mature birds, methods to control cannibalism include reducing lighting, reducing bird density, increasing the number of feeders, and trimming the beaks. If an individual bird has been pecked severely on the skin and separate housing is not available, spraying or painting the affected area with tree pruning tar (pruning sealer) is a quick remedy. After the sealer has been sprayed or painted on the affected area, the bird should be restrained until the sealant is dry. The tar protects the exposed area from fluid loss, is nontoxic on open wounds, and has the advantage of “identifying” the perpetrators by staining their beaks black. If small numbers of birds are the aggressors, these birds can be given red spectacles that attach to their nares, red contact lenses, or have their beaks retrimmed to reduce trauma in other birds.

Trauma: This is the most common condition of backyard poultry and includes predator injury, entrapment of limbs in cages or other equipment, cannibalism, crushing injuries (stepped on, trapped in doors, etc), and self-mutilation (spurs, beak, nails). Most adult poultry are highly resilient and seem able to recover from severe injuries if the wound has not penetrated into the respiratory or abdominal cavity. Supportive therapy includes providing warmth (via brooder lamp), adequate hydration, and force-feeding warm molasses/sweetened feed. Hydration can be encouraged by offering a half concentration powdered milk instead of water. Superficial wounds can be treated with antibiotic cream and parenteral antibiotics. Most poultry will show evidence of recovery in 2–3 days. If there is no improvement after a few days, the prognosis for full recovery is generally poor.

Fatty Liver: Although all laying birds retain more fat in their livers than non-layers

or males, fatty liver (*see* p 2820) is characterized by extreme fat deposition, sudden drop in egg production, and increased mortality. The hens are often obese and have pale combs, and the wattles and combs may be covered with dandruff. The cause is thought to be a combination of fatty feed and decreased exercise. Hens and poultry fed predominantly scratch diet (poultry treats, table scraps) are predisposed. Mortality is due to liver rupture and hemorrhaging, with large blood clots found in the abdomen on necropsy. Treatment is by prevention; most backyard birds have adequate outdoor access for exercise, but the diet must be controlled. Lipotropic agents and dietary supplements (alfalfa, wheat bran, fish meal, dried brewer's yeast, soybean mill feed, vitamin E, and torula yeast) have been used with inconsistent results.

Cage Layer Fatigue (Osteoporosis): Cage-layer fatigue (*see* p 2897) is common in chickens, Coturnix quail, and Khaki Campbell ducks. Birds are unable to stand and have brittle bones. The ribs are often deviated in a sigmoid shape or fractured at the junction of the sternum and vertebra. Paralyzed birds are alert and responsive unless dehydrated. Possible causes include vitamin D₃, calcium, and phosphorus deficiencies and/or imbalances. Birds may die acutely (often from fractured spinal vertebrae and severed spinal cords) or can rapidly (4–7 days) recover after placement on the floor with easy access to food and water. With backyard poultry, treatment with vitamin D₃ IM or calcium gluconate IV can be helpful. Oyster shells and other large particle calcium sources can be added to the diet ad lib to prevent this condition. The oyster shell must not be ground so small that it passes through the intestinal tract, because it is essential to have slow release of calcium from larger particles being ground in the gizzard. The strain of bird and type of housing also affect incidence. The key is to ensure good nutrition (and good cortical bone formation) just before onset of lay. However, prolonged increase in dietary calcium before production can result in urolithiasis and/or a permanent cessation of parathyroid gland activity.

Cloacal Prolapse or “Vent Blow-Out”: The vent will prolapse temporarily during normal delivery of an egg. However, slow retraction due to obesity or in poorly developed hens (those that come into lay too early) will attract cannibalism, trauma, and edema formation, which will often

prevent retraction. Typically, these chickens are culled, and prevention is practiced by controlling obesity, stocking density of cages, lighting schedules, precocious onset of lay, and proper beak trimming. For backyard poultry, stopping lay (reduced light, sharp reduction in feed), isolating from other birds, and keeping the vent clean until retraction are sometimes effective in mild cases. If chicks are hatched in the fall, increasing light in the spring can induce them to come into lay when they are physically immature. Controlling light is extremely important in this circumstance.

Egg Binding: Egg binding is common in pullets brought into production too early or in obese hens. It can range from a temporary egg-binding observed in pullets that lay large eggs to complete obstruction of the oviduct. There can be eggs in the abdominal cavity (retropulsed); single or multiple eggs in the oviduct; or shell membranes, shells, and yolk/albumin concretions in the oviduct. The impaction can generally be identified on abdominal palpation, ultrasound, and/or radiographic examination. Commercial hens are culled. Backyard poultry can sometimes be treated by external reduction (smashing) of the egg within the oviduct and natural elimination, or by surgical removal of the entire oviduct (not ovary). Wrapping the bird in a warm towel and massaging the abdomen toward the vent after use of generous amounts of lubrication around the cloaca can sometimes induce propulsion if the binding is caught early enough. The surgical approach is generally midline; care should be taken to minimize damage to the air sacs. After removal of the oviduct, eggs deposited into the abdominal cavity will be absorbed. Most hens will assume male characteristics (crowing, aggression, spurs) after surgery and are called “pollards” (genetically female, phenotypically male).

COMMON INFECTIOUS DISEASES

The following list includes some of the more common conditions encountered in backyard poultry practice.

Parasitism

As in other species, the common parasites in poultry are mites, lice, ticks, worms, and protozoa. Two common mites of poultry are the Northern fowl mite (*Ornithonyssus sylviarum*) and the red mite (see also p 2877). The Northern fowl mite is most commonly found around the vent, tail, and breast. These mites are easily observed as

small, reddish-brown flecks. Red mites (*Dermanyssus gallinae*) feed only at night, making daytime diagnosis difficult. They can be found in cracks and seams near bedding areas and appear like flea dust or salt and pepper-like deposits. Red mites cause feather loss, irritation, and anemia. Several types of lice live on poultry, and lice or nits can be seen at the base of the feathers. In severe infestations, growth and egg production can be affected. Insecticides are available for treatment. Fowl ticks (see p 2876) comprise a group of soft ticks that parasitize many species of poultry and wild birds. Ticks are easily missed, because they spend relatively little time on the bird. Heavy infestations can cause anemia or tick paralysis, and ticks can be vectors for *Borrelia anserina* (spirochetosis). Spraying of buildings with insecticide is the treatment of choice.

Roundworms and tapeworms are the most common internal poultry parasites and are generally the result of soil contamination and poor management. Unless infestations are heavy, clinical disease is usually not evident. A fecal examination should be performed before treatment to assess levels of infestation (and monitor effectiveness of treatment), because most domestic poultry will have some degree of internal parasitism. Piperazine can be used for roundworms, although its effectiveness can be minimal and drug resistance is a problem; off-label fenbendazole or levamisole can be used for tapeworms. These compounds should not be used in laying hens. Proper litter management will reduce parasite loads and reinfestation. As in commercial poultry production, control of coccidia is one of the more costly problems in raising backyard poultry. Coccidia are found primarily in the intestinal tract of most poultry but are also found in the kidney in geese. Coccidiosis is generally seen in young birds (1–4 mo old), although it can be seen in any bird >10–14 days old. Signs include diarrhea that is often bloody and frequently leads to loss in production, general malaise, and death. Coccidia thrive in moist, heavily soiled litter, and disease is often a result of too high a density of birds. Prevention is by supplying coccidiostats in the feed, which can be given to birds as early as in their starter diet. Outbreaks can be treated with treatment dose of selected coccidiostats and extra-label sulfa drugs. Sulfa drugs have a long withdrawal period and should not be used in laying hens. Routine yearly fecal examinations are recommended for all backyard flocks. (See also coccidiosis, p 2791).

Viral Diseases

Marek's Disease: Marek's disease (MD) is a common viral disease of chickens, both in commercial production and backyard flocks (see p 2849). The primary lesions are tumors of the viscera, muscle, skin, and peripheral nerves. Nerve lesions can be an early indicator of the disease and result in a condition termed "range paralysis." Birds with visceral tumors often have cachexia as the only clinical sign. Tumors of the muscles and skin are frequently palpable. Tumors that affect the eyes (ocular Marek's) could be seen as a grayish color change in the pupils or irregular margins of the pupils, with lack of proper pupillary light reflex. MD cannot be treated but can be prevented by vaccination at hatch. When backyard poultry are acquired or hatched onsite, every attempt should be made to vaccinate for MD. Vaccinations may not be effective if administered to birds > 1–2 wk old. Clinical MD generally affects birds 4–14 wk old; however, it is not uncommon in older birds, and death loss is often sporadic rather than explosive. If tumors are found in the viscera of deceased birds, carcasses should be submitted to a diagnostic laboratory for differential diagnosis between MD and avian leukosis (see p 2851), another common lymphoid tumor disease. Avian leukosis is seen in birds > 14 wk old, and tumors are similar to those found with MD. Avian leukosis has no treatment or vaccination.

Infectious Bronchitis: Infectious bronchitis virus (IBV; see p 2909) causes a rapidly spreading respiratory disease in young chicks. Production is reduced and egg shell abnormalities are seen in laying hens. Certain strains of IBV also cause kidney disease. Chicks infected early in life may have permanent damage to the oviduct, so they do not produce eggs or become false layers (see p 2897). IBV is highly transmissible, but most birds recover with supportive treatment. Antibiotics can be administered in the water to prevent secondary infection. Vaccines are available; however, backyard chickens are usually not vaccinated unless they come in contact with other chickens.

Newcastle Disease: Newcastle disease virus (NDV; see p 2856) affects numerous species of birds and is the reason for quarantine regulations for birds entering the USA. Exotic NDV is highly fatal and is not present in the USA at this time. Past outbreaks have resulted in the slaughter of thousands of birds. Milder forms of NDV are present in the USA and are primarily characterized

by respiratory disease and a drop in egg production. Mortality is variable and depends on the strain of the virus. As with infectious bronchitis virus, vaccination is available but is generally given to backyard poultry only if exposed to other birds.

Fowlpox: Fowlpox virus (see p 2824) causes crusty and nodular lesions primarily on the unfeathered portions of the bird. Occasionally, poxvirus can cause lesions in the mouth and trachea, causing death due to suffocation (wet form). If the bird recovers, immunity is generally lifelong. Not all pox outbreaks are caused by fowlpox virus but can be caused by related strains such as turkey pox, psittacine pox, quail pox, etc. Strains are usually species specific but can occasionally affect other species (eg, pigeon pox). One strain may not cross-protect with another. Vaccination is available and should be given to flocks on premises with a previous history of pox or with presence of pox in nearby birds. Poxvirus is transmitted through contact of infected lesions with open wounds and by insect bites (mosquitoes), and insect control is key to prevent spread.

Avian Encephalomyelitis: Avian encephalomyelitis (AE; see p 2888) is seen in chickens, turkeys, pheasants, and quail. It primarily affects chicks 1–3 wk old. Nearly all commercial flocks are infected, but clinical disease is low because of maternal antibodies. AE can be transmitted vertically in eggs laid between 5 and 13 days after infection and is an enteric infection under natural conditions. The spread is more rapid in floor-raised birds than in cage-raised birds. There is no treatment, and vaccination of breeders (both chicken and turkey) for maternal antibodies to protect the young during early life is critical to prevention. Because many specialty breeders, particularly those that sell stock to an intermediate supplier, do not vaccinate, AE is a fairly common viral disease in backyard poultry. Vaccination should be given after 8 wk of age but by at least 4 wk before production.

Bacterial Infections

Salmonellosis: In general, *Salmonella* Pullorum (see p 2865) and *S* Gallinarum (fowl typhoid; see p 2866) cause the greatest problem for poultry, whereas *S* Typhimurium, *S* Enteritidis, *S* Heidelberg, and *S* Kentucky are important in terms of public health. *S* Pullorum is egg transmitted, causes a diarrheal disease in young chicks and poults, and results in high mortality. Adult

birds are asymptomatic carriers. Diagnosis is based on disease history and isolation of the bacteria. Prevention is achieved by purchasing birds from a breeder flock that is NPIP certified (National Poultry Improvement Plan) clean of *S Pullorum* and typhoid. Treatment is not recommended, because it can cause birds to become carriers. Fowl typhoid is seen in chickens, turkeys, and many other game and wild birds. Fowl typhoid is similar in disease presentation and diagnosis to *S Pullorum*, although mature birds can show clinical signs of fowl typhoid. Clinical signs are infrequently observed in poultry infected with *S Enteritidis* and *S Typhimurium*, although most paratyphoid *Salmonella* infections are asymptomatic in most poultry. Flocks can be monitored by obtaining egg samples and environmental samples to culture the organism.

Colibacillosis: Colibacillosis (see also p 2814) is caused by *Escherichia coli* and is usually secondary to other infections such as infectious bronchitis virus and mycoplasmosis. *E coli* is seen in most species and age groups. A wide variety of clinical signs affecting the respiratory, reproductive, and intestinal systems can be seen. Vigorous adherence to biosecurity and sanitation programs can effectively prevent the organism from causing disease. Many antibiotics can be used for treatment, and sensitivity to the antibiotic should be tested. Treatment is usually successful if the disease is in the early stages.

Mycoplasmosis (Chronic Respiratory Disease): Chronic respiratory disease in poultry (primarily chickens and turkeys) is generally caused by *Mycoplasma gallisepticum* infection (see p 2841). *M gallisepticum* is a reportable disease in turkeys in select states in the USA. Pathogenicity of *M gallisepticum* is enhanced by infection with other organisms. Clinical signs of respiratory disease develop slowly in a flock, and feed consumption drops. Infection of the sinuses with purulent exudate (swollen face) is common in turkeys. Serology and isolation and identification of the organism can be used for diagnosis. Prevention, as with the salmonellae, rests with establishment of a clean flock by eliminating the infected flock, completely sanitizing the premises, and obtaining clean stock. Vaccination is available on a state-by-state basis. Treatment is expensive, and the disease often recurs after treatment is stopped. Other important mycoplasmas in poultry include *M synoviae*

(infectious synovitis) and *M meleagridis* (venereal infection and airsacculitis).

Fungal Diseases

Aspergillosis: Aspergillosis (see also p 2901), or brooder pneumonia, is seen in many poultry and other species of birds. Birds <3 wk old are most commonly affected, and infection is obtained from hatchers or brooders contaminated with fungal spores. Morbidity is variable, and mortality can be high in clinically affected birds. Culturing the fungus or demonstrating typical fungal hyphae in fresh preparations from lesions are used for diagnosis. Prevention is accomplished by thoroughly cleaning hatchers, incubators, waterers, feeders, and ventilation fans and by keeping litter clean and dry. Treatment is expensive and may not be effective. Ketoconazole and nystatin have been used.

Favus: Favus, or ringworm, also known as white comb, is a fungal disease caused by *Microsporum gallinae*, which is of minor importance in all fowl, especially chickens and turkeys. Affected birds have small, white, chalky deposits on the comb, which can enlarge and coalesce to form a dull white, moldy layer that could be several millimeters thick. The disease is self-limiting, and the comb heals after several months. Typically, if the disease is limited to the comb, the health of the bird is not affected, but if feathered portions are involved, the bird may become emaciated and die. Favus is a public health concern.

Antibiotic Usage

Antibiotics are readily available in feed stores and online poultry supply sites; however, use of antibiotics must be carefully considered. Each antibiotic is labeled for different species and the use of the poultry, and administering the correct dosage may be difficult. In some instances, antibiotics are useful to treat and control disease. Certain antibiotics such as chloramphenicol, glycopeptides, and fluoroquinolones are prohibited for extralabel use in food animals, including backyard poultry. A veterinarian should be consulted; judicious use of antibiotics may be recommended after appropriate diagnostics. However, vaccination, good biosecurity, good management, proper sanitation practices, and a good plane of nutrition are key to control of disease and are far more effective than antibiotic usage.

FERRETS

The domestic ferret (*Mustela putorius furo*) is in the order Carnivora, family Mustelidae, and has been in captivity for more than 2,000 years. Ferrets are used as research animals, often in studies of the respiratory system and as a model for *Helicobacter* sp infection. They have become popular pets in recent years in the USA. They are also used as hunting animals in Europe, Australia, and New Zealand.

MANAGEMENT

The male ferret (hob) can weigh as much as 2 kg when intact, with an average weight of 1.2 kg when neutered. The female (jill) can weigh as much as 1.2 kg when intact, with an average weight of 0.8 kg when spayed. Sexual maturity is reached at 4–8 mo and occurs in the first spring after birth. The vast majority of ferrets are spayed or neutered before 6 wk of age, primarily because females are induced ovulators and can develop severe hyperestrogenemia if not bred. Ferrets also have less of the musky smell that is characteristic of Mustelids if they are gonadectomized early in life. The anal scent glands are usually removed at the time of the neuter or spay. Most physiologic data for ferrets are similar to those of the domestic cat, except that creatinine should not be >0.9 mg/dL in ferrets. Ferrets require high levels of fat and protein in the diet and should be fed commercial ferret food or high-quality cat or kitten food. Most adult ferrets have a large spleen. This is usually caused by extramedullary hematopoiesis and is nonpathogenic; ultrasonography and aspiration can be used for a definitive diagnosis.

Vaccination: Ferrets are vaccinated annually for rabies and canine distemper. There is one FDA-approved rabies vaccine for ferrets in the USA. It should be given to ferrets >16 wk old and repeated annually. If this vaccine is unavailable, a recombinant vaccine should be substituted. Canine distemper vaccines for ferrets should be of chick embryo or recombinant origin. Vaccines of mink or ferret culture (eg, most multivalent vaccines for dogs) should not be used, because they may cause seroconversion and disease. There is currently one FDA-approved distemper vaccine in the USA for ferrets. Ferrets should be

vaccinated at ~8, 10, and 12 wk of age and then yearly. Vaccine reactions occur frequently in ferrets; vaccinated animals should be monitored for 20–30 min after vaccination, and only one vaccine (ie, rabies or distemper) should be given at a time. Ferrets raised commercially are often vaccinated for *Clostridium botulinum* type C at 6–8 wk old.

INFECTIOUS DISEASES

Bacterial Diseases: *Helicobacter mustelae* is found in the stomach and duodenum of all ferrets after weaning. It is an opportunistic pathogen and can induce chronic, persistent gastritis and ulcer formation similar to the disease in people. Gastric lymphoma may occur in chronic cases. Clinical signs include inappetence, vomiting, bruxism, diarrhea, melena, and hypersalivation. Lethargy, weight loss, and dehydration can also occur. These animals may be painful on cranial abdominal palpation because of the ulcers induced or enhanced by the presence of this bacterium. Definitive diagnosis requires examination of tissue from surgical or endoscopic biopsy but is not commonly performed because of the ubiquitous nature of this organism in the ferret GI tract. Silver stains and urease tests should be performed on the biopsy specimens when attempting to determine a definitive diagnosis. A molecular assay is available for fecal samples. Treatment is with multidrug regimens, including amoxicillin (20 mg/kg, PO, bid), metronidazole (20 mg/kg, PO, bid), and bismuth subsalicylate (1 mL/kg, PO, bid). Clarithromycin (25 mg/kg/day, PO) and omeprazole (1 mg/kg/day, PO) can be used for refractory cases. Treatment is usually for 21 days. Because of the opportunistic nature of this pathogen, it is important to look for underlying problems such as gastroenteritis, foreign bodies, or stress. Treatment for *Helicobacter* is commonly initiated when gastroenteritis or foreign bodies are diagnosed or when a gastrotomy is performed.

Lawsonia intracellularis can cause a proliferative bowel disease, especially in younger ferrets. Signs include diarrhea,

weight loss, and rectal prolapse. Treatment is with chloramphenicol (25 mg/kg, PO, bid) for 14–21 days.

Salmonellosis in ferrets is rare but associated with feeding raw or undercooked meat or unpasteurized milk. Signs include bloody diarrhea, conjunctivitis, and anemia. *Salmonella* Typhimurium, *S* Newport, and *S* Choleraesuis may be involved. Treatment is with aggressive supportive care and antibiotics. Ferrets are susceptible to *Mycobacterium avium*, *M bovis*, and *Mycobacterium tuberculosis*. Intradermal testing is not reliable. Bacterial cystitis is rare in ferrets and is usually associated with urolithiasis and prostatomegaly. *Escherichia coli*, *Staphylococcus aureus*, and *Proteus* spp are most commonly identified. Bacterial pneumonias in ferrets are caused by *Streptococcus zooepidemicus*, *Mycobacterium* spp, and gram-negative bacteria such as *E coli* and *Klebsiella pneumoniae*. Other bacterial infections are similar to those seen in other carnivores.

Viral Diseases: Ferrets are susceptible to **canine distemper virus**. Transmission is by aerosol or exposure to infected secretions. Clinical signs begin 7–10 days after infection and start as fever and dermatitis on the chin and inguinal area, progressing to anorexia, erythema of mucus membranes, and mucopurulent ocular and nasal discharge. Brown crusts on the face and eyelids and hyperkeratosis of the footpads also occur. Respiratory signs develop and progress rapidly. Diagnosis is by history, clinical signs, and positive immunofluorescent antibody testing or histopathology. Mortality is close to 100% and typically occurs 12–14 days after infection.

The **human influenza virus** causes fever, lethargy, anorexia, nasal discharge, sneezing, and depression in ferrets. Treatment is supportive and includes antibiotics for secondary infections, antihistamines, and amantadine (6 mg/kg, nasally, bid). Recovery is usually within 7–14 days.

Two coronaviruses cause disease in ferrets. The ferret enteric coronavirus causes **epizootic catarrhal enteritis**. This disease is highly transmissible and is often brought into a group of ferrets by an asymptomatic juvenile animal. Clinical signs begin 2–14 days after introduction of the new ferret or exposure through fomites and include anorexia, vomiting, green or mucoid diarrhea, melena, dehydration, lethargy, and weight loss. The disease is most severe in older ferrets, which may take months to fully recover. The virus causes blunting of the intestinal villi and conse-

quent maldigestion and malabsorption. Definitive diagnosis is difficult, although scanning electron microscopy of the feces may identify coronavirus. Increased ALT and alkaline phosphatase may occur secondary to hepatic lipidosis. Treatment is supportive and includes fluids, nutritional support, broad-spectrum antibiotics, and GI protectants. Prevention is by quarantine of new ferrets, thorough cleaning of new bedding and toys, and washing hands and changing clothes after handling other ferrets.

A second related coronavirus called ferret systemic coronavirus causes a systemic pyogranulomatous inflammatory disease resembling the dry form of feline infectious peritonitis. This disease is seen in young ferrets (average age 11 mo) and is progressive throughout several weeks to months. Clinical signs include anorexia, weight loss, diarrhea, and enlarged intra-abdominal and, less commonly, peripheral lymph nodes. Hypergammaglobulinemia, anemia, and CNS signs can be seen as the disease progresses. This disease was initially called disseminated idiopathic myofasciitis because of the white nodules found in many tissues on necropsy. These nodules are pyogranulomatous inflammation and involve many organs, including peritoneum, adipose tissue, viscera, and blood vessels. A pyogranulomatous pneumonia has also recently been reported. Treatment is supportive with immunosuppressants such as prednisolone and anecdotal reports of use of polyprenyl immunostimulants, which have resulted in some increase in survival time. Average survival time is ~2 mo.

Aleutian disease is a parvovirus originally seen in mink, but at least two distinct ferret strains of the virus have been identified (see p 1872). The virus causes immune complex deposition in organs, which results in a variety of nonspecific clinical signs such as progressive weight loss, weakness, ataxia, hepatomegaly, and splenomegaly. A severe hypergammaglobulinemia is the most consistent finding on blood work. A presumptive diagnosis is based on clinical signs and hyperglobulinemia. The two most common tests for the virus antibody are counterimmunoelectrophoresis and immunofluorescent antibody tests. Definitive diagnosis is difficult, because many apparently normal ferrets have positive titers. The organism has been found in the urine, feces, and blood of symptomatic and asymptomatic animals. Treatment with anti-inflammatories and immunosuppressants such as prednisolone

and cyclophosphamide can be considered and may have clinical benefit. Treatment of infected mink kits with gamma globulin—containing Aleutian disease virus antibody has decreased mortality rates, but this treatment has not been attempted in ferrets. There is currently no vaccine available for this disease in ferrets.

Fungal Diseases: Ferrets are susceptible to *Microsporum canis* and *Trichophyton mentagrophytes*. Transmission is by direct contact or fomites and is often associated with overcrowding and exposure to cats. Infection is more common in kits and young ferrets and is often seasonal and self-limiting. A pyogranulomatous dermatitis and fungal pododermatitis has been associated with *Microsporum nanum*. Other fungal diseases in ferrets include cryptococcal meningitis and blastomycosis causing granulomatous meningoencephalitis. Fungal pneumonia is uncommon in ferrets but can be caused by *Blastomyces dermatitidis* and *Coccidioides immitis* in endemic areas. Cryptococcosis from *Cryptococcus bacillisporus* and *C. neoformans* var *grubii* has been diagnosed in ferrets. Signs include pneumonia, pleuritis, rhinitis, and regional lymph node enlargement.

Parasitic Diseases: Ear mites are the most common ectoparasite in ferrets and are caused by *Otodectes cynotis*. The same ear mite is found in dogs and cats, and it can be passed between species. Diagnosis and treatment are as for dogs and cats (see OTITIS EXTERNA, p 527). Fleas are also common in ferrets and can be transmitted between ferrets and other household pets. Diagnosis is by visualization, and treatment is the same as for dogs and cats (see FLEAS AND FLEA ALLERGY DERMATITIS, p 880). Many of the long-acting topical treatments, such as fipronil, last longer in ferrets because of the increased sebum in the coat. Mange in ferrets is caused by *Sarcoptes scabiei* and can be seen as a generalized dermatitis or can be limited to the feet, toes, and pads in a pedal form unique to ferrets.

Heartworm disease, caused by *Dirofilaria immitis*, can be found in ferrets, especially if given outdoor access in endemic areas. Disease can be caused by even a single worm. Clinical signs include lethargy, coughing, dyspnea, and ascites. Ferrets are typically infected with a very small number of worms (1–20), making diagnosis difficult. Echocardiography is warranted, because the parasites often obstruct blood flow and cause right-side heart failure. Echocardiography may also be

helpful in identification of the worms in the right ventricle, pulmonary arteries, and vena cavae. Peripheral microfilaremiias uncommon in ferrets; therefore, antigen testing is more beneficial. Treatment using long-term antithrombotic drugs and adulticides can be done but may cause problems. Low-dose ivermectin (0.05 mg/kg, SC, monthly until clinical signs and microfilaremia resolve) is the current recommended treatment (see HEARTWORM DISEASE, p 127).

Coccidiosis can cause disease in young ferrets including diarrhea, lethargy, and rectal prolapse. Diagnosis and treatment are similar to those in dogs. Rectal prolapse can also occur with coccidiosis and usually resolves after treating the underlying disease. Topical hemorrhoidal creams may be helpful.

NEOPLASIA

Cutaneous mast cell tumors are probably the most common nonendocrine tumor in ferrets. These tumors can appear anywhere on the body but typically affect the trunk and neck. The tumor appears as a raised, irregular, and often scabbed mass. Systemic signs are rare, but the tumors may bleed when scratched. Treatment is by excision. Local treatment with strontium may also be beneficial.

Lymphoma is common in ferrets and can affect many organ systems, including the lymph nodes, spleen, liver, heart, thymus, and kidneys. Disease of the spine and CNS has also been seen. Lymphoma of young ferrets is often rapidly progressive, whereas it is often a chronic disease in adults. Clusters of lymphoma have been seen in related or cohabitating ferrets, and a viral agent is suspected in those cases. Diagnostics should include a CBC, chemistry panel, radiographs, ultrasonography, and aspirates of any suspected tissues. Treatment protocols for ferrets have not been standardized but can include removal of the neoplastic tissue if possible, chemotherapy, and/or radiation therapy. Immunosuppression is a common problem with chemotherapy in ferrets, and frequent CBCs are imperative with any treatment protocol.

Chordomas and chondrosarcomas have been reported in ferrets. Chordomas typically appear as firm masses on the tail. They may become ulcerated from dragging on the ground but otherwise cause few problems. These tumors have also been reported at the cervical region, causing paresis and ataxia. Surgical removal is suggested when possible. Chondrosarcomas can develop anywhere along the spine,

ribs, or sternum and tend to cause spinal cord compression and associated clinical signs. Treatment should include removal, if possible.

Splenomegaly is common in adult ferrets and is usually caused by extramedullary hematopoiesis; however, lymphoma and hemangiosarcoma can occur. An irregular or firm spleen should be investigated with ultrasonography and aspiration.

ENDOCRINE DISORDERS

Insulinomas are very common in ferrets >2–3 yr old. These functional tumors of the pancreatic β cells cause increased insulin levels, resulting in hypoglycemia and its associated clinical signs such as weakness, lethargy, posterior paresis, hypersalivation, bruxism, and seizures. Diagnosis is based on demonstration of hypoglycemia and corresponding normal or increased insulin levels. Other blood tests are usually normal. Ultrasonography is only occasionally useful in demonstrating these pancreatic masses. Medical and surgical treatments are possible, but there is no cure, and owners should be made aware of the chronic and progressive nature of this disease. Surgical treatment involves removing discrete tumors via nodulectomies or partial pancreatectomy. Microscopic tumors within the entire pancreas are common; therefore, removal of the entire tumor is unlikely. A period of euglycemia occurs after surgery in some cases, but most cases require continued medical treatment. Major benefits of surgery are decreased severity of signs, ease of management, and moderately increased survival time. Medical management includes use of prednisone (0.5–2 mg/kg, PO, bid) and diazoxide (5–30 mg/kg, PO, bid) to counteract the effects of the tumor; however, this does not affect the tumor directly. Prednisone increases resting blood glucose levels and down-regulates peripheral insulin receptors, whereas diazoxide decreases insulin release from the β cells and competes at peripheral insulin receptors. These drugs can be used independently or synergistically. Typically, prednisone is used first until the dosage approaches 2 mg/kg and then diazoxide is added. Medical treatment is lifelong, and glucose levels should be monitored 5–7 days after changing doses and at least every 3 mo afterward.

Hyperadrenocorticism in ferrets is caused by excessive secretion of the sex hormones progesterone, testosterone (in the form of androstenedione), and estrogen by the zona reticularis of the adrenal gland. It can be seen in ferrets as young as 1.5 yr

old. The most common clinical sign is hair loss beginning on the tail and rump and progressing up the flank and head. In females, a swollen vulva and enlarged mamillae may also be seen, whereas males may develop aggression and stranguria secondary to prostatic enlargement. Bone marrow suppression may be seen in either sex, with severe hyperestrogenemia. A presumptive diagnosis is made after history and physical examination. The enlarged adrenal glands are often palpable cranial to either kidney. CBCs and chemistry panels are typically normal. Radiographs are not useful, because the masses do not calcify as commonly as in other species. Ultrasonography can demonstrate enlargement of the gland(s). Definitive diagnosis requires measurement of the three sex hormones, which can be performed in a panel (at University of Tennessee).

Medical and surgical treatments exist. Surgical removal of the adrenal gland(s) is more likely to be curative than medical management, but there is still a recurrence rate of ~40% after surgery. The left gland is easier to remove, because the right gland is closely associated with the caudal vena cava. If both sides are affected, a subtotal adrenalectomy can be performed. Histology of these glands may reveal hyperplasia, adenoma, or adenocarcinoma. Functionally, all three grades are similar, and metastasis is unlikely. Hypoadrenocorticism may develop if both adrenal glands are completely or partially removed. This may be treated with mineralocorticoid and glucocorticoid supplementation. Medical management of hyperadrenocorticism is aimed at reducing the clinical signs but does not affect the adrenal tumor itself. Leuprolide acetate is the most common drug used. The mechanism is not completely understood but is probably related to down-regulation of peripheral hormone receptors. Leuprolide is a repositol formulation of a GnRH agonist that is formulated in 1-mo (100–400 mcg, IM) and 4-mo (2–4 mg, IM) preparations. Owners should be advised that this is a lifelong treatment to control the clinical signs of the disease. Recently, some clinicians have treated hyperadrenocorticism medically only during breeding months, typically November to March. Deslorelin acetate, a similar GnRH agonist, is also available. This is a longer-acting implant that lasts 10–17 mo. This drug is well tolerated by ferrets. Melatonin can also be used at 1 mg per ferret per day, orally or in an injectable, repositol formulation, which is reported to last 4 mo. This drug counteracts the alopecia and may help with other signs as well, but, like leuprolide, is

only symptomatic treatment. Drugs used to control sex hormone levels in people are beginning to be used in ferrets and show promise in controlling clinical signs.

OTHER NONINFECTIOUS DISEASES

Gastric foreign bodies are common in ferrets because of the animal's inquisitive nature. Foreign bodies are usually soft rubber or plastic items but can also be trichobezoars. Clinical signs include anorexia, bruxism, hypersalivation, cranial abdominal pain, diarrhea, and melena. Vomiting is more common with gastritis than with foreign bodies. Diagnosis is with plain or contrast radiography. Treatment involves surgical or endoscopic removal. Gastritis should be treated after removal of the foreign body.

Dilated cardiomyopathy can occur in ferrets, usually those > 4 yr old. Clinical signs can be similar to those of insulinoma, so both should be excluded when examining a ferret with lethargy, weakness, ascites, increased respiratory effort, or exercise intolerance. Diagnosis is by radiography and echocardiography. Treatment is based on echocardiographic abnormalities and includes furosemide, digoxin, enalapril, benazepril, and pimobendan. A formulary should be consulted for dosing instructions.

Renal disease in ferrets is similar to that in other species. Renal cysts are common in adult ferrets and usually do not cause a problem unless present in large numbers. Uroliths can develop in ferrets fed diets high in plant proteins and are usually composed of struvite.

HEDGEHOGS

Hedgehogs are in the family Erinaceidae, within the order Insectivora. The central African hedgehog (*Atelerix albiventris*), also known as the white-bellied, fourtoed, or African pygmy hedgehog, is native to dry, open habitats in central and eastern Africa. They are nocturnal and very active, jogging for miles in search of invertebrate prey. In the USA, it is illegal to own a hedgehog as a pet in some states and municipalities; in other states, a permit is required. Additionally, a USDA permit is required to breed, transport, sell, or exhibit hedgehogs.

Anatomy, Physiology, and Behavior:

The dorsum is covered in a dense coat of keratin spines; each spine has a basal bulb that firmly attaches it within the follicle, with a narrowed portion at the skin surface. Healthy spines are difficult to pull from the follicle without breakage. The spined skin has a thin and hairless epidermis and a thick, fibrous dermis with much fat and few blood vessels. A wary hedgehog will raise the spines and crouch. If a hedgehog is frightened, contraction of the panniculus muscle pulls the loose spiny skin over the entire body. The panniculus is thickened at the rim to form the orbicularis, a purse-string-like muscle that closes the spined skin over the animal. For selected physiologic data for African pygmy hedgehogs, see TABLE 10.

Hedgehogs have brachydont teeth. The first incisor in each quadrant is large

and projects forward, and there is a gap between the maxillary first incisors. The stomach is simple, and a vomiting reflex is present. The male has a conspicuous prepuce that opens mid-abdomen. There is no scrotal sac; the testes are located in a para-anal recess surrounded by fat and can be palpated in reproductively active males. The female urogenital opening is a few millimeters cranial to the anus. The uterus is bicornuate with a single cervix and no uterine body. Hedgehogs are polyestrous and breed throughout the year in captivity. Ovulation is believed to be induced, and sterile matings with pseudopregnancy may occur. Hedgehogs are born hairless, with closed eyes and ears; at birth the spines are covered by a membrane that is removed within the first few hours of life.

Hedgehogs are adept at climbing, digging, swimming, and jogging. While they have sensitive olfaction and hearing, their sense of vision is not as well developed. Foraging hedgehogs normally emit a variety of snuffling sounds; agitated hedgehogs make a loud hissing sound that may be punctuated with various puffing and cough-like sounds. With intense distress, a scream may be emitted. With patience, most hedgehogs learn to accept handling.

Hedgehogs demonstrate a unique behavior called self-anointing, or anting. This behavior may be elicited by a variety of substances, particularly those with a strong odor. The hedgehog takes the material into the mouth,

TABLE 10 PHYSIOLOGIC DATA FOR AFRICAN PYGMY HEDGEHOGS

Average body weight	Male: 400–600 g Female: 300–400 g
Life span	Average 4–6 yr, may live to 8 yr
Body temperature	95.7°–98.6°F (35.4°–37.0°C)
Adult dental formula	2 (I3/2: C1/1: P3/2: M3/3) = 36 (variations have been noted)
GI transit time	12–16 hr
Heart rate	180–280 bpm
Respiratory rate	25–50 bpm
Age at sexual maturity	2–3 mo
Reproductive life span	Male: throughout life Female: 2–3 yr
Gestation	34–37 days
Litter size	3–4 (range 1–9)
Birth weight	10–18 g
Eyes open	14–18 days
Deciduous teeth eruption	Begins on day 18; all deciduous teeth erupted by 9 wk
Permanent teeth eruption	Begins at 7–9 wk
Age at weaning	5–6 wk (start eating solids at 3 wk)

mixes it with frothy saliva, and applies the mixture to its spines with the tongue. The purpose of this behavior is unknown.

MANAGEMENT

Housing: Wild hedgehogs are solitary; as pets they are usually maintained in individual cages. Some fanciers successfully house multiple animals together, but this can lead to disproportionate feeding and injuries from fighting. Healthy hedgehogs are very active; 2 × 3 ft are minimal floor dimensions. Hedgehogs are able to climb and can escape through small holes, so the cage must be secure and lidded. Glass tanks and plastic-bottomed cages with wire walls are suitable, provided that the wire spacing is sufficiently close. Widely spaced wires can lead to limb entrapment or death if the hedgehog's head becomes ensnared by its spines. A hiding place is essential. The cage substrate should be soft and absorbent. Recycled newspaper bedding is a good choice; aspen shavings, alfalfa pellets, and hay are other options. Wire, cedar, corncob, and dusty or scented substrates are not recommended, and cloth bedding poses a risk of limb entrapment. The substrate should be 3–4 in. deep to allow for digging.

Ambient temperature should be 72°–90°F (22°–32°C); 75°–85°F (24°–29°C) is optimal. Hedgehogs may go into a torpid state if too cool or too warm; this is believed to be unhealthy for pet hedgehogs. A heating pad placed underneath the enclosure or a ceramic reptile heater may be used. Low humidity (<40%) is preferred. Hedgehogs avoid bright light; however, a day cycle of 10–14 hr of mild light should be provided. Although some owners may attempt to convert their pets to a diurnal schedule, most remain nocturnal.

Some hedgehogs use a litter tray; natural plant litters used for cats make the best litter substrate. Clay, clumping-type litter, or sand may stick to the animal and should not be used. Many hedgehogs defecate in their hide boxes and exercise wheels, so daily spot cleaning is often necessary. Exercise wheels with solid metal or plastic running surfaces are highly recommended. Hedgehog legs can become entrapped in wire wheels. Hedgehogs should be let out daily for exercise. Cardboard tubes, straw, safe climbing structures, swimming tubs, and other toys provide interest. Dirty hedgehogs may be bathed with a mild pet shampoo and use of a soft-bristle vegetable brush.

Diet: The ideal diet is a commercially prepared hedgehog food. If hedgehog food is not used, premium food for less active cats or dog food are alternatives. Food should be rationed to prevent obesity.

Depending on the animal's weight and activity, 3–4 tsp (15–20 mL) of the main diet is typically fed daily. Growing animals and reproductively active females may be fed ad lib, and calcium-rich foods are recommended.

In addition to the main diet, ~1–2 tsp (5–10 mL) of varied moist foods and/or invertebrate prey (eg, canned cat or dog food, cooked meat or egg, low-fat cottage cheese, mealworms, earthworms, waxworms, gut-loaded crickets) and ~1 tsp (5 mL) of vegetable/fruit mix (eg, beans, cooked carrots, squash, peas, tomatoes, leafy greens, banana, grape, apple, pear, berries) should also be provided daily. Invertebrate prey and dry food items may be hidden in the bedding to promote foraging. Hedgehogs should not be fed raw meat or eggs, which may harbor *Salmonella*. Milk can cause diarrhea. Vitamin or mineral supplementation is not necessary for hedgehogs fed a commercial diet. Hedgehogs are often slow to accept new foods, and diet changes must be made with care. Fresh water should be available at all times. Most hedgehogs can learn to drink from water bottles.

Breeding and Neonatal Care: Females should be at least 6 mo old before breeding. A weight gain of ≥50 g within 3 wk of breeding suggests pregnancy. At 30 days, abdominal and mammary enlargement may be detected. Infanticide and cannibalism of the young can occur; the female needs strict privacy from other hedgehogs and people starting ~5 days before delivery and continuing 5–14 days after parturition.

In cases of lactation failure or abandonment, fostering of the pups (or “hoglets”) to another dam with similarly aged pups is usually successful. If a surrogate dam is unavailable, a canine milk replacer may be fed through a feeding tube or syringe; however, hand-rearing of hedgehogs is associated with high mortality. Weaning generally occurs at 5–6 wk, and the young may be moved to separate cages at 8 wk. Daily handling starting at 3 wk will result in hedgehogs that remain tame.

Restraint and Examination: Because most hedgehogs roll up when restrained, a thorough examination usually requires chemical restraint. Before sedation, the hedgehog should be observed in the

examination room. Healthy, untroubled hedgehogs should be active and walk with the ventrum raised off the table, but weak or wary hedgehogs tend to crouch. The nose is normally moist and active. Respiration is normally silent, except when the hedgehog hisses in defense. Normal feces are dark brown and very soft to pellet-like. The skin in the spiny areas may have a mildly dry or flaky appearance, but excessive flaking, quill loss, erythema, and crusting are abnormal.

Once the hedgehog is sedated or anesthetized (eg, with isoflurane at a light plane), the remainder of the examination can be performed. Hydration may be assessed by eyelid turgor. The eyes should be clear, and the pinnal margins should be free of crusting or ragged edges. The teeth should be white and the gingiva a uniform pink. The oral cavity and tongue should be inspected for ulcers, foreign material, and masses. Normal lymph nodes are difficult to palpate, but they may become enlarged in cases of neoplasia or infection. The heart should have a regular rhythm and no murmurs, and a femoral pulse should be palpable. The abdominal contour should be flat but may be distended by obesity, organomegaly, masses, or fluid. The prepuce or vulva should be checked for inflammation, discharge, or adherent debris. Testicles may be palpable in the para-anal area. The toes should be inspected for encircling fibers and overgrown nails.

Clinical Techniques: The jugular vein can be used to collect blood samples; its anatomic location is similar to that in other small mammals. Alternatively, the cranial vena cava may be used, but there is a greater risk of cardiac puncture because of the relatively cranial position of the hedgehog heart. The femoral, lateral saphenous, or cephalic veins may be used for injections or to collect small samples (up to 0.5 mL).

SC injections can be given in the spiny or furred areas; the furred skin is more elastic and vascular but less accessible. The dermis under the spiny skin is poorly vascularized, so drugs or fluid given in this location may not be absorbed for several hours. The junction of furred and spined skin provides an accessible and reliable site. IM injections may be given in the triceps, quadriceps, gluteal, or orbicularis muscles. IV catheters are usually dislodged if the animal curls. An intraosseous catheter may be placed in the tibial crest using a 22- or 25-gauge needle or 1-in. spinal needle; the catheter remains accessible even when the animal is curled.

Radiography may be useful, but the hedgehog's spines can obscure detail. For lateral views, the spines can be pulled away from the chest and abdomen and secured with a large plastic clip. Anesthesia is generally required for proper positioning.

Oral medication may be difficult to administer. Some animals accept liquid medications that have been compounded with fruit flavor. Alternatively, medication may be injected into mealworms or mixed with a favorite food. Applying topical medications is complicated by the presence of spines and self-grooming, and some odors may initiate anting behavior (*see* p 1828).

A cage temperature of 80°–85°F (27°–29°C) is recommended for ill hedgehogs. Voluntary feeding is facilitated by providing the animal's customary diet and by offering live invertebrates. Anorectic animals should be fed a high-calorie canine or feline diet via syringe or tube. For ongoing assisted feeding, a pharyngostomy or esophagostomy tube can be placed.

Hedgehogs are not bacterial fermenters, and there are no particular concerns regarding antibiotic use. For appropriate drugs and dosages in this species, consult the *Exotic Animal Formulary* (2013) or other sources.

Anesthesia and Surgery: A 4- to 6-hr fast is recommended before anesthetic procedures longer than 20 min. Isoflurane is commonly used for induction and maintenance. Hypersalivation may occur, and premedication with atropine is advised. Ketamine, diazepam, midazolam, xylazine, and toletamine/zolazepam have also been used but may prolong recovery. Tracheal intubation may be indicated for longer or oral procedures and is accomplished with a 1.0–1.5 mm endotracheal tube, Teflon IV catheter, or feeding tube.

Spines are removed by clipping or with steady traction. Hedgehogs may self-mutilate traumatic or surgical wounds; prompt primary closure with subcuticular sutures should be used whenever possible. Bandages and dilute chlorhexidine baths are well tolerated. If the cutaneous muscle is damaged, it must be closed in a separate layer. Contraction of the rolling-up musculature can cause wound dehiscence. Elizabethan collars are not practical.

Ovariohysterectomy is similar to the procedure in other mammals, although substantial fat surrounds the ovaries and mesosalpinx. Castration is performed through a para-anal skin incision over each testicle; a closed technique is preferred.

Preventive Medicine: Hedgehogs have a short life span and often hide signs of illness; therefore, examinations (under isoflurane anesthesia) every 6 mo with blood testing are recommended. A 2-yr-old hedgehog should be considered geriatric. There are currently no vaccines labeled for use in hedgehogs. Because hedgehogs are not usually housed in mixed gender groups, castration and ovariohysterectomy are not generally requested or recommended. The incidence of uterine and mammary tumors is a concern; however, the effect of early age ovariohysterectomy on tumor reduction is unknown.

DISEASES

Sick hedgehogs with a variety of illnesses, including acariasis, dental problems, pneumonia, gastric ulceration, neoplasia, and hepatic disease, often present with nonspecific clinical signs such as lethargy, weakness, and anorexia. This frequent presentation serves to emphasize the importance of diagnostic testing, even if anesthesia is required.

Cardiovascular and Hematologic

Diseases: Dilated cardiomyopathy (*see* p 115) is a common postmortem finding, with an incidence of 38% in captive African hedgehogs. The etiology is not known; however, genetic and nutritional causes have been suggested. Affected hedgehogs are typically ≥ 3 yr old, although it may be seen in animals as young as 1 yr of age. Males are slightly overrepresented. Signs include dyspnea, decreased activity, weight loss, an auscultable murmur, ascites, and acute death. Radiographs typically demonstrate varying degrees of cardiac enlargement, pulmonary edema, pleural effusion, hepatic congestion, and abdominal fluid. Common gross necropsy findings associated with cardiovascular disease in hedgehogs include cardiomegaly, hepatomegaly, pulmonary edema and/or congestion, hydrothorax, ascites, and pulmonary or renal infarcts. Normal echocardiographic measurements have been published for the African pygmy hedgehog. These reference intervals, along with subjective evaluation of wall motion and chamber size, can be used to confirm the diagnosis of dilated cardiomyopathy. Hematologic and biochemical testing are useful to screen for concurrent problems and to monitor the effects of therapeutic agents. Therapy with furosemide, enalapril, and digoxin may be helpful. Alternatively, furosemide, pimobendan, and supplementation with oral carnitine have been used. The

long-term prognosis for hedgehogs with congestive heart failure is poor.

Saddle thrombus and pulmonary thromboemboli have been seen. Myocardial mineralization and splenic extramedullary hematopoiesis may exist in pet hedgehogs with concurrent diseases; the clinical significance of these lesions is unknown. Congenital erythropoietic porphyria was reported in a 6-mo-old male inbred pet African hedgehog.

Gastrointestinal and Hepatic Diseases:

GI obstructions are most often caused by ingestion of rubber, hair, or carpet fibers. Signs include acute anorexia, lethargy, and collapse. Vomiting may be present but often is not. Diagnosis of obstruction is complicated by the fact that gaseous dilation of the GI tract can be a nonspecific finding in ill hedgehogs. A fatal intestinal mesenteric torsion has also been reported. Alimentary inflammation, including esophagitis, gastritis, enteritis, colitis, and gastric ulceration with perforation, has also been seen. Most of these hedgehogs had nonspecific signs such as decreased appetite and weight loss; vomiting and diarrhea were not seen. A case of gastroesophageal intussusception and megaesophagus has been reported in a hedgehog. This animal's clinical signs included dyspnea, vocalization, and salivation; vomiting ensued before death.

Enteritis may be caused by *Salmonella* or other bacteria. Salmonellosis in hedgehogs may be clinically silent or may cause diarrhea, weight loss, decreased appetite, dehydration, lethargy, and death. Diagnosis should be confirmed with fecal culture, using *Salmonella*-enriching medium. Although treatment is indicated in hedgehogs with clinical signs of disease, owners should be advised of the zoonotic potential and the risks of creating antibiotic resistance. Alimentary candidiasis (*Candida albicans*) and cryptosporidiosis are other reported infectious diseases. Although numerous species of nematodes, cestodes, and protozoa have been identified in wild hedgehogs, their significance in pets appears to be minimal.

Diarrhea also can be associated with some commercial diets or inappropriate foods such as milk. GI neoplasia, particularly lymphosarcoma, is relatively common. Other considerations for GI signs include dietary change, toxins, hepatic disease, and malnutrition. Hedgehog digestion does not rely on bacterial fermentation, and there is no evidence of antibiotic sensitivity as is seen in herbivorous mammals. Hematochezia should be clearly differentiated from urinary or vaginal bloody discharge.

Hepatic lipidosis is relatively common and may be a sequela of cardiomyopathy, neoplasia, starvation, obesity, toxicosis, pregnancy, or infectious disease. Signs may include lethargy, inappetence, icterus, diarrhea, and signs of hepatic encephalopathy. Diagnosis is supported by testing for hepatic enzymes, plasma bilirubin, and bile acids. Radiography and ultrasound-guided liver aspirates may also be performed. Treatment for hepatic lipidosis is similar to that in other species. Other important causes of liver failure include primary and metastatic hepatic neoplasia. Hepatic necrosis caused by human herpes simplex virus 1 was reported in a hedgehog that received dexamethasone.

Integumentary Diseases: Acariasis caused by *Caparinia* spp (psoroptic mite) is very common. Infestation with *Notoedres* spp (sarcoptic mite) has also been reported in hedgehogs. Signs include lethargy, decreased appetite, hyperkeratosis, seborrhea, quill loss, loose quills, and white or brownish crusts (mite droppings) at the base of the quills and around the eyes. Hedgehogs may scratch or rub themselves, but many individuals do not have obvious pruritus. Some animals have subclinical infestations. Diagnosis is confirmed by identifying mites and eggs (nits) via skin scraping. Treatment consists of ivermectin or a combination of ivermectin and amitraz. All bedding must be removed, and cage furnishings disinfected or discarded. During treatment, the cage is lined with paper that must be changed daily. All hedgehogs in the home should be treated concurrently.

Pet hedgehogs may be infested with fleas; however, cat and dog fleas generally do not infest African pygmy hedgehogs. This is likely because of the hedgehog's low body temperature. Treatment consists of topical or systemic flea control agents. Shampoo and powder products that are safe for kittens appear to be safe for hedgehogs. Tropical rat mites, *Ornithonyssus bacoti*, may also cause flaky skin and loss of spines; fipronil spray is an effective treatment.

Dermatophytosis is a common clinical disease in African pygmy hedgehogs; however, infection without significant clinical signs is also possible. Dermatophytes (*Trichophyton erinacei*, *T mentagrophytes*, *Microsporum* spp, and *Arthroderma benhamiae*) cause crusting dermatitis, especially around the face and pinnae. Quill loss may also be noted. Although some animals may scratch with the hindlimbs or rub against stationary objects, many individuals do not display

signs of pruritus. Some infections are secondary to other dermatopathies, such as acariasis or trauma. Diagnosis is confirmed by culturing spines in dermatophyte test medium. Treatment consists of topical antifungal agents, with systemic griseofulvin or ketoconazole if needed. Lime-sulfur dips may also be used. Other hedgehogs in the home may be subclinically infected, and treatment of all animals is recommended.

Contact dermatitis may result from unsanitary bedding. Cellulitis has been linked to secondary myositis and sepsis; the primary cause in most of these cases was trauma. *Staphylococcus simulans* was reported to cause dermatitis characterized by a broad, well-circumscribed area of hyperkeratosis and alopecia on the back of a hedgehog. Allergic dermatitis has been anecdotally described; restricted antigen diets, antihistamines, and glucocorticoids may be helpful. Pruritus may be observed with development of new spines, as occurs in young hedgehogs. Pemphigus foliaceus has been reported; loss of spines, flaking skin, moist erythema, and epidermal collarettes were seen. Dexamethasone injections were reported to be an effective treatment.

Skin neoplasia is common. Squamous cell carcinoma, lymphosarcoma, and sebaceous gland carcinoma have been described. Papillomas of suspected viral etiology have been reported; recurrence in other sites after excision is common. Cutaneous and subcutaneous nodules may also be caused by abscesses, mycobacteriosis, and *Cuterebra* larvae.

Musculoskeletal Diseases: Myositis secondary to cellulitis has been reported. Osteoarthritis has also been seen. Bone cysts should be considered as a differential for mandibular masses, along with neoplasia and trauma. Fractures can occur when a limb becomes entrapped in a wire cage or exercise wheel. Splinting can be performed for distal limb fractures. Surgical correction may also be performed, but any fixation device must be able to withstand the hedgehog's strong rolling-up mechanism. Lameness may be caused by ingrown toenails, arthritis, nutritional deficiencies, pododermatitis, constriction of a foot or digit by fibrous material, neurologic disease, or neoplasia.

Neoplasia: Neoplasia in hedgehogs is very common in both sexes. A variety of tumor types affecting every body system has been reported. According to one survey, the body systems in which most tumors were found were the integumentary, hemolymphatic, alimentary, and endocrine

systems. The most common tumors are mammary gland tumors, lymphosarcoma, and oral squamous cell carcinoma. The median age at time of diagnosis is 3.5 yr, although tumors may be seen in animals as young as 2 yr old. In one survey, >80% of the tumors were malignant. Proliferative uterine tumors or polyps are common and are associated with vaginal bleeding, hematuria, and weight loss. Ovariohysterectomy allows prolonged survival of hedgehogs with uterine tumors. Some sarcomas have been associated with retroviral infection.

Signs depend on the location and severity of disease and may include palpable masses, weight loss, anorexia, lethargy, diarrhea, dyspnea, and ascites. Diagnosis is based on cytology or histopathology. Diagnostic imaging and blood testing may help determine the extent of the disease and establish a prognosis. Treatment generally includes surgical excision and supportive care, although other treatment modalities may be helpful. Not every mass in pet hedgehogs is neoplastic; for example, abscesses, bone cysts, papillomas, and uterine polyps are seen.

Neurologic Diseases: Neurologic signs (particularly ataxia) may be caused by torpor, hepatic encephalopathy, postpartum eclampsia, malnutrition, trauma, intervertebral disc disease, toxins, infarcts, infectious causes (eg, parasitic migration, rabies), otitis media, demyelination, polioencephalomalacia, or neoplasia.

Hedgehogs kept in cold (or sometimes excessively high) temperatures may enter a state of torpor or dormancy. In this state, the hedgehog has a greatly diminished response to stimulation, decreased heart and respiratory rates, and possibly increased susceptibility to infection. Dormancy can last for several weeks, during which the hedgehog may have periods of activity with ataxia.

Hypocalcemia may result from postpartum eclampsia, malnutrition, or for unknown reasons, and usually responds to calcium supplementation.

Intervertebral disc disease has been reported. Both cervical and lumbar lesions have been identified; multiple discs were affected in each of these hedgehogs. Radiographic findings included spondylosis, disc-space narrowing, and disc mineralization. Necropsy findings included degeneration of the nucleus pulposus and annulus fibrosus, dorsal extrusion of disc material, and mineralization of the nucleus pulposus.

One case had evidence of fibrocartilaginous embolism. Temporary improvement with corticosteroids has been described in two cases of intervertebral disc disease.

Vestibular signs may be caused by otitis media/internal or central neurologic disease.

Demylinating paralysis (wobbly hedgehog syndrome) occurs in as many as 10% of pet hedgehogs. Onset can occur at any age but is more common in animals <2 yr old. An early sign is the inability to close the hood. This progresses to mild, intermittent ataxia. The signs gradually increase in severity and include falling, tremors, exophthalmos, scoliosis, seizures, muscle atrophy, self-mutilation, and severe weight loss. The paralysis usually ascends from hindlimbs to forelimbs and usually leads to complete paralysis within 9–15 mo after the onset of signs. Death occurs within 18–25 mo. Appetite is usually normal until the terminal stages, when most hedgehogs become dysphagic. The diagnosis is confirmed at necropsy. Histopathologic lesions include vacuolization of white matter (cerebrum, cerebellum, brainstem, and spinal cord), axonal swelling, degeneration of spinal cord ventral tracts, and axonal and myelin degeneration in brain white matter. Peripheral nerves may also be involved. Inflammation of the CNS is not associated with wobbly hedgehog syndrome. The etiology is unknown, but a hereditary basis is suspected. Numerous treatments have been attempted without success. Euthanasia is warranted when the quality of life is compromised. A single case of pneumonia virus of mice in an African hedgehog with suspected wobbly hedgehog syndrome, resulting in nonsuppurative encephalitis with vacuolization of the white matter, has been reported.

Nutritional Disorders: Obesity is common. Healthy hedgehogs should be able to roll up completely, without any fat deposits protruding. Treatment includes reducing high-fat foods, rationing the main diet, and increasing exercise. Weight reduction should be gradual to prevent hepatic lipidosis, and owners should monitor their pet's weight. Nutritional excess or deficiency may occur with unbalanced diets; for example, calcium deficiency may result from a diet consisting mainly of invertebrates. Moist diets may predispose hedgehogs to periodontal disease. Other nutritional diseases are uncommon.

Ocular Diseases: Hedgehogs are prone to corneal ulcers and other ocular injuries. Diagnosis and treatment are as for other species,

although administration of topical medication can be difficult. Blind hedgehogs navigate their captive environments with minimal detriment to their quality of life.

According to one report, ocular proptosis is relatively common and carries a poor prognosis for viability of the eye. Hedgehogs have a shallow orbit that may predispose them to proptosis, especially if excessive fat accumulation or orbital inflammation is present. Concurrent neurologic disease may result in ocular trauma.

Oral and Dental Diseases: Oral neoplasia, particularly squamous cell carcinoma, is common in hedgehogs. Dental disease, including calculus, gingivitis, and periodontitis, is also common. Periodontal disease is often associated with a bacterial component. The addition of abrasive items to the diet (eg, hard kibble, charcoal, or bone) and antibiotics are recommended for prevention and treatment of periodontal disease, respectively. Dental prophylaxis, periosteal antibiotics, and tooth extraction may be necessary to treat severe dental disease. If advanced periodontal disease requires extraction of all the teeth, hedgehogs can be maintained on soft food. Tooth fractures and dental abscesses are also seen. *Actinomyces* infection has been reported; anaerobic culture and treatment should be considered for dental abscesses in hedgehogs.

Excessive tooth wear occurs in older hedgehogs, and hedgehogs with this condition should be fed a soft diet. Hedgehog teeth do not grow continuously and should not be trimmed. Hedgehogs are susceptible to wedging of hard items (eg, peanuts) against the palate. Stomatitis may develop in males that bite their mates; treatment is with soft food and antibiotics.

Otic Diseases: Pinnal dermatitis is common; skin crusts, accumulated secretions, and a ragged pinnal margin may be seen. Dermatophytes and acariasis are important causes; other possibilities include nutritional deficiencies, dry skin, seborrhea with hyperkeratosis, and extension of ear canal disease. Ear mites (*Notodres cati*) are occasionally seen; signs, diagnosis, and treatment are as for cats (see p 921). Bacterial or yeast otitis externa is also seen; these infections are often secondary to acariasis or another cause of chronic inflammation. Signs include purulent discharge, odor, and sensitivity of the face and ear. Otic cytology, skin scrapings, cleansing, and topical antimicrobial/anti-inflammatory therapy are used as for other species. Otitis media/interna can also be seen.

Reproductive Diseases: Posthitis may be caused by substrate entrapment in the prepuce. Hemorrhagic vulvar discharge is often caused by uterine neoplasia or endometrial polyps. Pyometra and metritis have been reported. Dystocia also is seen and treated as in other small mammals. Premature births occasionally occur; the prognosis for young without a suckling reflex is poor. Agalactia may be suspected if neonates lose condition within 72 hr after birth. Diagnosis may be confirmed by attempting to express the mammary glands; however, this usually requires anesthesia and may cause the dam to abandon or cannibalize her young. Causes of agalactia include malnutrition, stress, lack of oxytocin, inadequate mammary development in young females, and mastitis. Supportive care for weak neonates includes warming to normal body temperature over 1–3 hr, fluid support, and caloric support once normothermia has been achieved.

Respiratory Diseases: Predisposing factors for upper and lower respiratory tract infection are suboptimal environmental temperature; aromatic, dusty, or unsanitary bedding; concurrent disease causing immunocompromise; and aspiration of material from an oral infection. Signs include nasal discharge, increased respiratory noise, dyspnea, lethargy, inappetence, and sudden death. Radiographs, hematologic testing, and culture of tracheal or lung lobe aspirates are useful in diagnosis. Treatment includes antibiotics, nebulization, supportive care, and correction of underlying problems. Differential diagnoses for dyspnea are pulmonary neoplasia and cardiac disease.

A case of fatal corynebacterial bronchopneumonia has been reported in a pet African hedgehog. *Pasteurella* spp and *Bordetella bronchiseptica* can cause respiratory infections in European hedgehogs and are possibly important in *Aterix* as well. Lungworms can also cause pneumonia, but this is unlikely in indoor pets. The existence of cytomegalovirus in African hedgehogs has been questioned; in any case, it is highly unlikely in domestically raised pets.

Urinary Diseases: Cystitis and urolithiasis cause changes in urine color, stranguria, pollakiuria, inappetence, and lethargy. Urinalysis with culture and radiographs should be obtained. Renal disease is also common (50% prevalence in a necropsy survey) and in many cases may be secondary to systemic disease. Genetic or dietary

factors may contribute to the high prevalence. Nephritis, tubular necrosis, nephrocalcinosis, glomerulosclerosis, renal infarcts, polycystic kidneys, neoplasia, and various glomerulonephropathies have been identified. Signs associated with renal disease tend to be nonspecific, although polyuria and/or polydipsia may be noted. Diagnosis should be based on urinalysis and serum chemistry panels. Treatment consists of correcting the underlying cause, fluid therapy, and supportive care.

Zoonoses: Several strains of *Salmonella* are found in pet hedgehogs, including *S. Tilene*, *S. Typhimurium*, and *S. Enteritidis*. Many cases of transmission to people have been documented, particularly in young children. It should be assumed that all pet hedgehogs can carry and transmit *Salmonella*. Because infected animals may shed intermittently, a negative culture cannot exclude the carrier state. Treatment aimed at eliminating the carrier state is unlikely to be successful and may lead to antibiotic resistance.

Human dermatophytosis from pet hedgehogs is also well documented. African pygmy hedgehogs can be subclinical carriers of *Trichophyton mentagrophytes* var *erinacei*, *Microsporum* spp, and *Arthroderma benhamiae*. In addition, some people are extremely sensitive to contact with African hedgehog spines and develop transient, markedly pruritic urticaria after handling a hedgehog.

Wild African hedgehogs are susceptible to foot-and-mouth disease. To prevent introduction of this disease to the USA, importation of African hedgehogs was banned by the USDA in 1991.

Rabies has not been reported in wild or captive African hedgehogs, but the salivation that occurs during anting is occasionally mistaken as a sign of rabies. A single report of rabies in a wild European hedgehog exists.

Human herpes simplex virus 1 was recovered from the liver of a pet African hedgehog that died acutely after glucocorticoid treatment for intervertebral disc disease. Monkeypox virus DNA was recovered from an African hedgehog housed with many other exotic species at a pet distributor facility in Illinois. *Candida* infection of the footpads and intestine of the African pygmy hedgehog has been reported. Acute intestinal cryptosporidiosis has been reported. A single case of Chagas' disease (*Trypanosoma cruzi*) was reported in a captive African hedgehog housed outdoors in Texas.

African pygmy hedgehogs are considered susceptible to a variety of infectious agents, based on susceptibility observed in other hedgehog species. Possible bacterial zoonoses include *Yersinia pseudotuberculosis*, *Y pestis*, *Mycobacterium marinum*, *M avium intracellulare*, *Coxiella burnetii*

(Q fever), and *Leptospira* spp. Possible viral zoonoses include Crimean-Congo hemorrhagic fever, arboviral tickborne encephalitis, and paramyxoviruses of the Morbillivirus group. *Chlamydia psittaci* and *Toxoplasma gondii* have been isolated from wild European hedgehogs.

LABORATORY ANIMALS

REGULATORY REQUIREMENTS

Most American laboratories must adhere to two main sets of animal welfare regulations: the Animal Welfare Act (AWA; created in 1966) and the Public Health Service Policy on Humane Care and Use of Laboratory Animals (PHS Policy; originally enacted in 1985).

The Animal and Plant Health Inspection Service (APHIS) of the USDA oversees enforcement of the AWA, which covers the care of research animals and includes guidelines for the oversight and conduct of studies intended to minimize or prevent pain or distress of laboratory animals. The AWA also regulates zoos, exhibitors, animal dealers, and those who transport animals in commerce. All warm-blooded species are regulated by the AWA, whether alive or dead, except for domestic mice and rats bred for scientific purposes, birds, and farm animals used in agricultural research. Provisions for veterinary care have existed under the AWA since 1970; requirements for exercise for dogs and ensuring the psychological well-being of nonhuman primates were added in 1985. The AWA is enforced through a self-reporting mechanism along with routine, unannounced inspections by APHIS. Failure to meet the requirements of the AWA can result in fines, citations, criminal proceedings, or revoked registration with disqualification to use AWA-regulated species in research.

The PHS Policy is based on a set of research animal care standards, the *Guide for the Care and Use of Laboratory Animals*, first published in 1963. The PHS Policy requires institutions to use this guide as a basis for developing and implementing institutional programs for research involving animals. The PHS Policy has been modified only once, in 2002, while the Guide, now in its 8th edition, was last revised in 2011. The policy applies to all research institutions awarded federal grants and covers all

vertebrate animals, not just those that are warm-blooded. Regulatory compliance is based on a system of self-regulation whereby institutions must provide the following to federal officials: a written Animal Welfare Assurance that describes their compliance with the PHS Policy, updates via an annual report, timely reporting of all incidents of noncompliance, and site visits for cause or other purposes. Failure to adhere to PHS Policy can result in revocation of federal funding for some or all research projects at the institution.

The 8th edition of the *Guide for the Care and Use of Laboratory Animals*, released in 2011, at 220 pages represented a 76% increase in information, guidance, and prescribed action from the content of the 7th edition (1996). It is organized into five chapters that cover the subject areas of 1) key defining concepts, including applicability, a brief review of the ethical principles in the humane care and use of animals in research, and clarifying definitions; 2) articulation of the basics of an animal care and use program, most prominently oversight structure, salient aspects of safety, and requirements for training; 3) the environment, housing, and management of research animals; 4) veterinary care; and 5) animal research facility design and physical plant operation. While there were abundant changes in the Guide from the 7th to 8th edition, most momentous were the unprecedented responsibility delegated to the attending veterinarian (AV) for the welfare of any animal in research at all times during experimentation and in all phases of the animal's life and in establishing the unambiguous and absolute authority of the AV to prescribe treatment and other interventions, including removal of subjects from experimentation. Other significant additions addressed the accordance of cage space allocated to breeding rodents, the genetic management of rodent breeding colonies to ensure authenticity, the care of aquatic species, and an enhanced emphasis on the training of person-

nel when applicable in proper animal care and methods of use, particularly in aseptic surgery and humane euthanasia technique.

Program Accreditation: The Association for Assessment and Accreditation of Laboratory Animal Care International (AAALAC), a private, nonprofit organization that promotes the humane treatment of animals in science through voluntary accreditation and assessment programs, was incorporated in 1965. More than 890 companies, universities, hospitals, government agencies, and other research institutions in 37 countries have voluntarily earned AAALAC accreditation as of 2013. Institutions that seek AAALAC accreditation are subject to comprehensive peer review of their animal care and use program every 3 years; this accreditation is given credence by the National Institutes of Health as a means of demonstrating compliance with PHS Policy.

Veterinary Care: Under provisions of the AWA, all persons who use animals in research or for exhibition, sell them at the wholesale level, or transport them in commerce must have established programs of veterinary care and animal husbandry. APHIS requires the owner of each licensed and registered facility to define a program of veterinary care (PVC), including the employment of an AV. In cases in which the AV is not a full-time employee, the facility owner must prepare a written PVC and schedule an appropriate frequency of visits by the AV. These visits must be on at least an annual basis. Whatever the employment arrangement, the facility owner must give the AV sufficient authority to ensure adequate veterinary care. The PVC must incorporate appropriate facilities, personnel, equipment, and services to meet this standard; ensure the availability of emergency, weekend, and holiday care for animals; include the requirement for the daily observation of all animals by employees to assess the animals' health and well-being; and define channels for the direct and frequent communication between facility personnel and the AV.

Responsibilities of the AV include using suitable methods to prevent, control, diagnose, and treat diseases and injuries; providing adequate guidance and training of personnel who care for animals regarding handling, immobilization, anesthesia, analgesia, tranquilization, and euthanasia; and ensuring that the preprocedural and post-procedural care of animals is in accordance with established veterinary medical and nursing procedures. Beyond

these general responsibilities, the AV is responsible for reviewing the facility's PVC at least once a year to ensure that the following meet contemporary standards of veterinary care for each species: vaccinations, handling of biologics and drugs, product safety assurance, parasite control, emergency care, euthanasia methodology, nutrition, pest control and product safety, quarantine procedures, exercise (dogs only), environmental and social enrichment (nonhuman primates only), water quality (when marine mammals are involved), and, for wild or exotic animals, capture and restraint methods.

Institutional Animal Care and Use Committee: Since 1985, the AWA and PHS Policy have required that Institutional Animal Care and Use Committees (IACUC) oversee not only the care, but also the use, of animals in research. The responsibilities of the IACUC are delineated in these laws and the associated federal policy and regulations. According to the AWA, the IACUC must consist of at least one veterinarian with training in laboratory animal science and expertise in the species under consideration, at least one practicing research scientist, and at least one person not affiliated with the institution. The PHS Policy requires a minimum of five members, including at least one of each of the following: veterinarian, scientist, nonscientist, and nonaffiliated member.

Each IACUC has three main areas of responsibility: review of research protocols; semiannual evaluations of the institution's animal care and use, which includes inspections of animal housing areas and laboratories where animal procedures are performed; and judiciary activities such as investigating animal welfare concerns and adjudicating disagreements. Review of research protocols by the IACUC involves considering the merits of the animal study in the context of a broad range of complex, scientific, animal welfare, and veterinary topics. The IACUC also has the responsibility to monitor the compliance of ongoing studies and the authority to suspend research not performed in accordance with the conditions or with unforeseen negative consequences. Since 1985, the IACUC has been the primary means of animal welfare oversight within research institutions in the USA.

Emergency Preparedness: History shows that animal research facilities are regularly and often unpredictably subject to the effects of natural events, manmade actions, or failures of technology that

imperial animals, experiments, and facilities. While principles of disaster preparedness and response have been integral to the Guide since its 7th edition, in 2013 the USDA instituted requirements for emergency and disaster preparedness and response plans and mandated training programs for appropriate personnel. As such, the Guide and USDA policy in conjunction make it mandatory that each institution craft and train personnel in a comprehensive emergency operations and disaster responsiveness plan.

ANIMALS USED IN RESEARCH

Research institutions registered under the AWA are required to submit an annual report to APHIS that details, among other specifications, a listing of the common names and the numbers of reportable species used. In 2010, there were 1,104 research institutions in the USA registered under the requirements of the AWA. These institutions reported the total use of 1,134,693 regulated animals. The most abundant species used were guinea pigs (213,629), rabbits (210,172), and the combination of several species of hamsters (145,895) of which >90% were estimated to be of the Syrian variety. Other animals used included nonhuman primates (71,317), dogs (64,930), pigs (53,260), domestic cats (21,578), sheep (13,271), and a combination of marine mammals, other farm animals, and other species not identified (341,214). There is no federal reporting requirement for mice, rats, birds, amphibians, or fish, making precise numbers difficult to determine. Research subjects of these species, for the most part, are obtained via a combination of in-house breeding colonies and from commercial vendors, with production and sales data from the latter being proprietary and not disclosed publicly. Wild-caught birds and aquatic species sometimes may be captured for experimental purposes. Since 2000, the estimated total number of mice and rats used for research purposes annually in the USA has ranged fairly consistently from 20 to 30 million. There are millions of zebra fish and thousands of amphibians, likewise, used annually.

The domestic mouse, *Mus musculus* and related subspecies (see MICE AND RATS AS LABORATORY ANIMALS, p 2032), is popular as a mammalian research model because of its small size, adaptability, docility, low husbandry costs, fecundity, well-defined health and genetic backgrounds, and relative ease of genetic manipulation. The development of genetic engineering techniques of inserting foreign genes (transgenes) into the mouse genome and the ability to delete genes,

leading to what are known as “knockout” mice, profoundly increased the use of mice as research subjects. Since these advances, countless mutant genotypes of mice have been developed, ranging from subtle defects in immune function to full-fledged, inherited diseases virtually homologous with those of higher mammals.

Among other rodents, the domestic Norway rat (*Rattus norvegicus*) is second only to the mouse as a research subject. Rats (see p 2032) share many of the attributes of mice that make them attractive for use in research, but because they are larger than mice, they are suited for a greater variety of manipulations. Numerous mutant and inbred strains and outbred stocks of rats are used in a broad array of studies, including topics such as aging, cancer, reproductive physiology, drug effects, behavior, addiction, alcoholism/cirrhosis, arthritis, brain and nerve injury, hypertension, embryology, teratology, endocrine diseases, neurophysiology, infectious disease, stroke, organ transplantation, and surgically induced disease. The genetic engineering of mutant rat types, however, has lagged behind mice and is only beginning to show effect.

Excluding mice and rats, guinea pigs and rabbits are the most common mammals used in research, although their numbers have declined from peaks in the 1980s. Although the guinea pig (*Cavia porcellus*) was among the first animals to be used in medical research, its popularity has diminished relative to that of mice and rats because of its long gestation period (59–72 days), small litter size (2–5), poor vascular access, and difficulties in anesthesia. Guinea pigs are still used in notable ways in immunology, in vaccine and infectious disease research, and as hearing models. Rabbits are used most often in product safety testing; for polyclonal antibody production; and in studies of vision, orthopedics, and cardiology.

In addition to the Syrian hamster (*Mesocricetus auratus*), a few other species of hamsters are used in research, including the Armenian, Siberian (Djungarian), Chinese, European, and Turkish species. Hamsters are readily available, reproduce easily, and are relatively free of spontaneous diseases but susceptible to many induced viral diseases. They are used for studies of obesity, induced carcinogenesis, prostatic disease, toxicity, infectious diseases (including slow viruses), dental caries, chronic bronchitis, and teratogenesis.

Other rodent species used in research include gerbils, deer mice, chinchillas, cotton rats, rice rats, multimammate rats, Egyptian spiny mice, degus, voles, and woodchucks, among others.

While rodent models are unarguably the most common for scientific use, larger animal models provide unique opportunities for biomedical research. Dogs are used in studies of cardiology, endocrinology, orthopedics, prosthetic devices, surgical techniques, pharmacokinetics, and product safety. Since use of dogs began declining in 1984, livestock have been used more frequently. This has been a consequence of regulatory and public pressure related to the use of dogs, but it is also due to attributes of comparative anatomy and physiology that make livestock more conducive to particular investigations. For example, swine are used for cardiovascular research (particularly atherosclerosis), in studies of digestive physiology, as surgical models, and for xenotransplantation. Sheep are used for studies of neonatal development, human vaccine improvement, asthma pathogenesis and treatment, drug delivery, circadian rhythms, and surgical techniques.

Nonhuman primates remain critical in studies of vision, the neurosciences, infectious diseases, vaccines, and product safety testing. In recent years, they have become increasingly valuable as models of immunodeficiency virus infection and the neurodegenerative diseases associated with aging.

Although the absolute number of cats used in research has been in steady decline since 1980, cats are still important models in the neurosciences and in the study of infectious diseases.

The most important aquatic species used in research are the zebra fish and the African clawed frog.

Other species used in scientific research include goats, calves, horses, ferrets, armadillos, opossums, domestic and wild birds, reptiles, amphibians, other species of fish, and invertebrates.

MANAGEMENT

Consistently delivered quality programs of husbandry and veterinary care provide the foundation that enables valid scientific research. For proper management of research animals, the animal care and research staff must be responsible, sensitive to the animals' health and well-being, well trained in the humane care and use of laboratory animals, highly motivated, experienced, and diligent in performing their duties and responsibilities. Standard operating procedures must be established, and training and supervision provided to assure a consistently applied and uniformly high level of animal care. Within research facilities, environmental conditions must be carefully controlled so that, along with

conscientiously applied programs of animal care and use, the best possible conditions for conducting research are provided. The *Guide for the Care and Use of Laboratory Animals* is still the primary reference for information on basic principles and standards for laboratory animal management.

Laboratory rodents that are disease- and pathogen-free and that do not possess antibodies indicative of past infection are readily available from commercial vendors. Procuring such animals from high-quality sources, transporting them in filtered shipping containers, and maintaining them in facilities with both physical and procedural barriers to the introduction of infectious agents are effective measures to prevent disease within a colony that may confound or ruin experiments.

Although there are colonies of some species of primates that are free of most agents that cause infectious disease in these species, many primates used are of feral or wild origin. For this reason, appropriate quarantine, isolation, and conditioning programs should be implemented in addition to the program followed in the importers' facilities.

Housing: Cages, pens, or runs should provide adequate space to allow for normal physiologic needs, permit postural adjustments, and meet requirements for species-specific behavior. When possible, compatible groups of social animals should be housed together. Primary enclosures should be constructed of durable materials, easily cleaned and sanitized, and designed for comfort and safety. Static microisolation (filter top) cages and more advanced individually ventilated caging systems have been used widely for rodent housing to impede cage-to-cage transmission of infectious agents. However, infection can be transmitted horizontally or vertically from parents to progeny in breeding colonies; naive mice introduced for cross-breeding and back-crossing can perpetuate infection; and experimental mice potentially can be exposed to pathogens via a contaminated environment, shared watering valves, research devices, or when taken to laboratories. Individual ventilation of cages serves to delay deterioration of the environment within the cage and maintain a more consistent and wholesome microenvironment; it also saves space in the facility and can be engineered to minimize odors, allergens, dust, and heat exhausted into the macroenvironment. A potential drawback of ventilated cages is that hairless genotypes and neonates may be prone to chilling. This risk can be reduced by providing nesting material.

Federal law in the USA requires that laboratory dogs have an opportunity to exercise regularly and have sensory contact with other dogs unless restricted by experimental or behavioral considerations. Housing for nonhuman primates must provide social and environmental enrichment to promote psychological well-being compatible with the experimental and practical constraints of the housing situation. Successful enrichment strategies for nonhuman primates have included pair or group housing; variation in the dietary content and method of presentation; diversification of the internal cage environment with ancillary apparatus (eg, perches, swings, or ladders); provision of devices to enhance visual, auditory, or tactile stimulation; and participation in challenging, nonaversive behavioral laboratory studies. Efforts to extend and adapt environmental enrichment practices to other laboratory animal species warrant consideration and have been implemented in many institutions.

Temperature, relative humidity, ventilation rates, lighting conditions (spectrum, intensity, and photoperiod), gaseous pollutants (eg, ammonia), and noise should be carefully controlled at all times and monitored as appropriate. Unstable environmental conditions can have a profound effect on the comfort, well-being, and metabolism of animals and therefore on the quality of experimental data derived. In general, temperature should be maintained at 68°–79°F (20°–26°C) for most rodents; 61°–72°F (16°–22°C) for rabbits; 59°–64°F (15°–18°C) for ferrets; 64°–84°F (18°–29°C) for primates, dogs, and cats; and 61°–81°F (16°–27°C) for most farm animals and poultry. Within these ranges, optimal systems should maintain temperatures within $\pm 1^\circ\text{F}$ of the set point. Relative humidity should be maintained at 30%–70% for most species and preferably within 10% of the set point. Ventilation rates should be 10–15 fresh air changes/hr. Air should not be recirculated unless it has been treated to remove particulate and gaseous contaminants. Lighting should be distributed evenly and sufficiently intense to promote animal well-being and to allow personnel to observe the animals and to perform all husbandry and sanitation duties safely and effectively. Diurnal or day-night cycles, as determined by species' requirements, should be controlled by automatic timers to maintain circadian and neuroendocrine regulation. The microenvironment within certain types of caging may be very different from that of the macroenvironment of the room. Carefully conducted research is needed to more precisely define the optimal environ-

mental and social conditions for each species or group of species at the cage level.

Bedding: Bedding materials should be nonirritating, absorbent, free of chemical contamination and pathogens, and unpalatable. Adequate quantities should be used to dilute and limit contact with excreta, promote air quality and other environmental factors by suppressing microbial growth, and keep animals dry and clean between changes of bedding or caging. The major types of contact bedding used are derived from ground corncobs, hardwood chips, recycled paper, heat-treated softwood shavings, and virgin cellulose. Untreated softwoods are not recommended because they contain volatile oils that may alter hepatic enzyme systems and affect certain kinds of research. Depending on research requirements, bedding may be sterilized by autoclaving or irradiation before use or used as is.

Feeding: Feed should be of adequate quantity, palatable, free of contaminants, nutritionally adequate, easily accessible, and provided using means that meet behavioral needs according to specific species requirements. Feeds specifically manufactured for research animal use are preferred, because they are more likely to be uniformly constituted, free of contaminants, of known shelf life, and mill dated. Feed should be manufactured, transported, stored, and used in ways that minimize its deterioration, contamination, or infestation. Most small animals consume food in relation to their energy requirements as influenced by the environment and dictated by their genotype and are fed ad lib; rabbits, laboratory carnivores, swine, aquatic amphibians, and primates may be restricted to measured quantities of feed each day. As a general rule, laboratory animals minimally consume 4%–6% of their body weight in food daily. In addition to commercially prepared and usually pelleted natural ingredient diets of varying specification (eg, quality control and assurance of ingredients), semisynthetic or completely synthetic diets and all-liquid preparations can be formulated for use in certain kinds of research. Autoclavable or irradiated diets are available for rodents and can be used when sterilization of feed is desired.

Water: Potable, uncontaminated water should be provided in adequate quantities to meet specific species requirements. Quality assurance programs that measure pH, hardness, chemical content, and microbial load are recommended. Highly purified,

deionized, acidified, chlorinated, or sterile water may be required under certain experimental or husbandry conditions. Water is usually provided ad lib in manually filled or automated watering devices. Particularly in the housing of rodents, an automated water supply enhances the advantages of ventilated caging systems and reduces operational costs/expenses, increases safety for animal care technicians, saves labor, reduces disruptions of the mice by caretakers, and provides consistently high water quality. The drawback of the use of automated drinking water supply for rodents is the risk of hypothermia, drowning, or dehydration of cage inhabitants as a consequence of failure of the in-cage water delivery valve.

Water quality is the most important environmental variable for aquatic species and a key determinant of health. Inadequate water quality or fluctuations of water temperature are physiologic stressors that impact the intake, digestion, and use of food; alter the immune system; and predispose to opportunistic infection. Water for aquatic vertebrates should be free of nitrite, ammonia, and chlorine, with total coliform counts not exceeding 200/mL. The pH should be 6.5–8.5. Although aquatic amphibians may be maintained in small containers of standing water, water recirculation with biologic filtration and periodic partial replenishment with fresh water, just as with fish, are helpful in suppressing bacterial counts and preventing the build-up of toxic chemicals. The ideal water temperature range for maintaining the aquatic amphibians used most popularly in research, the tetraploid South African clawed frog (*Xenopus laevis*) and the axolotl (*Ambystoma mexicanum*), is 65°–72°F (18°–22°C). For *X. tropicalis*, a smaller, more rapidly maturing, diploid species of clawed frog from forested west Africa, water temperature should be 70°–85°F (21°–29°C). (See also AMPHIBIANS, p 1734.) Zebrafish and other tropical species used in research are best maintained at a consistent water temperature within the range 80°–90°F (27°–32°C).

Sanitation: A uniformly high level of animal enclosure and facility sanitation is mandatory to ensure that animals are clean and dry, air quality is adequate (without using masking agents), and primary enclosure surfaces and accessories are clean. Housing rooms and ancillary support space should be cleaned and sanitized as often as necessary to keep them free of dirt, debris, and potentially harmful contamination. For rodents in solid-bottom cages, usually 1–3 changes per week will suffice; for rodents, rabbits, and nonhuman primates in

suspended cages over excreta pans and for mice in ventilated caging systems, cage changes every other week should be adequate. For larger animals, excreta and soiled bedding should be removed daily, and primary enclosures cleaned and sanitized daily, or at minimum every other week. Water bottles and other watering or feeding devices should be cleaned and sanitized at least weekly. Automated watering devices on cages, racks, or in rooms should be designed and programmed to flush continually or regularly or they should be manually drained, rinsed, and sanitized at regular, frequent intervals. Heating cages and other equipment to 180°F (82.2°C) or using appropriate chemical disinfection (eg, hypochlorite solutions) kills nonspore-forming pathogenic bacteria and viruses. All caging and other equipment should be rinsed thoroughly after treatment with detergents or disinfectants. The effectiveness of the programs of sanitation should be evaluated regularly using appropriate microbiologic, organic material detection systems or other means.

Vermin Control: Professionally directed programs to prevent, identify, and eradicate or control insects or escaped, feral, or wild rodents must be instituted, regularly scheduled, and consistently documented. The use of pesticides should be as a last resort and generally be confined to areas not used for animals or for storage of feed or bedding. If these agents are used in proximity to animals or their food and bedding, researchers should be informed of the use. Relatively inert substances, such as silica aerogel or boric acid powder, are recommended and are useful for control of crawling insects, eg, cockroaches.

COLONY MONITORING

While most commercially reared rodents, some rabbits, and relatively fewer dogs, cats, and primates can be obtained as SPF animals, resident animal colonies must be monitored for naturally occurring disease as a measure of the effectiveness of the prevention and control program. Investigators should be informed regularly as to the health status of their research animals. In addition to monitoring for infectious disease, a quality assurance program should monitor for genetic integrity, especially for inbred mouse strains that are bred and maintained in the research facility, as well as for environmental factors (quality of feed, water, and bedding; efficacy of sanitation programs; air handling and quality; lighting; noise; etc) that can affect colony health.

Colony health monitoring consists of a defined program of regular physical and laboratory evaluations of animals within a unit, as well as a morbidity and mortality reporting system that enables timely identification of potential problems. Thorough investigations of illnesses, deaths, and unusual experimental outcomes in a colony are essential components of such a program. For selected physiologic data of some laboratory animals, see TABLE 11.

While certain general principles apply, a health monitoring program must be specifically developed for each species maintained in a facility. For example, generally, all primates are quarantined and isolated on arrival. Physical examinations, tuberculin testing, and baseline hematologic and other clinical pathologic tests should be performed. In addition, serologic evaluation for Macacine herpesvirus type 1 (formerly Cercopithecine herpesvirus type 1, Herpesvirus simiae, B virus), simian retroviruses, and other specific agents may be performed, depending on the species of primate. Primates should be released from quarantine only when both the health status and suitability for use are determined. Furthermore, primates should have regular health surveillance screens, each consisting of defined elements. Depending on the nature and value of the colony and research use, screenings may range from quarterly to semiannual or annual in frequency. (See also NONHUMAN PRIMATES, p 1876.)

For colony-bred rats and mice, programs for disease monitoring can consist of any or all of the following: vendor surveillance, quarantine and isolation evaluation, ongoing clinical and postmortem evaluation during the course of studies, sentinel animal programs, and evaluation at termination of the study. In addition, all transplantable tumors, cells, or other biologic products destined for animal passage should either be screened for murine and zoonotic pathogens or colony management practices used to appropriately isolate animals receiving these materials. Of particular concern to colony health is the occasional and justifiable need to obtain animals from less well-defined sources, such as an investigator's colony at another institution or other nonapproved source. The presence of infectious agents either in transplantable tumors or noncommercial animal sources can pose a substantial threat to resident colonies and personnel. Colony monitoring of rodents is typically based on serology, bacteriologic, and parasitic evaluations supported by the evaluation of environmental, fecal, and fur samples through the use of molecular biologic techniques such as PCR.

Although the use of filter top caging technology to impede cage-to-cage transmission of infectious agents in rodent colonies has resulted in a dramatic reduction in enzootic disease transmission and protection of naive animals from epizootics, it has created challenges for

TABLE 11 SELECTED PHYSIOLOGIC DATA OF LABORATORY ANIMALS^a

Species	Gestation Period (days)	Litter Size	Age and Body Weight at Sexual Maturity
Mice	19–21	6–10	6 wk (20–30 g)
Rats	21–23	6–14	2–3 mo (0.2–0.3 kg)
Guinea pigs	59–72	1–4	3–4 mo (0.4–0.5 kg)
Hamsters, golden	15–18	4–10	2 mo (85–110 g)
Gerbils	25	2–9	3 mo (60–100 g)
Rabbits	30–33	4–12	5–6 mo (3–4 kg)
Squirrel monkeys	150	1	3–5 yr (0.6–1.1 kg)
Rhesus monkeys	164	1–2	3–4 yr (5–11 kg)
Chimpanzees	227–235	1	7–10 yr (40–50 kg)
Baboons	164–186	1	4–7 yr (11–30 kg)

^b Typical of an average adult; varies with body mass index, number of animals per cage, moisture in feed, temperature, etc.

^c Results obtained under anesthesia.

sentinel programs. Because most diseases of laboratory rodents do not cause clinical signs and there can be high and unpredictable turnover of research rodents, health surveillance programs are traditionally based on the premise that infectious agents can be transmitted to sentinels, which can then be tested for a variety of pathogens. This provides assurance that the research colonies are free of specific pathogens and alerts personnel to the presence of infection. Before the widespread use of filter top caging, dedicated sentinels in open cages were readily exposed to airborne fomite particles and true aerosols from infected animals in the colony.

The same filter tops that protect colony animals from contagion, however, also hinder the exposure of sentinels to these same agents. For many reasons, dedicated sentinels are preferred over the alternative of monitoring colony rodents. State-of-the-art sentinel programs have thus come to rely on the regular exposure of sentinels to soiled bedding as the means of exposure to colony animals. This indirect exposure has been found to be suboptimal for the detection of many bacterial pathogens, agents transmitted by true aerosol, and fur mites. Agents that are shed intermittently, those with a self-limited, single window of shedding, those that require a high dose to be infective, and those that may deteriorate rapidly are difficult to detect by exposure to soiled bedding. The sentinels

themselves may add confounding influences if their age or genetic background makes them relatively resistant to infection.

The primary contemporary challenges to the health of research rodents—particularly mice—are the noroviruses, parvoviruses, *Helicobacter* spp, pinworms, and fur mites that infect or infest colonies, perturbing biologic processes and introducing variation into research data. For the most part, these agents, along with mouse hepatitis virus, are thought to have gained entry to research colonies largely via the trading of live mice of unique genotypes between institutions. The situation has been complicated by the inability of quarantine programs to reliably detect these agents. However, there is a body of substantial, compelling, anecdotal evidence that nonsterilized diets may be a source of introduction for some pathogens (eg, mouse parvovirus). Murine norovirus has been shown to be the most widespread virus in domestic mouse colonies. The virus likely existed in research mice for decades, but it was not described until 2003. Mouse parvovirus was definitively discovered 10 years earlier. These viruses may persist for lengthy periods in mice and can contaminate and remain infectious in the environment for months, making them ideally suited to persevere in colonies kept in filter top cage systems.

LLAMAS AND ALPACAS

The four members of the South American camelids (SACs) are the llama, alpaca, guanaco, and vicuña. Although their progenitors originated in North America, these species evolved in the South American Andes, with the wild guanaco and vicuña serving as the foundation stock for the domesticated llama and alpaca, respectively.

Mature, average alpacas weigh 60–80 kg and stand 76–97 cm at the withers. Alpacas are primarily used as fiber-producing animals. The fiber grows rapidly and ideally requires shearing every 12–24 mo. Mature llamas are significantly larger animals, weighing an average of 120–200 kg and standing 102–127 cm at the withers. Llamas were primarily developed as pack animals and can carry loads of 25–40 kg. Both domestic SACs are meat staples for indigenous peoples. Males and females of both species have approximately similar mature weights. Guanacos are similar in size to llamas but weigh somewhat less. Unlike llamas and alpacas, in which coloration patterns vary markedly, guanacos and vicuña have a “wild pattern” characterized by a light brown or tan coat over the neck, back, and outside of the legs, with white on the underbelly and medial surface of the legs. Vicuñas are slightly taller than alpacas, with a longer neck, much shorter fiber, and a characteristic “bib” of long fibers in the chest region. Vicuñas have extremely fine fiber and are managed and protected in much of South America.

All SACs have 74 chromosomes and can interbreed, producing fertile F1 progeny. The most common, naturally occurring cross is a llama-alpaca mating, producing a “huarizo” that is intermediate in size, body characteristics, and fiber quality. Recent attempts to increase fiber quality and quantity have involved alpaca-vicuña crosses resulting in paco-vicuñas. Intact male llamas and alpacas are called studs (machos in Spanish), whereas castrated males are referred to as geldings. Females are called females (hembras in Spanish). The neonates and young up to 6 mo of age are called crias, whereas juveniles are called tuis in the local Quechua language.

Most llamas have characteristic “banana-shaped” ears, a level back, and a high tail set. There are no distinct llama breeds, but several types based on fiber

length and crimp have emerged. A “suri-style” llama has recently been introduced into the North American market.

In contrast, there are two morphologically distinct types of alpacas: the Huacaya and Suri. The more common Huacayas have a lofted fiber coat with variable coverage down the legs and around the face. Suri have a flat-lying corded fiber structure (“dreadlocks”) with less coverage on the head. Alpacas have shorter “spear-shaped” ears, a lower tail set, slightly more humping to the back, and a sloping rear end that results in a slight sickle hock appearance.

SACs are most closely related to the Old World camelids (Bactriari and Dromedary), having the same number of chromosomes, similar anatomy and physiology, and general patterns of disease susceptibility. Although conventional ruminants are frequently used as reference points for drug dosage extrapolation, disease susceptibility, and management decisions, it is important to remember that SACs and common domestic ruminants are not the same.

MANAGEMENT

Llamas and alpacas are adaptable to a wide climatic range and have been successfully raised in regions with winter temperatures as low as -20°C (-4°F) if reasonable wind shelter is provided. Heat stress is a significant problem if animals have moderate to heavy fiber coats and are subjected to high temperature and humidity. Shearing, leaving remaining fiber at least 2 cm long to prevent sunburns, and providing access to shade and sufficient water usually allow SACs to handle moderately high temperature and humidity. Air conditioning, misters, and damp sand pits are helpful to maintain heavy fiber coats in warm, humid climates. Llamas and alpacas can adapt well to damp climates as long as the temperature does not get too high, and few problems of either footrot or “rain scald” are encountered.

Llamas and alpacas can be housed with other species, including sheep, goats, and horses. Individual llamas (ideally geldings) have been successfully used as guard animals with sheep flocks and goat herds. Llamas and alpacas are herd animals and do poorly if isolated from cohorts or other animals; ill animals should be housed with

TABLE 12 SELECTED DRUGS USED IN LLAMAS AND ALPACAS

Drug	Dosage	Comment
SEDATION/ANESTHESIA		
Xylazine	0.1–0.2 mg/kg, IV	For sedation
	0.3–0.4 mg/kg, IV	For recumbency
Butorphanol	0.1–0.2 mg/kg, IM or IV	For sedation
KXB: ketamine (4 mg/kg), xylazine (0.4 mg/kg), and butorphanol (0.04 mg/kg)	1 mL/22.5 kg, IM (llamas) 1 mL/18 kg, IM (alpacas)	Mix 1,000 mg ketamine with 100 mg xylazine and 10 mg butorphanol; if needed to maintain anesthesia, ½ initial dose can be given IV in the medial saphenous vein
ANTIBIOTICS		
Aqueous procaine penicillin	20–40,000 units/kg, SC	
Long-acting tetracycline	18–20 mg/kg, SC, every 2–3 days	
Ceftiofur	2.2 mg/kg, IM or IV, bid	
Trimethoprim/sulfamethoxazole	3/15 mg/kg, IV, bid	
Ampicillin sodium	6 mg/kg, IM or IV, bid	
Enrofloxacin	5 mg/kg, IV, bid	
Gentamicin	0.75 mg/kg, IV, tid 4–5 mg/kg/day, IV	
Tobramycin	4 mg/kg/day, IV	
Amikacin	12 mg/kg/day, IV	
REPRODUCTIVE		
hCG ^a	5,000 IU	
GnRH	1 mcg/kg	
Cloprostenol	100–150 mcg, IM, repeated in 24 hr	
Dinoprost tromethamine	5 mg, SC, repeated in 24 hr	
ANTHELMINTICS		
Ivermectin	0.2 mg/kg	
Pyrantel pamoate	18 mg/kg	
Fenbendazole	5–10 mg/kg	
Clorsulon	7–14 mg/kg	
Albendazole	10 mg/kg	

TABLE 12 SELECTED DRUGS USED IN LLAMAS AND ALPACAS (continued)

Drug	Dosage	Comment
COCCIDIAL		
Ponazuril ^b	20 mg/kg/day for 3 days	Ideally should be followed by sulfadimethoxine, 55 mg/kg, SC on day 1, then 27.5 mg/kg, SC, for 2 additional days
GASTRIC		
Omeprazole	0.4 mg/kg, bid	
MANGE, LOCAL THERAPY		
Mixture of:		Shake before use and apply mixture to local lesions with a paint brush every 5 days for 5 treatments
Mineral oil	2 oz	
DMSO, 10%	2 oz	
Ivermectin, injectable	4 mL	
Gentamicin	1 g	

^a Human chorionic gonadotropin^b For treatment of *Eimeria macusaniensis*

herdmates if appropriate. If sufficient space is available, large groups of males (or females) can be pastured together. In the presence of nonpregnant females, however, intact males and recently castrated geldings will commonly spend much of their time fighting, typically biting at the ears, neck, and scrotum. Llamas and alpacas generally do not destroy fences and can usually be confined behind a 1.5-m or 1.2-m fence, respectively. Barbed wire is not needed for containment, and electric fences have been successfully used.

A somewhat unique behavioral characteristic of SACs is the use of communal dung piles. Animals urinate and defecate on the same pile, with favorite sites being in the depths of barns and other inconvenient locations. Normal feces are pelleted and firm. Unless forage becomes very limited, animals will not graze in areas around or downstream from dung piles. The urethral diameter in both males and females is relatively small, and the process of urination takes much longer than in other species of comparable size.

Handling: Llamas and alpacas are highly trainable, and most animals can be easily taught to come into a barn or corral for

food. An arm around the base of the neck and another arm holding the tail or flank region on the opposite side can restrain many animals. Halter-trained SACs can be easily led into a smaller area for examination and treatment. Specially designed llama chutes should be used for reproductive examinations and other potentially uncomfortable procedures. In contrast, alpacas respond better to most procedures if assistants, and not restraint chutes, are used to hold the animals. With both llamas and alpacas, it is particularly important to maintain control of the animal's head. The neck is very muscular and can move with amazing speed. Sedation is not needed for most procedures. A small catch pen crowded with animals will afford adequate control to administer injections and perform body condition scoring.

Feeding and Nutrition: Mature males, and most females during midgestation, will maintain appropriate body condition on 10%–14% crude protein grass hay with total digestible nutrients (TDN) of 50%–55%. Late gestation and heavily lactating females require a slightly higher percentage of crude protein and TDN of 60%–65%. Under basal conditions, most camelids eat 1.8%–2% of

body wt/day on a dry-matter basis. Legumes are usually not needed and may contribute to obesity. Palpating the amount of tissue over the lumbar vertebrae and ribs can best assess body condition. Body condition is generally scored from 1 (thin) to 9 (fat), with 5 being ideal.

Seasonal vitamin D deficiency, characterized by diminished growth, angular limb deformities, kyphosis, and a reluctance to move, can be a problem in heavily fibered animals raised in regions with poor sun exposure during winter months. The problem is most severe in rapidly growing, fall-born crias. Serum phosphorus of <3 mg/dL, a calcium:phosphorus ratio of $>3:1$, and vitamin D concentrations of <15 nmol/L in crias <6 mo old are diagnostic. Normal phosphorus and vitamin D concentrations in this age group are 6.5–9 mg/dL and >50 nmol/L, respectively.

To date, there does not appear to be a nutritional justification for routinely incorporating ionophores into the diet of camelids. However, because pelleted or mixed-grain feeds intended for camelid consumption may be formulated in the same facilities that handle ionophores, camelid feed has been accidentally contaminated. Such an incident resulted in a high incidence of death, and other health compromises to animals exposed during the period of consumption are not fully known. Routine and effective purging of feed milling facilities should allow for production of camelid feed without contamination; however, human error and equipment failure can still compromise any feed product.

Copper toxicity is a much greater concern than copper deficiency in camelids. Although there is a requirement for copper in camelid diets, mistakes in formulation and use of multiple supplements without full knowledge of total copper intake has resulted in toxicity. Most reported cases of toxicity have been due to chronic intake rather than acute deaths.

Anesthesia: There are several options for sedation and anesthesia of camelids (see TABLE 12). Generally, alpacas require more drug than llamas to achieve the same results. For short procedures, it is usually not necessary to withhold food and water; however, when deemed necessary, both should be withheld at the same time, reducing the tendency to regurgitate.

Xylazine can be used for sedation without recumbency. Higher dosages will result in recumbency and provide a light plane of anesthesia for 20–30 min. Simultaneous

administration of xylazine, ketamine, and butorphanol usually provides 20–30 min of recumbent restraint. Butorphanol can provide sedation of short duration and is especially useful for head, ear, and dental procedures.

Llamas and alpacas tolerate general anesthesia well and usually do not require tranquilization before induction. Induction and maintenance of anesthesia is similar to that in other domestic species; however, tracheal intubation requires some practice.

Clinical Pathology: Hematology and clinical chemistries are similar to those in other species, with a few significant differences. Camelid RBCs are relatively small and elliptical and may produce anomalous results when evaluated using an automated cell counter. Normal PCV is 27%–45%, normal RBC counts are $10.1\text{--}17.3 \times 10^6/\mu\text{L}$, and normal WBC counts are 8,000–21,400/ μL .

Basal glucose concentrations in llamas and alpacas are more typical of monogastric species than ruminants. Basal levels are 82–160 mg/dL, but glucose levels >300 mg/dL are common after stressful events. For additional hematologic and serum biochemical reference ranges, see TABLES 6 and 7, p 3176.

Drug Use: No drugs are currently approved for use in llamas and alpacas, so all use is extra-label. SACs in North America have the potential to be food animals, making drug withdrawal time a consideration. See TABLE 12 for antibiotics that have been used for treatment of sensitive bacteria in SACs.

Although drug use in exotic species is commonly based on approaches used in other species and often has favorable results, adverse outcomes have prevailed with numerous drugs in camelids.

Camelids are prone to lidocaine toxicity, so its use should be minimized. If deemed necessary, lidocaine should be diluted to 0.5% and used sparingly; the total dose should not exceed 4 mg/kg (1 mL of 2% lidocaine/5 kg). Lidocaine toxicity is characterized by lethargy, ataxia, slow and labored breathing, weakness, hypotension, and diminished response to stimuli. Diazepam should be available and administered at 0.1–0.5 mg/kg in case of lidocaine toxicity.

Although dexamethasone is used in other animals to stimulate surfactant activity in fetal lungs, as little as 0.5 mg in pregnant camelids has consistently caused fetal death and complications, including retained

placenta and uterine prolapse. Virtually any steroid-containing product that a female camelid comes in contact with, especially during the third trimester, will cause abortion. Even a cria with steroid cream on the muzzle nursing a dam has caused abortion.

Tilmicosin has caused enough deaths in camelids to warrant the recommendation that it should not be used in these species. The cardiovascular system is the target of toxicity, which may be due to calcium channel blockade.

The prolonged-release form of ceftiofur has produced neurologic changes, including blindness. IV administration should be avoided. However, many camelids have been successfully treated SC without problems.

Normally used to reverse xylazine sedation, tolazoline has produced severe signs, including initially anxiety, hyperesthesia, profuse salivation, and tachypnea. Convulsions, hypotension, and GI hypermotility resulting in diarrhea also develop. Doses >2 mg/kg are incriminated, as well as too rapid IV administration. Because death has also resulted after administration of tolazoline, use of yohimbine is likely a better approach.

Dinoprost tromethamine (prostaglandin $F_{2\alpha}$) use in camelids has often resulted in rapid death, likely due to bronchiolar constriction and pulmonary edema.

Leptospirosis 5-way killed vaccine has caused type 2 hypersensitivity and anaphylaxis in camelids. Similar reactions have been reported occasionally in cattle and swine, so it is likely that sensitivity will increase in camelid herds in which vaccination against leptospirosis is indicated.

Atropine, whether administered locally in the eye or parenterally, has resulted in pupillary dilation observed to persist in camelids for as long as a week. Treated animals must be kept out of direct sunlight until pupillary response is normal.

Camelids have relatively thin skin, and use of topical eprinomectin can result in dermatitis and blisters.

After a llama herd was treated for biting lice with topical permethrin 10%, some animals were observed to be breathing hard and drooling; recovery was uneventful.

Although numerous potential adverse effects from therapeutic use of trimethoprim-sulfamethoxazole have been reported in the literature, it appears that acute death after IV administration is rare. The rate of administration or existing condition being treated may be a predisposing factor in the outcome.

Commonly and immediately after camelids are injected with B-complex vitamins or levamisole, they demonstrate signs of hyperexcitement and itching. In the case of multiple procedures or administration of several injections, those anticipated to sting should be done last.

REPRODUCTION

Reproductive Physiology

Females: Relative to body size, the nonpregnant reproductive tract of SACs is relatively small. Uterine morphology is similar to that of a mare, with relatively short horns and uterine body. The cervix can be felt on rectal palpation and has two or three cartilaginous rings. The urethra opens onto the floor of the vagina. A suburethral diverticulum is present.

Ovarian activity typically begins at 10–12 mo of age. Camelids are induced ovulators. At the onset of puberty, follicular waves occur, with a dominant follicle developing every 12–14 days. Because of the small size of females and the potential for dystocia associated with early breeding, females are usually not bred until they are >18 mo old and weigh 40 kg (alpaca) or 90 kg (llama). When a female is truly receptive, she will usually assume a position of sternal recumbency (cushing) within seconds to a few minutes after introduction of a male and allow the male to breed. While mounting, the male will typically begin a vocalization described as “orgling.” The volume of the ejaculate is relatively small (2–5 mL) and is mostly deposited directly into the body of the uterus after cervical dilation. Ejaculation occurs over an extended period of time. An ovulation induction factor in the semen stimulates reflex ovulation ~24–30 hr after mating. A functional corpus luteum (CL) is present 2–3 days after ovulation. The fertilized oocyte is usually found in the uterus by day 7 after mating, with implantation occurring by ~30 days of gestation. The type of placentation is diffuse epitheliochorial, developing in both horns. Although ovulation occurs from either ovary, uniquely, ~95% or more of the pregnancies are carried in the left horn. Live births of twins are extremely uncommon, with most twin pregnancies being resorbed or aborted early in gestation.

A female with a functional CL will aggressively refuse the male's efforts to mount. An indication of pregnancy is the female's rejection of the male if he is reintroduced >15 days after the initial

breeding. Progesterone concentrations of >1 ng/mL are typical in females with a functional CL and can be used for confirmation of both ovulation at 6–9 days after mating and of pregnancy at >21 days after mating. Persistent CL are periodically seen and account for most false-positive results when using serum progesterone for pregnancy confirmation. Rectal palpation for pregnancy diagnosis is practical in llamas at >45 days of gestation. It is usually not possible to safely perform rectal palpation in alpacas, unless the palpator has small hands. Pregnancy can positively be diagnosed by transrectal ultrasound from ~28 days of gestation, although it is possible to be suspicious as early as 10–12 days based on presence of fluid and to be reasonably sure by day 21 when a hyper-echoic “embryo” is seen. Ultrasonographic transabdominal approach from 45–60 days can be expected to produce positive results.

Normal gestation in camelids is $\sim 342 \pm 10$ days, with alpacas being somewhat shorter. Most normal births ($>70\%$) occur in the morning. Dystocias due to excessively large crias are rare. There are few reliable indications of pending delivery. Stage I labor typically lasts 1–6 hr and may be accompanied by increased frequency of urination, increased “humming,” and separation from the herd. Stage II labor is rapid (typically <30 min), with delivery of a cria weighing 5.5–8 kg (alpaca) or 11–16 kg (llama). Stage III should be complete within 4–6 hr. All stages are usually longer in a first-time delivery. Retained placentas are rare. Uterine involution begins shortly after birth, and most females can conceive within 14–21 days after delivery. Females have four teats and do not exhibit significant mammary enlargement during the prepartum period. Mastitis is rare.

Males: Both testicles should be fully descended at birth. Testes should be at least 2×4 cm and 3×6 cm in mature alpacas and llamas, respectively. Relative to body size, the testes are smaller than those of many other domestic livestock species and are held close to the body wall. The urethra is relatively small and contains a urethral diverticulum at the level of the ischial arch, making retrograde catheterization difficult to impossible. The unstimulated prepuce points backward, accounting for the rear-directed urination, while the forward-pointing penis is fibrous, with a sigmoid flexure. A cartilaginous process is present at the tip of the penis, and the urethra opens 1–2 cm back from the tip. Urinary calculi are relatively uncommon and have a poor

prognosis because of the small urethral diameter (3.5–5 French).

Although androgen production may begin at <8 mo of age, and some sperm can be collected by vaginal retrieval as early as 14 mo of age, normal preputial adhesions prevent full penile extension and copulation until ≥ 18 –24 mo of age. Most males enter breeding programs when 18–24 mo old, and most are fertile by 30 mo of age. Sexual maturity may be later in alpacas than in llamas.

Semen evaluation is difficult in camelids because of the small total volume of semen and the dribble ejaculation. Although males can be trained to mount a phantom or dummy equipped with an artificial vagina, semen collection usually requires heavy sedation or anesthesia and electroejaculation. Semen collection, even from males of known fertility, is inconsistent. The most reliable semen evaluation is afforded by postbreeding retrieval from the vagina of a receptive dam.

Management of Reproductive Problems

Fertility problems are relatively common in llamas and alpacas. Although most problems primarily involve females, problems with males include hypoplastic testes, penile injuries, and heat stress, which is characterized by scrotal edema, decreased activity, and reluctance to breed. After heat stress, fertility can be permanently impaired or reduced for up to 6 wk. Shearing, adequate shade, and sufficient water help prevent the problem. When working with inexperienced males, vaginal intromission should be visually confirmed.

Because of the relatively high incidence of congenital anomalies, anatomic problems must be considered as causes of infertility in nulliparous animals. In multiparous animals, vaginal strictures, uterine infections, and cervical damage are also relatively common. Complete uterine strictures are possible sequelae of dystocia. The diagnostic approach to all these conditions is similar to that used in mares, except that rectal palpation cannot usually be safely done in alpacas unless sedated. If uterine biopsies or cultures are appropriate, they should be performed when the dam has a dominant follicle, which relaxes the cervix.

Rupture of a mature follicle (>7 mm) can reliably be induced with human chorionic gonadotropin or GnRH. Increased progesterone concentration (>1 ng/mL) 7 days after copulation or hormonal

treatment is indicative of CL formation. Although persistent CL have been identified, they are relatively rare. Prostaglandin treatment will result in regression of a persistent CL and abortion throughout gestation. Induction of parturition with prostaglandins or glucocorticoids is not recommended. Rapid death of llamas and alpacas has occurred after prostaglandin therapy, especially at high doses and when administered by other than SC route.

HERD HEALTH

Neonatal Care: Crias should be on their feet and attempting to nurse within 2 hr after birth and every 1–2 hr thereafter for the first few days. While weight gain for the first 24 hr postpartum may be minimal, thereafter llamas should gain 250–500 g/day and alpacas 100–250 g/day. Healthy crias should approximately double their birth weight by 1 mo of age.

Routine cria care should include weighing and single dipping the navel in 7% tincture of iodine or 0.5% chlorhexidine three times during the first 24 hr after birth. If appropriate for the area, supplemental selenium could be provided by injection (0.5 mg for alpacas, 1 mg for llamas). At birth is an ideal time to take a blood sample if there is any concern of failure of passive transfer of colostral antibodies. Having a baseline sample to measure PCV and total proteins to compare with a subsequent sample at 24 hr will provide valuable information regarding failure of passive transfer and hydration.

Parasite Control: Parasite control programs vary according to climatic conditions, population density, and parasite load, and should be developed according to local conditions.

No drugs have been approved for use in SACs. However, anthelmintics that are generally recognized as safe and effective include ivermectin, pyrantel pamoate, and fenbendazole. Parasite resistance has been developed in all ruminant species, making it necessary to develop a strategic deworming program, particularly in locations where the meningeal worm is present. Liver flukes can be a significant problem. Control with clorsulon or albendazole is usually effective, although repeated clorsulon treatment every 6–8 wk may be necessary.

Vaccinations: Most vaccination protocols for SACs have been empirically derived. Most animals should receive *Clostridium*

perfringens type C and D vaccinations and tetanus toxoid. In regions where liver fluke (*Fasciola hepatica*) infections or snake envenomations are a problem, use of polyvalent vaccines against *C novyi*, *C septicum*, *C sordellii*, and *C chauvoei* are warranted. One successful approach has been to give an initial vaccination at 3 mo of age, a booster 30 days later, and annual boosters thereafter. Llamas and alpacas are immunocompetent at birth, so neonatal vaccination can begin in the first week of life, followed by two boosters at 3-wk intervals.

Abortions secondary to *Leptospira* spp infections are regionally a problem and can usually be prevented using an initial vaccination, followed by boosters twice a year. Killed rabies vaccines have been used with unknown efficacy in endemic areas. Any attempt to control other viral diseases (including West Nile virus infection) should only involve use of killed vaccines.

Dental Development and Care: The dental pad of llamas and alpacas is similar to that of a cow. At birth, the first two pairs of lower incisors are normally through the gum line; lack of eruption is one indication of prematurity. The central, middle, and lateral mandibular deciduous incisors are replaced at ~2–2½, 3–3½, and 4–6 yr, respectively, although determining age by the teeth is notoriously inaccurate in these species.

A unique feature of SACs is the development of the upper I3 and upper and lower canine teeth on both sides into “fighting” teeth that may grow to >3 cm long. The teeth can cause serious damage to other males during fights and usually need to be cut flush to the gum with obstetrical wire or a grinder beginning with eruption at 18–24 mo of age and repeated as needed in intact males. If castration is to be performed, eruption of the fighting teeth signals an ideal time to schedule both procedures. Growth of fighting teeth usually stops after castration. Fighting teeth in most females barely penetrate the gumline and seldom, if ever, need to be cut. Tooth extraction to avoid periodic trimming is impractical because of very deep, curved roots.

The incisors are open-rooted in alpacas and continue to grow throughout life. Poor occlusion of the incisors and dental pad necessitate periodic tooth trimming and appears to be more of a problem in alpacas than in llamas. Cheek teeth are rooted, normally sharp, and do not require regular

floating. Premolar and molar occlusion should be checked and problems corrected in older animals exhibiting difficulty in chewing or weight loss.

Abscessed lower second premolar and first and second molars are seen as a hard, well-developed swelling on the lateral surface of the mandible over the affected teeth. A draining tract may or may not be present. The area is usually not painful on palpation, and most animals maintain body condition. No bacterial agent has been consistently isolated from the abscesses. Prolonged antibiotic therapy is palliative, although rarely curative. Tooth extraction usually requires making a lateral incision over the affected teeth, splitting the tooth because of the divergent roots and repelling the tooth into the oral cavity. Care should be taken during extraction to avoid mandibular fracture.

Nail Trimming: Some animals rarely need foot care, whereas others require nail trimming every 2–3 mo. Diet, genetics, and environment likely play a role. The nails should be trimmed flush with the bottom of the pad. Occasionally and especially with overgrown toes, “quicking” may occur but generally is inconsequential.

DISEASES

Congenital and Inherited Anomalies

Although few congenital anomalies have conclusively been shown to be genetic in origin, it is assumed that defects inherited in other species are probably inherited in SACs as well. Accordingly, this should be considered in breeding decisions. Facial and cardiac defects are reported to be the most frequent inherited anomalies. A historically narrow gene pool is likely the reason that congenital defects are relatively common in SACs. Affected individuals commonly have more than one defect.

Choanal atresia, a condition caused by failure of the inner nares (choanae) to open during embryologic development, is the most widespread congenital defect. It can be unilateral or bilateral and may result in complete or partial blockage. Accordingly, the primary clinical presentation is a variable degree of respiratory distress in the neonate. Distress becomes more apparent during nursing, and crias commonly gasp as milk is inhaled. Surgical correction is not recommended.

Wry face is characterized by a slight (<5°) to severe (>60°) lateral deviation of

the maxilla. The mandible may or may not have a similar deviation. When severe, occlusion of the nares and lack of apposition of the incisors and dental pad usually necessitate euthanasia of the cria. There appears to be a relationship of this defect to choanal atresia, in that they occasionally occur together.

Ocular and ear conditions include juvenile cataracts (seen occasionally), blocked nasolacrimal ducts, and an association between blue eyes and deafness in some lines of white animals. Fused (tip or base) and short (“gopher”) ears are recognized heritable defects, the latter appearing to be a dominant trait.

Cardiac defects are relatively common, with ventricular septal defects heading the list.

Numerous **musculoskeletal defects** have been identified, including syndactyly and polydactyly. Arthrogryposis, rotated talus, angular limb deformities of the front limbs, and tendon laxity are also seen.

Other congenital anomalies identified in llamas and alpacas include **atresia ani**, **atresia coli**, **umbilical hernias**, and several different types of **tail defects**, including a pronounced lateral deviation of the tail at the base.

Urogenital defects are much more common in SACs than in other species. Significant defects in females include uterus unicornis, hypoplastic ovaries, double cervixes, segmental aplasia of the vagina or uterus, and clitoral hypertrophy suggesting intersex conditions. Unilateral absence of a kidney is periodically seen, commonly in association with choanal atresia. Total absence of kidneys has also been seen. Congenital conditions in males include hypospadias, retained testicles, testicular hypoplasia, persistent frenulum, ectopic testicles, and corkscrew penis.

Bacterial Diseases

Brucellosis, tuberculosis, and Johne's disease (paratuberculosis) have been identified in SACs, although the naturally occurring incidence of these infections is low. There are reported cases of both type C and D *Clostridium perfringens*, which has prompted the use of toxoid vaccination as a routine measure in most herds. Although SACs are not apparently highly susceptible to tetanus, most herd vaccinations using the C/D toxoid include tetanus toxoid.

C. perfringens type A is a very important pathogen under stressful circumstances, especially in South America, and results in a high death rate in crias <4 wk old. Entero-

toxogenic strains of *C perfringens* type A are believed to be particularly lethal. Clinical signs are similar to those of type A infections in other species, with a rapid onset of neurologic changes followed shortly by death.

Anthrax has been diagnosed in SACs, but vaccination should only be done in endemic areas using a killed product.

Respiratory infections in North America caused by bacteria remain relatively rare, but in South America the condition referred to as alpaca fever is caused by *Streptococcus zooepidemicus*. The onset of this condition is often preceded by stressful conditions.

Individual cases and herd problems with abscesses caused by *Corynebacterium pseudotuberculosis* have been reported. Contact with sheep and shearing wounds are likely contributing factors.

Viral Diseases

Most camelids are seropositive for a presumptively nonpathogenic adenovirus that is specific to llamas. Occasionally, an animal will develop a titer to bovine diarrhea virus, and a few animals have developed a mild diarrhea, respiratory disease, and even abortion presumably in response to the virus. Exposure during pregnancy also can lead to persistent infection in crias. Equine herpesvirus 1 infections with associated neurologic signs and blindness have been seen in a small number of SACs, particularly when cohabitating with equids. Growing numbers of neurologic cases in SACs have been found to be due to Eastern equine encephalomyelitis virus. Bluetongue virus likely will emerge as a clinical entity in SACs as it evolves with greater distribution and pathogenicity. An outbreak in 2007 of respiratory disease, principally in alpacas, was found to be due to what is referred to as alpaca respiratory coronavirus. Stress conditions often predispose to the onset of clinical presentations that vary from mild upper respiratory tract disease to severe respiratory disease and death.

During the spread of West Nile virus across North America, SACs were found to be susceptible, with most developing a titer consistent with exposure. Some became severely affected and died. Naive and immunosuppressed animals are most likely to be at risk. West Nile virus vaccines approved for horses have been found to produce a good immune response. SACs can also contract foot and mouth disease, although clinical disease is usually relatively mild; the carrier status of infected animals is presumed to be of short duration.

Mycoplasma Infection

A common condition that was formerly referred to as eperythrozoonosis is now known to be caused by *Mycoplasma haemolamae*. A high percentage of the SAC population has been exposed by insect vectors, contaminated needles, or transplantally. Animals with a healthy immune system develop a state of premunity (infected but immune); they demonstrate the organism in RBCs only when stressed or truly immunosuppressed. PCR diagnostic tests are available. Treatment of clinically affected anemic animals with long-acting tetracyclines does not entirely clear the infection but improves the anemia.

Fungal infections

As with most animals, ubiquitous contact with fungal organisms in SACs will occasionally lead to clinical disease. Notable clinical possibilities include coccidioidomycosis, candidiasis, aspergillosis, cryptococcomycosis, mucormycosis, and mycotoxins. The most significant fungal infection in SACs is coccidioidomycosis; it is an endemic problem in the southwest USA, potentially affecting all resident animals (as well as the human population). An important consideration is that SACs showing chronic respiratory signs even in nonendemic locales may have been exposed during shows or breeding time while in endemic areas.

Gastrointestinal Diseases

The oral cavity and esophagus of SACs are unremarkable. The stomach has three distinct compartments (C-1, 2, and 3) that do not correlate directly with the four chambers of the ruminant stomach. Although not classed as ruminants, they do eructate, regurgitate, and remasticate and would be

Mycoplasma infection in llama RBCs. Courtesy of Dr. LaRue Johnson.

considered as foregut fermenters in C-1 and 2. Only the distal fifth of C-3 is analogous to the acid-secreting monogastric stomach. The spiral colon is generally a flat, single spiral prone to blockage when the centripetal loop turns to become centrifugal.

Megaesophagus: Moderate to severe dilatation of the esophagus is relatively common in llamas and alpacas, especially after instances of choking. Signs include chronic weight loss frequently associated with postprandial regurgitation or "frothing" of food. There is no identified age or sex predilection, and no consistent cause has been established. A suspected case of megaesophagus should be confirmed with barium contrast radiography. No treatments (surgical or changes in feeding practices) have been consistently successful. The longterm prognosis is fair to poor, with some animals maintaining condition for an extended period and others continuing to lose weight.

Stomach Atony: Gastric atony is an occasional problem of unknown cause. Signs include decreased or complete cessation of food consumption, loss of body condition, and depression. Other GI problems, including diarrhea, may be present. Supportive therapy, including fluids, is frequently helpful. Lack of food for 3–5 days also usually causes the death of bacteria and protozoa in C-1 and C-2. Transfaunation (0.5–1 L) of camelid C-1 or strained rumen contents (sheep or cow), administered by gavage, frequently results in a dramatic improvement in appetite and reestablishment of appropriate flora.

Ulcers: Partial and complete thickness erosions of the acid-secreting distal portion of C-3 and most proximal portion of the duodenum occur. Signs may include decreased food consumption, intermittent to severe colic, and depression. Although the cause has not been clearly established, stress appears to be a significant component, with problems often developing 3–5 days after change of environment affecting social structure, serious injuries, and illnesses.

No reliable premortem diagnostic procedures are available; treatment is usually based on history and clinical signs. Theoretically beneficial oral medications have not proved effective. Parenteral administration of omeprazole reduces acid production. Stress reduction, including clinical housing with a cohort animal, parenteral antibiotics, and supportive therapy, are helpful.

Hepatic Disease: The visceral surface of the liver normally has multiple fissures, whereas the parietal surface is smooth and lobation is indistinct. There is no gallbladder. SACs appear to be particularly susceptible to *Fasciola hepatica*, with fecal shedding beginning 10–12 wk after infection. Clinical signs can include ill thrift, diminished growth, and acute death. Icterus is rarely seen. Increased serum bile acids ($>25 \mu\text{mol/L}$) and enzyme concentrations (normal, alkaline phosphatase 15–121 IU/L and AST 66–235 IU/L) are also diagnostically useful.

Hepatic lipidosis is a relatively common problem in SACs. Clinical signs associated with liver failure in other species are frequently seen, although acute death without prior indication of pending problems also has been reported. The cause is not clearly established, but stress and/or abrupt decrease or change in food consumption appear to play a role. Treatment is symptomatic. Mortality in untreated animals is frequently high.

Small- and Large-intestinal Diseases:

Diarrhea is relatively uncommon in llamas and alpacas. Shortly after birth, SAC crias may experience a mild diarrhea due to abundant dam milk production, essentially a substrate purge. The primary recognized infectious causes of diarrhea in neonates include rotavirus, coronavirus, cryptosporidia, and enteropathogenic strains of *Escherichia coli*. Some crias also have a transitory diarrhea 2–3 wk after birth, at about the time they experience new food matter. At this same time, some crias develop colic signs due to blockage in the spiral colon. Diarrhea in older neonates is more likely associated with *Eimeria* spp infection, especially associated with the stress of weaning. Identified causes of diarrhea in older animals include *Yersinia pseudotuberculosis*, *Salmonella* spp, *Giardia* spp, and *Cryptosporidium parvum*. Treatment options are the same as for other species (ie, fluid and electrolyte replacement and appropriate antibacterials).

Diarrhea in adult SACs is relatively rare but often accompanies a change of feed. Serious conditions characterized by diarrhea include eosinophilic enteritis, infection with *Eimeria macusaniensis* or *Mycobacterium paratuberculosis*, or severe nematode parasitism. Compared with that in cattle with Johne's disease, the clinical course in SACs tends to be short and fatal. When diagnosed by fecal examination,

E. macusaniensis must be promptly treated, because infection can cause marked debilitation. Although variable, current therapy recommendations include oral ponazuril followed by parenteral sulfadimethoxine.

Lymphosarcoma is the only neoplasia found with significant frequency in SACs. It can occur as either a juvenile lymphoma or a primitive malignant round cell tumor. Clinical signs and course vary depending on organ involvement.

Respiratory Diseases

Auscultation of llamas and alpacas is difficult and frequently unrewarding. Little air movement is heard under normal conditions, and identification of areas of infection, congestion, or consolidation is typically difficult. Lateral radiographs may be required for diagnosis of pneumonia. Bacterial infections of the lung are relatively rare, with *Streptococcus* and *Corynebacterium* spp being the most common isolates.

Chronic obstructive pulmonary disease appears to be increasing in frequency. Animals allowed to live to their expected life span is a factor, but feeding practices can contribute to onset as well as exacerbation of clinical signs—coughing, shortness of breath, and expiratory dyspnea. Therapy includes changing the feeding regimen to reduce dust, molds, and pollen. Bronchodilators and steroids may be helpful but remain unproved.

Skin Diseases

Unique features of normal camelid skin histologically include a marked vascularity and significant presence of eosinophils. Several skin conditions are shared with sheep and goats, including ringworm, contagious ecthyma, dermatophilosis, and occasionally pizzle rot.

Shearing Injury and Sunburn:

Complications associated with shearing are common. Lacerations may occur where there are loose folds of skin, eg, near the axilla. These often heal uneventfully with or without suturing. Hot shears may cause burns that lead to thick scabs, usually on the dorsum of the back, that may resemble “wool rot.” A history of shearing by a novice often helps confirm the diagnosis. Antibiotic ointment is generally beneficial for these iatrogenic lesions.

Sunburn also can occur after shearing, especially in light-skinned animals. If found in the acute stage, protection from further

exposure and application of aloe vera lotion have proved useful. Later appearance of sunburned sites varies from mild peeling to ulcers.

Ulcerative Pododermatitis: Llamas and alpacas kept in moist conditions develop “immersion foot,” characterized by footpad blistering and sloughing, with variations depending on infection by anaerobic bacteria. Debridement, antiseptics, and foot protection may be required for prolonged periods to facilitate resolution. Treatment with penicillin is always indicated unless unique bacterial isolates are involved. These cases require a relatively long healing period.

Mange, Lice, and Ticks: All four genera of mange mites (ie, *Sarcoptes*, *Psoroptes*, *Chorioptes*, and *Demodex*) have been diagnosed in camelids. Alopecia, hyperkeratosis, and scaling accompanied by pruritus tend to characterize all species. The clinical signs may resemble those of zinc deficiency. Deep skin scrapings or biopsies are ideal to make a definitive diagnosis. Although various options for therapy exist, most mange cases will respond to routine parenteral doses of ivermectin repeated every 10–14 days. Oral therapy does not appear to be as effective. *Chorioptes* infestation may require higher doses repeated every 14–21 days and local therapy. Refractory *Sarcoptes* cases involving the lower legs have benefited from the same topical treatment.

With louse infestation, it is important to determine whether pediculosis is due to biting (*Damalinea breviceps*) or sucking (*Microthoracius cameli*) lice. This can be accomplished with the aid of a hand lens or microscope. Use of transparent tape to retrieve lice for diagnosis from within the depths of wool can be attempted. Sucking lice can be treated with injectable ivermectin as per routine mange therapy. However, biting lice are not affected by parenteral ivermectin. Topical application of synthetic pyrethrin preparations has been effective, but critical doses for these species have not been established. Preventive measures for lice and mange include routine treatment of new herd additions as well as animals visiting and returning for breeding purposes or from shows. Ticks have caused tick paralysis as is seen in other species. In addition, ticks gaining access to ears have caused inner ear afflictions resulting in Horner syndrome as well as encephalitic death.

Copper Deficiency: Copper deficiency is characterized by depigmentation of fiber with a wiry or steely texture. Juveniles grow poorly and are predisposed to infections. Confirmation of deficiency is best based on comparison of liver copper levels with species normals. Therapy requires dietary supplementation. However, excessive supplementation will cause copper toxicity, which has been diagnosed more commonly than deficiency.

Dorsal Nasal Alopecia (Dark Nose Syndrome): The most common clinical sign of dorsal nasal alopecia is usually alopecia over the bridge of the nose. The skin is normal or variably scaly, hyperpigmented, and thickened. Dark-haired animals are predisposed, presumably because insects prefer the warmer surface of a dark background. In some animals, the condition may be secondary to rubbing the nose; in others, it may be a fly bite exacerbation.

Systemic or topical steroids produce some transient response, but steroids may cause abortion in camelids. In northern climates, the condition tends to spontaneously improve during winter months. Alopecia of the ears has also been seen, particularly in black alpacas.

Idiopathic Hyperkeratosis (Zinc-responsive Dermatitis): Onset of idiopathic hyperkeratosis is possible at any age. The lesions appear as nonpruritic papules with a tightly adherent crust. Papules progress to plaques and then large areas of thickening and crusting. Lesions are most common in the less densely haired areas of the perineum, ventral abdomen, inguinal region, medial thighs, axilla, and medial forearms, but the face may also be involved. The signs may wax and wane. Diagnosis is by skin biopsy. Treatment is 1 g zinc sulfate or 2–4 g zinc methionine per day. Calcium supplementation should be minimized and alfalfa hay discontinued. Affected animals may be zinc responsive but not deficient.

Idiopathic Nasal/Perioral Hyperkeratotic Dermatitis (Munge): Most animals with munge are 6 mo to 2 yr old at onset. Variable degrees of hyperkeratosis (heavy, adherent crusts) in paranasal and perioral regions are seen. Less commonly, the bridge of the nose and periocular and periaural regions are affected. Inflammatory lesions may wax and wane. Differential diagnoses include viral contagious pustular dermatitis, dermatophilosis, dermatophytosis, bacterial dermatitis, and autoimmune/immune-mediated disease. Treatment is directed at resolving secondary bacterial infections (ie, daily 10% povidone iodine scrubs plus application of 7% tincture of iodine). If lesions do not respond to antibiotics, adding topical glucocorticoid preparations or intralesional triamcinolone acetonide (2 mg/mL) may be beneficial. Some animals do not respond to any of the described therapies, including those with juvenile llama deficiency syndrome, which has been shown to affect both llamas and alpacas; in these cases, an evaluation of the immune response is indicated.

MARINE MAMMALS

Marine mammals are a diverse group of species that include cetaceans, pinnipeds, sirenians, sea otters, and polar bears. The cetaceans consist of two major groups with different physiology and anatomy: toothed whales (Odontocetes) and baleen whales (Mysticetes). The pinnipeds consist of three major groups: true seals (Phocidae), eared seals (Otariidae), and walruses (Odobenidae). Sirenians (Sireniidae) are of a single family that includes manatees and dugongs. The sea otter (*Enhydra lutris*) is a marine member of the Mustelidae, and the polar bear (*Ursus maritimus*) is the only member of the Ursidae that is considered marine.

Few pharmaceuticals or vaccines are approved for use in marine mammals. Many recommendations can be made based on personal experience or published reports, but clinicians should be cautious in their application.

MANAGEMENT

The general rule in maintaining marine mammals in captivity is to duplicate their natural environment as closely as possible. Most live in marine habitats, although some species migrate into freshwater; Baikal seals (*Phoca sibirica*) and five species of river dolphins have adapted completely to freshwater habitats. Manatee subspecies vary in the time they spend in freshwater, but the dugong (*Dugong dugong*) is completely marine.

Marine cetaceans should be kept in water with a salinity of 25–35 g/L, preferably using balanced sea salts. Water for captive marine cetaceans should be maintained as close to the pH of mid-ocean waters (8–8.3) as possible. Freshwater cetaceans and seals require water similar to that of their natural habitat. In the USA, the Marine Mammal Protection Act of 1972 specifies that coliform bacterial counts of water for captive marine mammals must be $\leq 1,000$ MPN (most probable number/100 mL).

Marine mammals kept in the extremes of their temperature tolerance range are more susceptible to environmental and infectious disease. In general, cetaceans and pinnipeds are better adapted to cold than to heat, but species-specific tolerances differ. Inappropriately combining different species for display purposes can result in compromises that jeopardize the well-being of some species.

Good air quality, especially in indoor facilities (10–20 air changes/hr) is as important as good water quality. Photoperiods, light spectral and intensity requirements, sound tolerances, and flight distance requirements are not well established for any cetacean. Extremes in any of these factors should be considered detrimental in the absence of specific data.

Environmental requirements of pinnipeds are similar to those of cetaceans except that pinnipeds can “haul out” on land. Although captive pinnipeds can be kept in freshwater, saltwater pools that meet the specifications listed above for cetaceans are preferred. Most pinnipeds obtain their metabolic water requirements in food and do not require access to freshwater if provided fish with a high fat content. However, it is common practice to allow pinnipeds access to potable water.

Pools for captive pinnipeds should provide shelter from wind and some shade. Haul out requirements are different for each species, and some pinnipeds (eg, the Northern fur seal [*Callorhinus ursinus*]) require very specific timing of access to land (eg, only at the pupping season).

Sirenians are warmwater species with water requirements similar to those of cetaceans, although the most common sirenian in the USA, the Florida manatee (*Trichechus manatus latirostris*), migrates between marine and freshwater environments seasonally. Manatees do better in captivity if salinity is changed seasonally to match migration in the wild.

In captivity, the sea otter thrives best in a cold marine water system. Because the fur of the sea otter is its major protection against hypothermia, the water must be kept free of oils and organic material that could mat or damage the coat.

The polar bear naturally lives on arctic and subarctic ice. It has successfully adapted to subtropical climates in captivity but is more susceptible to dermatologic disease in warm climates. Polar bears traditionally have been provided with freshwater in captivity. Proper attention to filtration and water quality is beneficial.

Restraint: Marine mammals must be restrained for thorough examinations. Trained cetaceans and pinnipeds can be taught behaviors to facilitate examination

and collection of diagnostic samples. For these animals, the presence of familiar attendants is important.

For complex procedures or untrained animals, the safest approach to restraining a cetacean is to remove it from the water. Captive enclosures should allow water drainage so that cetaceans can be stranded without the use of nets. As the animal begins to lose buoyancy in the draining water, it should be positioned over thick foam pads to minimize struggling and injury. Nets are an alternative for corralling small cetaceans kept in sea pens or encountered in the wild; however, experienced personnel are required to minimize the risk of drowning or injury to the animal or staff. Netted cetaceans are placed on foam or specially designed stretchers or floats that can suspend the animal above water level.

Small cetaceans (dolphins) can often be restrained by the weight of three or four attendants—one person controls the peduncle of the tail fluke and the others apply weight to the animal's body. The pectoral fins should be folded alongside the animal in a natural position to avoid permanent damage. In larger cetaceans (whales), the powerful tail fluke may be secured with mechanical restraints.

Capturing pinnipeds is generally easier on dry ground, although small animals can be captured in the water with end-release hoop nets. Larger animals should not be netted in water but should be coaxed or driven from the water or have the water drained from their pool. On land, hoop nets can be used on larger animals. Cargo nets, baffle boards, and "come-along" poles also can be helpful. Once captured, small seals can be restrained for some procedures by an experienced handler sitting on the seal's back and holding the head. Larger pinnipeds or more complex procedures require an appropriately designed squeeze cage.

Sirenians are relatively docile; problems in restraint are generally due to their bulk and weight, and caution is recommended because they tend to roll. They can be handled in much the same way as cetaceans. Sea otters can be restrained like most other large mustelids. Hoop nets can be used to remove them from pools. Once they are out of the water, restraint bags, squeeze boxes, or other restraint devices for small wild carnivores can be used. Polar bears are large and dangerous, and manual restraint is not advised.

Anesthesia: Physiologic adaptations to diving and marine environments make gen-

eral anesthesia of cetaceans and pinnipeds difficult. Anesthetic drugs commonly used in other animals often have narrow margins of safety or cause unexpected reactions in marine mammals. Tranquilizers, sedatives, and anesthetics should be administered to marine mammals only by personnel experienced in their use. Specialized anesthetic machines and respirators (apneustic plateau) are required for cetaceans. Sirenians rarely require general anesthesia or tranquilization for treatment. Sea otters can be sedated with diazepam (0.2 mg/kg body wt) or tiletamine-zolazepam (1 mg/kg). A combination of fentanyl (0.22 mg/kg) and diazepam (0.07 mg/kg) has been successful for sample collection in wild sea otters. Narcotic recycling has been seen. Surgical anesthesia can be obtained with higher dosages of fentanyl-diazepam (0.33 mg/kg/0.11 mg/kg); tiletamine-zolazepam (2 mg/kg); or halothane, isoflurane, or sevoflurane, with or without nitrous oxide. Polar bears are routinely immobilized with etorphine, tiletamine-zolazepam with or without medetomidine, ketamine with xylazine, or a variety of other agents used IM. The required dose is highly dependent on the individual animal and environment.

ENVIRONMENTAL DISEASES

Corneal Edema: Corneal opacity is frequent in captive pinnipeds kept in either freshwater or saltwater; it is also seen in captive cetaceans but is rare in wild animals. It can be due to various environmental problems. Transient cases can be caused by simply moving an animal to freshwater from saltwater or vice versa. Lack of shade and excessive bright light have been implicated. Poor water conditions (eg, high bacterial loads or overuse of oxidative disinfectants in the water) also have been associated with the disease. Nutritional deficiencies have been suggested as causes, but response to supplementation with vitamin C or A has not been dramatic. Feeding other oral antioxidants (lutein, grape seed extract) as a preventive measure is being evaluated. The condition is usually self-limiting if the underlying insult to the cornea is removed early enough in the pathogenesis.

Corneal Ulcers: Corneal ulcers are common in captive pinnipeds and cetaceans. They can be the result of direct trauma or the sequelae of unresolved or untreated cases of corneal edema.

Diagnosis is by observation of epithelial defects on corneas stained with fluorescein. Culture of the lesion (bacterial, fungal) before therapy can help direct treatment of nonresponsive cases with associated infections. In trained animals, small lesions can be treated topically. In untrained animals, subconjunctival injections of antibiotics and steroid are required. Oral doxycycline is being used in some pinniped cases to stabilize the cornea, and topical cyclosporine or tacrolimus is being used in tractable animals with some success in reducing recurrence. Extensive lesions benefit from protection by suturing the eyelids. Deep ulcers or lacerations in danger of eroding Descemet membrane should be stabilized with a thin methylacrylate patch. As in corneal edema, successful resolution and prevention of recurrence depend on removal of the underlying cause.

Foreign Bodies: Many captive marine mammals develop the habit of swallowing objects dropped into their pools. In cetaceans, the opening to the second compartment of the stomach is small, and foreign objects remain in the first compartment. In pinnipeds, the small pylorus prevents passage of most foreign bodies. Frequently, no clinical signs are evident. On occasion, anorexia, regurgitation, or lethargy may be seen. Diagnosis is often made by having witnessed the animal swallow an object. Smaller animals can be radiographed; in small cetaceans, the esophagus can be palpated to establish the presence of foreign bodies. Animals occasionally regurgitate foreign bodies; however, assisted removal is usually indicated. Removal is usually best performed by gastroscopy, which is also used as a method of diagnostic confirmation. All efforts should be made to prevent ingestion of foreign bodies. Training animals to retrieve for reward as a displacement to swallowing foreign objects is thought to be beneficial.

Gastrointestinal Ulcers: GI ulcers are a significant problem in captive marine mammals and are also found in free-ranging marine mammals. Ulcers of the first compartment of the cetacean stomach are a common necropsy finding and pose less severe clinical problems than do ulcers of the pyloric region or proximal duodenum. Gastric ulcers in pinnipeds frequently progress to perforation, which results in peritonitis and subsequent death. Gastric ulcers also are found in sirenians. Although ulcers in cetaceans perforate less frequently than in pinnipeds, they should be treated as a serious problem. Various causes, including

parasitic damage and increased histamine content of spoiled fish, may be involved in the cause of a GI ulcer, but the disease in captive animals should be considered associated with environmental or stress-related conditions. Dramatic environmental changes, including changes of personnel or companion animals, can precipitate serious GI ulceration in cetaceans or pinnipeds.

Clinical signs include lethargy, partial anorexia, abdominal splinting, pallor, and occasionally regurgitation. Animals with bleeding ulcers show anemia and possibly leukocytosis. Diagnosis generally is based on identification of manual human RBCs in gastric washes; confirmation is by endoscopic visualization of the lesions. Palliative treatment of nonperforating ulcers usually consists of administration of histamine blockers and alumina gel-based antacids with or without simethicone, along with frequent small meals. The underlying cause must be identified and corrected for successful resolution. Management of perforating ulcers with resulting peritonitis includes intensive broad-spectrum antibiotic and fluid therapy. As in people, stress-induced GI ulcers are more likely to develop in marine mammals that have previously had an ulcer.

Trauma: Traumatic lesions (eg, cuts, wounds from gunshots or propeller blades) are common in marine mammals. Propeller injuries are a major problem in manatees, which commonly enter heavily navigated recreational waters in Florida. Traumatic wounds should be cleaned, debrided, and generally allowed to heal as open wounds unless body cavities are breached. Antibiotics should be administered during convalescence to prevent gross infection. Maintenance of good water quality and a high plane of nutrition is beneficial to the healing process. Large wounds frequently heal uneventfully.

Oil Exposure: Exposure of marine mammals to spills of petroleum hydrocarbons is a major concern. Sea otters are particularly susceptible to such exposure because of their natural grooming habits and their lack of an insulating blubber layer. Hepatotoxicity, renal toxicity, GI damage, and loss of homeothermic ability are important effects of exposure to petroleum hydrocarbons; however, the most devastating effects are due to direct pulmonary damage from inhalation of volatile hydrocarbons.

Experimental evidence suggests cetaceans and pinnipeds will avoid petroleum spills if possible (unlike sea otters) and are relatively

resistant to toxicities from direct skin contact. Ingestion of large quantities of oil by these species is unlikely, and although baleen fouling occurs in mysticete whales, it usually resolves within 24–36 hr. Pinnipeds and cetaceans are susceptible to severe pulmonary damage due to inhalation of volatile hydrocarbons as are other mammals, including people. Efforts to reduce human exposure to hydrocarbons when dealing with oil-contaminated animals is a top priority. Treatment of exposed animals includes removal of oil from both the skin (using mild detergents, eg, 2% New Dawn) and the GI system (activated carbon gavage), along with physiologic supportive therapy. For sea otters, use of warm wash water and provision of soft freshwater reduces recovery time. It is critical to recognize that capture, transport, and holding stresses appear to lower the threshold of hydrocarbon toxicity in these animals.

NUTRITION AND NUTRITIONAL DISEASES

Generally, captive animals fed a diet that is solely or primarily fish are provided dead fish that have been frozen. The logistics and difficulty in providing this diet can lead to some special nutritional concerns. All fish are not of equal nutritional value; diets consisting of a single species of fish are unlikely to provide balanced nutrition for any animal. Similarly, one diet will not serve all piscivores equally. Only fish suitable for human consumption should be fed. (*See also* NUTRITION: EXOTIC AND ZOO ANIMALS, p 2297.)

Storage and thawing of frozen fish must be monitored carefully. Feed fish should be held at or below -19°F (-28°C) to slow deterioration of their nutritional value through oxidation of amino acids and unsaturated lipids. Dehydration of frozen fish can also be a problem for animals that obtain their water from food. Fatty fish should not be stored >6 mo. Few fish, with the possible exception of capelin, should be stored >1 yr. To retain optimal vitamin content and reduce moisture loss, frozen fish should be thawed in air under refrigeration. Thawing in water leaches away water-soluble vitamins. Thawing at room temperature encourages bacterial growth and spoilage.

The energy requirements of marine mammals vary with age, environmental temperatures, and condition. Young, growing bottlenosed dolphins and smaller pinnipeds generally require 9%–15% of their body wt in high-quality fish per day. Older animals may need only 4%–9% of their body

wt for maintenance. Larger species (whales, elephant seals) generally require less food per unit body weight (2%–5% of body wt) as adults.

Sirenians thrive on a diet of hydroponic grass and various lettuces and vegetables, supplemented with high-protein monkey chow, carrots, bananas, and multivitamin-mineral supplements used particularly to balance calcium to phosphorus ratios. It is thought that sirenians ingest considerable animal protein incidentally during grazing in the wild. Intake requirements have been estimated at 7%–9% of body wt daily. Sirenians are generally fed several times a day to accommodate their grazing feeding pattern.

Sea otters are usually fed diets consisting of various invertebrates (echinoderms, molluscs, occasional crustaceans) and fish. Adult animals require ~25%–30% of their body wt in food each day.

Polar bears in the wild have high-lipid diets, particularly in winter when they subsist heavily on seals. They are considered to have an exceptional dietary requirement for vitamin A, and some dermatologic conditions respond to daily supplementation of 20,000–1,000,000 IU in the diet. Polar bears are commonly fed large amounts of fish in captivity.

Neonatal Nutrition: Young, unweaned marine mammals are frequently encountered in strandings and must be fed a diet resembling their dam's milk. In captivity, neonates may be abandoned by their parents and require artificial rearing. The milk of marine mammals has a high lipid content. Most species are carbohydrate intolerant, and neonates fed formulas with carbohydrates develop severe, life-threatening bacterial gastroenteritis. Most neonatal marine mammals also require immense caloric density in replacement milks. Milk replacement formulas based on commercial component-based milk replacers (eg, Zoologic® Milk Matrix) have begun to supplant some of the very complex scratch-made formulas used in the past. When confronted with a marine mammal neonate to raise, contacting one of the major marine mammal rescue centers for advice is recommended.

Phocid and otarid seals can be reared on the same milk replacer-based formulas. Pinniped pups should be fed every 4 hr in their first week of life; gradually, the amount of formula fed should be increased and the feedings dropped to five per day. Harbor seal (*Phoca vitulina*) pups should be tube fed until 2–3 wk old, when they can be

weaned to small pieces of fish. Elephant seal pups require tube feeding until they are 4 wk old, when weaning can begin. California sea lion (*Zalophus californianus*) pups can be force fed fish as early as 4 wk of age and be free feeding by 6 wk.

Neonatal walruses (*Odobenus rosmarus*) have been reared on milk replacer-based formulas, as well as on whipping-cream base extended with ground molluscs (clams) rather than fish. They also seem to tolerate carbohydrates reasonably well. Walruses have a much longer nursing period than other pinnipeds.

Neonatal cetaceans have longer nursing periods than pinnipeds. Success at bottle rearing has improved with experience, and individuals from species ranging from common dolphins (*Delphinus delphis*) to gray whales (*Eschrichtius robustus*) have been reared successfully. The fat content of cetacean milks varies considerably; bottlenose dolphin (*Tursiops* spp) milk is ~17% fat (half that of most pinniped milks); beluga whale (*Delphinapterus leucas*) milk, 27%; harbour porpoise (*Phocoena phocoena*) milk, 46%; and mysticete blue whale (*Baleanoptera musculus*) milk, 42%. Formulas based on commercial component milk replacers supplemented with ground fish and oils have been fed successfully to bottlenose dolphins and harbour porpoises using a lamb's nipple or stomach tubing.

Neonatal sirenians begin to nibble sea grasses shortly after birth but may continue to nurse up to 18 mo. They can be reared on artificial milks with early weaning. Neonatal sea otters also have been reared successfully from birth on artificial formulas. Neonatal polar bears are extremely altricial and are a challenge because of an apparently immature immune system. Polar bear milk is high in fat (31%) and contains minimal lactose. Polar bears have been successfully reared on formulas with a whipping-cream or oil base.

Thiamine Deficiency: This can be seen in any piscivorous animal. Thiamine in the food is destroyed by the activity of thiaminase enzymes or antithiamine substances in the fish being fed. These active enzymes can also destroy supplemental thiamine placed in fish if the fish sits for long periods before feeding. Clinical signs of thiamine deficiency are primarily of CNS disturbances. Affected animals may show anorexia, regurgitation, or ataxia. The condition can progress to seizures, coma, and death.

Animals with signs of thiamine deficiency respond rapidly to IM injection of thiamine

hydrochloride (up to 1 mg/kg body wt), followed by oral supplementation. Control usually involves supplemental thiamine at 25 mg/kg food, preferably administered 2 hr before a main feeding.

Vitamin E Deficiency (Steatitis, White Fat Disease): The antioxidant properties of vitamin E are believed to play an important role in maintaining the integrity of cellular membranes. Oxidative processes during the storage of fish destroy vitamin E and other antioxidants. Steatitis has been induced experimentally in phocid seals, and relationships between vitamin E deficiency and hyponatremia are suspected. Captive piscivores commonly are supplemented PO with vitamin E at a rate of as much as 100 mg/kg of feed, which generally maintains high serum levels of the vitamin. This does not appear necessary if feeder fish are properly stored and thawed.

Hyponatremia (Salt Deficiency, Addison Disease): Hyponatremia in pinnipeds is closely related to adrenal exhaustion and development of Addison disease, which links the syndrome to environmental stressors rather than to a simple primary salt deficiency. It is most common in pinnipeds maintained in freshwater exhibits but can be seen in animals kept in saltwater. It is more common in phocid seals but occurs in otariids and other marine mammals. Signs include periodic weakness, anorexia, lethargy, incoordination, tremor, and convulsions. Serum sodium levels can fall to <140 mEq/L. Severely affected animals may collapse in an Addisonian crisis, which can be fatal.

Emergency therapy consists of sodium chloride infusion and replacement corticosteroids. Longterm management of advanced cases requires mineralocorticoid supplementation in conjunction with oral sodium chloride supplements and periodic monitoring of serum sodium levels. Provision of saltwater pools and supplementation of sodium chloride (3 g/kg food) in the diet of captive pinnipeds maintained in freshwater pools should be considered a poor second choice. Animals on salt supplementation should have continuous access to freshwater.

Histamine Toxicity (Scombroid Poisoning, Mackerel Poisoning): Scombroid fish (mackerel, tuna) and other dark-fleshed fish have a short shelf life, even when frozen at low temperatures. A complex of substances, including histamine formed

by bacterial decarboxylation of the large amount of histidine found in the flesh of the fish, is responsible for the signs seen in affected marine mammals. The toxicity can also occur with nonscombroid fishes, including poorly handled herring, anchovies, or pilchard. It is most common in pinnipeds but is seen in other marine mammals. Clinical signs include anorexia; lethargy; a red, inflamed mouth or throat; and conjunctivitis and increased lacrimation. Occasionally, vomiting, diarrhea, pruritus, urticaria, or postures indicative of abdominal pain are seen. Antihistamines, including cimetidine, may provide symptomatic relief, but the condition is generally self-limiting, and the animal begins feeding within 2–3 days. In more severe or acute cases, epinephrine is effective in counteracting the histamine reaction. Cortisone and diphenhydramine hydrochloride can be beneficial in the face of respiratory difficulty. Control consists of avoiding scombroid fish in the diet or paying careful attention to their quality, storage, and handling when used.

BACTERIAL DISEASES

Actinomycetes: Nocardiosis (*see p 666*) is commonly reported in debilitated marine mammals. Several species of *Nocardia* have been described from both captive and free-ranging marine mammals of many species, both pinniped and cetacean. Diagnosis is usually postmortem, and most affected animals present with a systemic form of disease. Infections due to *Actinomyces* or *Arcanobacterium* spp are receiving considerable attention and have also been diagnosed in many marine mammal species. *Arcanobacterium phocae* has been implicated in pathology in stranded California sea lion, common dolphin, gray seal, harbor seal, northern elephant seal, and sea otter. *Arcanobacterium animailium* has been isolated from harbour porpoise. To date, most cases are diagnosed postmortem, but the infection may be underreported.

Brucellosis: Since the 1990s, previously unknown strains of *Brucella* have been found in free-ranging pinnipeds and cetaceans from many countries. Two species have been classified: *B ceti* (cetaceans) and *B pinnipedialis* (seals). There appears to be host preferences.

Pathologic findings include placentitis, orchitis, abortion, mastitis, pneumonia, subcutaneous lesions, arthritis, meningoen-

cephalitis, and hepatic and splenic necrosis. Transmission may be horizontal and vertical.

The bacteria possess the same surface antigens commonly used for diagnosis in livestock. The prevalences of marine mammal brucellosis are not known, but cases appear to be widespread. The role of environmental factors in the emergence of marine mammal disease is unknown.

There is some evidence of potential for zoonotic infections, and there have been a few cases of human infections from marine mammals in those with contact with tissues. In one case, the cultured organism from the blood of a laboratory worker matched a marine mammal strain she was working with. Three other human cases in which marine mammal-associated *Brucella* strains were isolated had no documented contact with marine mammals but histories of eating raw shellfish or fish and contact with raw fish bait.

Clostridial Myositis: Severe myositis due to infections with *Clostridium* spp has been diagnosed in captive killer whales, pilot whales, bottlenose dolphins, California sea lions, and manatees. All marine mammals are probably susceptible. The disease is characterized by acute swelling, muscle necrosis, and accumulations of gas in affected tissues, accompanied by a severe leukocytosis. Untreated, it can be fatal. Diagnosis is based on detection of gram-positive bacilli in aspirates of the lesions and is confirmed by anaerobic culture and identification of the organism. Treatment includes systemic and local antibiotics, surgical drainage of abscessed areas, and flushing with hydrogen peroxide. Commercially available inactivated clostridial bacterins are used routinely in some facilities, although efficacy in marine mammals has not been studied. Botulism has been reported in captive California sea lions during an endemic outbreak of the disease in waterfowl. Affected animals stopped eating and appeared unable to swallow several days before dying.

Pneumonia: The chief cause of death in captive marine mammals (other than polar bears) is believed to be pneumonia. Most cases of marine mammal pneumonia have significant bacterial involvement, and most organisms cultured from terrestrial species have been identified in marine mammals. Pneumonia often can be considered the result of mismanagement, although even in carefully managed captive animals pneumonia-associated mortality is

common. Marine mammals require good air quality, including high rates of air exchange at the water surface in indoor facilities. Tempered air or acclimation to cold temperatures is also important to prevent lung disease, even in polar species. Animals acclimated to cold temperatures are usually quite hardy; however, sudden transition from warm environments to cold air, even with warmer water, can precipitate fulminating pneumonias, particularly in nutritionally or otherwise compromised animals. Clinical signs include lethargy, anorexia, severe halitosis, dyspnea, pyrexia, and marked leukocytosis. The disease can progress rapidly. Diagnosis is usually based on clinical signs and confirmed by response to therapy, although bronchoscopy and fine-needle aspirates are being used more extensively to establish the cause of pneumonic disease in marine mammals. Treatment consists of correction of environmental factors and appropriate intensive antibiotic and supportive therapy.

Erysipelas (Diamond Skin Disease):

Erysipelas can be a serious infectious disease of captive cetaceans and pinnipeds and has been recognized in wild harbour porpoises, bottlenose dolphins, and harbor seals. The organism, *Erysipelothrix rhusiopathiae*, which causes erysipelas in pigs and other domestic species, is a common contaminant of fish. A septicemic form of the disease in marine mammals can be peracute or acute; affected animals die suddenly either with no prodromal signs or with sudden depression, inappetence, or fever. A cutaneous form that causes typical rhomboidal skin lesions is a more chronic form of the disease. Animals with this form usually recover with timely antibiotic treatment.

Necropsy of peracute cases generally fails to reveal grossly discernible lesions other than widespread petechiation. Diagnosis is based on culture of the organism from the blood, spleen, or body cavities. Arthritis has been found in animals that have died with the chronic form.

Treatment of the peracute and acute forms has rarely been attempted, because the absence of prodromal signs obscures the diagnosis. Animals with the dermatologic form usually recover with administration of penicillins, tetracyclines, or chloramphenicol and supportive treatment.

Control seems primarily related to provision of high-quality fish that is properly stored and handled. Vaccination is contro-

versial, and vaccine breaks can occur. Vials of killed erysipelas bacterin should be cultured for surviving organisms before use in marine mammals. Modified-live bacterins should be avoided for the initial vaccination. Fatal anaphylaxis can occur on revaccination. For this reason, some vaccination programs have been reduced to one-time administration even though antibody titers fall below the presumed effective level.

If cetaceans are to be revaccinated, sensitivity tests should be performed by injecting a small amount of bacterin submucosally on the lower surface of the tongue. Hypersensitive animals develop swelling and redness at the injection site within 30 min. Because the vaccine is extremely irritating, no more than 3–5 mL should be used at any one site, even in nonsensitive mammals. A long needle (≥ 2 in. [5 cm]) should be used to assure that the vaccine is deposited in the muscle and not between muscle and blubber, or a sterile abscess can result. Bacterin should be administered in the dorsal musculature anterior and lateral to the dorsal fin. Administration posterior to the dorsal fin can result in a severe tissue reaction, immobilizing the animal for several days. To maintain high antibody titers, a booster after 6 mo and annual revaccination are required.

Leptospirosis: This has been diagnosed in otarid pinnipeds and bears. In seals, the disease is characterized by depression, reluctance to move, polydipsia, and pyrexia. It may also cause abortions and neonatal deaths in California sea lions and Northern fur seals. Lesions include a severe, diffuse, interstitial nephritis, with renal tubules packed with spirochetes. The gallbladder may contain inspissated black bile, but hepatitis may not be apparent grossly. Hyperplasia of Kupffer cells, erythrophagocytosis, and hemosiderosis are seen histologically. Gastroenteritis can be a feature. Antibodies to various *Leptospira* serovars (including *L. Canicola*, *L. Icterohaemorrhagiae*, *L. Autumnalis*, and *L. Pomona*) have been identified in many species, including sea otters and manatee. Treatment in pinnipeds is similar to that in dogs (see p 650). Control in captive animals requires serologic examination of new animals during quarantine. Captive animals can be vaccinated in endemic areas. Leptospirosis is zoonotic, and appropriate precautions should be taken.

Streptothricosis (Dolphin Pseudopox, Cutaneous Dermatophilosis): Streptothricosis, a subcutaneous bacterial infection with *Dermatophilus congolensis*, has been reported in pinnipeds and polar bears. It must be distinguished from sealpox. Simultaneous infections of streptothricosis and pox have been recorded in sea lions. Cutaneous streptothricosis usually manifests as sharply delineated nodules distributed over the entire body and usually progresses to death. Diagnosis is based on demonstration of the organism in biopsies or culture. Treatment with prolonged high dosages of systemic antibiotics can be successful.

Sporothrix schenckii, the cause of a subcutaneous mycosis, has been reported in Pacific white-sided dolphins (*Laegenorhynchus obliquidens*).

Mycobacteriosis: Marine mammals are susceptible to various mycobacteria. Evidence points to mycobacterial disease being possibly endemic in free-ranging otarids off the coast of Australia. Originally thought to be caused by *Mycobacterium bovis*, subsequent molecular assessment places the isolates from free-ranging southern hemisphere pinnipeds in a unique cluster assigned its own species in the *M tuberculosis* complex. Subantarctic fur seals (*Arctocephalus tropicalis*) are thought to be the common link in the spread of *M pinnipedii* to other pinniped species because they cohabit with the other known affected species, Australian sea lions (*Neophoca cinerea*) and New Zealand fur seals (*Arctocephalus forsteri*). Otherwise, mycobacteriosis has been a disease of captivity. Pinnipeds, cetaceans, and sirenians have developed disease due to *M bovis*, *M smegmatis*, *M chitae*, *M fortuitum*, *M chelonae*, and *M marinum*. Cutaneous and systemic forms are seen. There are strong indications that immunosuppression may be involved in development of infections by the atypical mycobacteria.

Intradermal testing with high concentrations of bovine or avian purified protein derivative tuberculin can be used to screen exposed animals; however, anergy occurs and the usefulness is controversial. In pinnipeds, injections in the webbing of the rear flippers should be read at 48 and 72 hr. ELISA screening has identified antibodies in seals but requires further evaluation before it can be considered a screening test. Diagnosis is made by culture and identification of the organism from lesion biopsies, tracheal washes, or feces. Mycobacteriosis in marine mammals is an emerging disease

and is possibly of public health significance. (See also TUBERCULOSIS AND OTHER MYCOBACTERIAL INFECTIONS, p 687.)

Mycoplasmosis: *Mycoplasma* spp have been isolated from the teeth, wounds, and respiratory tracts of seals. They have been associated with respiratory disease historically but can be found in healthy animals. They are frequently cultured from animals concurrently infected with respiratory viruses.

Miscellaneous Bacterial Diseases:

Marine mammals are probably susceptible to the entire range of pathogenic bacteria. *Pasteurella multocida* has caused several outbreaks of hemorrhagic enteritis with depression and abdominal distress, leading to acute death in dolphins and pinnipeds. It has also been reported to cause pneumonia in pinnipeds. In dolphins, *Mannheimia haemolytica* has been incriminated in hemorrhagic tracheitis that responded to chloramphenicol therapy.

Plesiomonas shigelloides has been responsible for gastroenteritis in harbor seals. *Burkholderia pseudomallei* has caused serious fatal outbreaks of disease in various marine mammals in captivity in the Far East. *Salmonella* spp have caused fatal gastroenteritis in manatees and beluga whales. *Staphylococcal* septicemia has caused the death of a dolphin with osteomyelitis of the spine (pyogenic spondylitis). Another case of intradiscal osteomyelitis, due to *Staphylococcus aureus*, was treated successfully with a prolonged course of cefazolin sodium and cephalixin. *S. aureus* also has been incriminated in a fatal pneumonia in a killer whale. *Vibrio* spp infect slow-healing wounds of cetaceans managed in open sea pens.

MYCOTIC DISEASES

Captive marine mammals seem particularly prone to fungal infections (see p 632). Most appear to be secondary to stress, environmental compromise, or other infectious disease. Some systemic mycoses have distinct geographic distributions. Diagnosis is based on clinical signs and confirmed by identification of the organism in biopsy or, preferably, culture. Wet mounts in lactophenol or cotton blue may render an immediate diagnosis with some of the morphologically distinct fungi. Tissue smears cleared in warm 10% potassium hydroxide can be examined to identify characteristic fruiting bodies or hyphae.

Topical medication of pinnipeds for dermatophytosis is feasible. Smaller cetaceans can be kept out of water in a sling for 2–24 hr, if areas of the body not being treated are kept moist. Otherwise, systemic therapy is used.

Aspergillosis: Fatal pulmonary aspergillosis has been diagnosed in several species of cetaceans, including bottlenose dolphins and killer whales, and in several pinnipeds, including Antarctic fur seals (*Arctocephalus gazella*), harbor seals, and California sea lions. In addition to disseminated aspergillosis, case reports of aspergillomas of the inner ear have been reported in free-ranging harbour porpoise, and cutaneous aspergillosis has been seen in gray seals (*Halichoerus grypus*) with concomitant mycobacteriosis. The respiratory form has been a postmortem diagnosis. Cutaneous lesions have responded to topical povidone-iodine with ketoconazole therapy (10 mg/kg/day, PO).

Candidiasis: This common mycotic disease in captive cetaceans occurs secondary to stress, unbalanced water disinfection with chlorines, or indiscriminate antibiotic therapy. Candidiasis is also reported in pinnipeds and has been found in cultures of wild cetacean blow holes and stomachs. In clinical disease in cetaceans, the lesions usually are found around body orifices. At necropsy, esophageal ulcers are often found, particularly in the area of the gastroesophageal junction. In phocid pinnipeds, inflammation at the mucocutaneous junctions, particularly at the commissures of the mouth and around the eyes, anus, and vulva, is the common presentation. Diagnosis is based on identification of the yeast in cultures or biopsy. Candidiasis generally responds well to ketoconazole (6 mg/kg/day, PO) along with correction of any environmental deficits. Supplementation with prednisolone (0.01 mg/kg) may be appropriate to compensate for ketoconazole inhibition of glucocorticoid production. Fluconazole (2 mg/kg, bid) has also been used successfully. One anecdotal report suggests a possible toxic reaction to ketoconazole in a northern elephant seal (*Mirounga angustirostris*). Early detection and treatment is usually successful. Another opportunistic yeast, *Cryptococcus neoformans*, has been diagnosed in fatal advanced pulmonary disease in a bottlenose dolphin. Prolonged treatment with itraconazole (120 days) at routine mammalian doses was

ineffective despite serum drug levels above the suggested therapeutic range.

Dermatophytosis: Mycotic dermatitis due to *Trichophyton* spp or *Microsporum canis* generally responds to topical povidone-iodine, oral griseofulvin, or both.

Lobomycosis: This disfiguring cutaneous disease is caused by infection with *Lacazia loboi*. The disease has been reported only in people and in Atlantic bottlenose *Sotalia* (*Sotalia fluviatilis*) dolphins. Culture of the organism has not been possible. Excisional therapy and systemic antifungal drugs have been used with varying success. Zoonotic transmission is strongly suspected in a case of a European handler of an infected dolphin. Most human cases have no history of marine mammal contact. Differential diagnoses include sporotrichosis, chromomycosis, paracoccidioidomycosis, and other fungal diseases characterized by extensive granuloma formation.

Systemic Mycoses: The systemic mycoses of marine mammals are a zoonotic risk, and precautions should be taken to prevent infection when handling dead and diseased animals. Cystofilobasidiales has caused fatal disease in a California sea lion. Blastomycosis has caused fatal disease in bottlenose dolphins, California sea lions, a Stellar sea lion (*Eumetopias jubatus*), Northern fur seals, and polar bears. Fatal systemic histoplasmosis has been reported in a captive harp seal (*Pagophilus groenlandicus*), a bottlenose dolphin, and a Pacific white-sided dolphin. Coccidioidomycosis has been found in bottlenose dolphins, California sea lions, and sea otters. Blastomycosis has been successfully treated with intensive management, including 70 days of itraconazole (3.5 mg/kg/day, PO) combined with antibiotic and supportive therapy when indicated.

Zygomycetes: Dermatologic conditions caused by various *Fusarium* spp have been reported in pygmy sperm whales (*Kogia breviceps*), Atlantic white-sided dolphins (*Laegenorhynchus acutus*), harbor seals, gray seals, California sea lions, and northern elephant seals. Diagnosis is based on culture or organism identification from biopsy. Cases have responded to ketoconazole (5 mg/kg/day for 10 days), fluconazole (0.5 mg/kg, bid for 21 days), or itraconazole (1 mg/kg/day for 120 days).

Mucor spp and *Entomophthora* spp have caused fatal disease in bottlenose dolphins, harbour porpoises, and harp seals. Other zygomycetes have been diagnosed as a cause of fatal disseminated disease in various species of marine mammals.

Localized fusariomycosis has been successfully treated in a captive beluga whale (*Delphinapterus leucas*) using voriconazole after surgical debridement. These infections should be considered diseases of debilitated animals; the underlying cause of the low host resistance to these opportunistic infections must be corrected if therapy is to be successful. Amphotericin B has been the therapy of choice for zygomycete infections, but newer imidazoles warrant consideration and may have clinical efficacy despite laboratory tests of resistance.

PARASITIC DISEASES

Marine mammals are susceptible to all of the major groups of parasites, including various nematodes, trematodes, cestodes, mites, lice, and acanthocephalans. Clinical experience with many of these is limited, whereas others are commonly seen in recently captured specimens.

Acanthocephalans: Cetaceans are the primary host of *Bolbosoma* spp but can be infested with parasites of the genus *Corynosoma*, which have pinnipeds and sea otters as primary hosts. *Bolbosoma* spp have been reported in pinnipeds. *C. enhydra* has only been reported from sea otters. Diagnosis is by detection of eggs in feces, but clinical disease and therapy are not well documented. Three species of *Profilicollis* (also found in birds) are reported to cause peritonitis associated with intestinal perforation in sea otters. Mortality usually occurs before the parasite produces ova. Premortem diagnosis is problematic. No successful treatment has been reported.

Acariasis: Nasal and lung mites are found in phocid and otarid seals. Lung mites cause rattling coughs. Nasal mites cause nasal discharge but apparently little discomfort. Diagnosis is made by identifying the mite in nasal secretions or sputum. The life cycles of these mites are not completely known. Infections have been cleared rapidly with two injections of ivermectin at 200 mcg/kg, 2 wk apart. Treatment of infected animals eliminates the problem in captive enclosures without environmental treatment.

Mites have been associated with large, roughened lesions of the laryngeal area of cetaceans, but their overall significance or treatment is unknown.

Demodectic mange has been diagnosed in California sea lions. Nonpruritic, alopecic lesions with hyperkeratosis, scaling, and excoriation develop on the flippers and other body surfaces that contact the substrate. Diagnosis is made by deep skin scrapings and identification of the mite. Secondary bacterial infection that results in pyoderma is seen in chronic cases. Treatment is the same as in dogs (see p 920). Predisposing factors in pinnipeds are unknown. The mites are not readily transmitted among contact animals.

Heavy infestations of sucking lice are common in wild pinnipeds and can cause severe anemia. The lice can be seen grossly and are readily transmitted. They are highly sensitive to ivermectin as well as to chlorinated hydrocarbon insecticides. Rotenone powder is also effective. The affected animal must be removed from the water, allowed to dry before being dusted, and kept out of the water for ≥ 12 hr. Treatments must be repeated in 10–12 days. Animals in captivity can be freed of parasites if no new sources of infestation are introduced.

Lungworm: Lungworms are common in all pinnipeds. Sea lions have *Parafilaroides decorus*, whereas true seals are usually parasitized by *Ostrostrongylus circumlitus*. The latter parasite is also found in the hearts of some phocids; however, it does not produce a microfilaremia. Both of these parasites use fish as intermediate hosts. There are at least four species of lungworms in various cetacean hosts, including *Halocercus lagenorhynchi*, which has caused prenatal infections in Atlantic bottlenose dolphins.

Lungworm infection can be diagnosed by examination of feces or bronchial mucus. Anorexia, coughing, and sometimes blood-flecked mucus are the first signs of pulmonary parasitism. Treatment of *P. decorus* infection consists of mucolytic agents administered intratracheally, antibiotics to treat any concomitant bacterial pneumonia, ivermectin, and concurrent prednisone or dexamethasone. Diagnosis of *O. circumlitus* in elephant seals is complicated by mortality occurring after generalized clinical signs of depression, dehydration, and neutrophilia before the parasites become patent and first-stage larvae can be detected in sputum or feces.

Some treatment success has been reported using intratracheal administration of levamisole phosphate (5 mg/kg/day for 5 days); however, combined therapy with ivermectin and fenbendazole given 3 days after initiation of the therapy with dexamethasone, antibiotics, and mucolytic agents may be more effective. Cetacean lungworms probably are also susceptible to levamisole and ivermectin; however, the sudden deaths of two beluga whales injected IM with levamisole phosphate suggest this drug administered by that route may be contraindicated. A percentage of pinnipeds also show neurologic reactions to IM injection of levamisole; PO or SC administration has been recommended.

Lungworm infections often remain asymptomatic for long periods, with clinical signs appearing only when an animal becomes debilitated for other reasons. In captivity, lungworm infections are usually self-limiting if larvae are not introduced in fresh fish intermediate hosts. Feeding frozen fish prevents reinfection.

Heartworm: Heartworms of the genus *Acanthocheilonema* are a common necropsy finding in pinnipeds. Phocid seals are affected by *A. spirocauda*, and otarids are infected subcutaneously by *A. odendhali*. Transmission of *A. spirocauda* is thought to be by the seal louse (*Echinophthirus horridus*). Both groups of pinnipeds can be infected with the canine heartworm, *Dirofilaria immitis*, in endemic areas; however, phocid seals are abnormal hosts. Dirofilariasis is diagnosed by identifying microfilariae in the blood. Transmission is thought to be by the same mosquitoes that bite dogs. A graded regimen of levamisole phosphate progressing to a high dosage (40 mg/kg/day for 1 wk) has successfully cleared infection in captive pinnipeds, with

the advantage of oral administration. Prevention in endemic areas has been successful with oral administration of ivermectin (canine dosages) monthly or diethylcarbamazine (3.3 mg/kg) weekly in food during the mosquito season (see also p 127).

Other Nematodes: The Anasakidae are pathogenic nematodes found in the stomach of marine mammals. Granulomas form at their attachment sites and can lead to blood loss, ulceration, and ultimately perforation and peritonitis. Raw fish is most often incriminated as the source of infection. Infections with *Contracaecum* spp are common in wild cetaceans and pinnipeds. Polar bears in captivity are prone to heavy ascarid infection. Gastric nematodes can be successfully treated with oral dichlorvos (30 mg/kg), fenbendazole (11 mg/kg), or mebendazole (9 mg/kg) given twice, 10 days apart. Ivermectin may be considered.

Hookworms (*Uncinaria* spp) are found in pinnipeds. Severe infections are known in fur seals. Newborn fur seal pups are infected via colostrum. Disophenol (12.5 mg/kg) or ivermectin (100 mcg/kg) injected SC have been effective against these parasites.

Many species of a large spirurid nematode (*Crassicauda* spp) infect the cranial sinuses, major vessels, kidneys, and mammary gland ducts of cetaceans. Successful treatments are not documented but are potentially possible with systemic parasiticides. The dual intermediate host requirement of these species in captivity usually means these infections are self-limiting.

Cestodiasis: *Diphyllobothrium pacificum* is commonly found in sea lions, and heavy infection is thought to cause intestinal obstruction. Praziquantel (10 mg/kg) is an effective treatment. Other cestodes commonly seen include *D. lanceolatum* in phocid seals, *Diplogonoporus tetraapterous* in all pinnipeds, and *Tetrabothrium forsteri* and *Strobilocephalus triangularis* in cetaceans. Cetaceans are also commonly infected with subcutaneous tapeworm cysts throughout the blubber. These usually are the larval forms of tapeworms of sharks. Several species of cestodes are reported in sea otters and polar bears but are not known to have clinical significance.

Trematodiasis: Fluke infections are common in pinnipeds and cetaceans; *Nasitrema* spp are found in the nasal passages and sinuses of cetaceans. Ova

Acanthocheilonema microfilariae. Courtesy of Dr. James McBain.

of these trematodes have been associated with necrotic foci in the brains of animals showing behavioral aberrations and have been incriminated as a cause of localized pneumonia in cetaceans. Infections are often accompanied by halitosis and brown mucus around the blowhole and occasionally by coughing. Diagnosis is based on demonstration of typical operculated trematode ova in blowhole swabs or feces. Oral praziquantel (10 mg/kg, two treatments 1 wk apart) is usually effective. Reinfection can be prevented by not feeding fresh or live fish.

Zalophotrema hepaticum is an important hepatic trematode of California sea lions; it causes biliary hypertrophy and fibrosis of the liver. Signs are usually seen in adults and include icterus, lethargy, and anorexia. Bilirubinemia and increased serum hepatic enzymes are common. Diagnosis is based on identification of trematode ova in the feces. Treatment with praziquantel (10 mg/kg) or with bithional (20 mg/kg) has been successful.

Various other trematodes infect the stomach, intestines, liver, pancreas, and other abdominal organs of marine mammals. Pancreatic fibrosis due to trematodiasis is a common necropsy finding.

Coccidiosis: Coccidia (*Eimeria phocae*) have been found in harbor seals with a fatal, bloody diarrhea. Clinical disease with this parasite is thought to be rare unless the host is stressed through capture, handling, or husbandry changes. At least two new species of intestinal coccidia have been identified in California sea lions. A coccidian, *Cystoisospora delphini*, has been reported as the cause of enteritis in bottlenose dolphins; however, some consider the parasite to have been a fish coccidia not associated with the disease. *E. trichechi* reported from the Amazonian manatee (*Trichechus inunguis*), and *E. nodulosa* reported from the Florida manatee, are also not associated with disease. These coccidia are probably susceptible to anticoccidial drugs used against other species, eg, amprolium. (See also p 203.)

Sarcocystis: *Sarcocystis neurona* is found in high prevalence in the California population of sea otters. Infection can be asymptomatic or cause severe encephalitis characterized by generalized neurologic signs. No successful treatment of neurologic cases has been reported. *Sarcocystis* spp have been found in the muscles of many

cetacean, otarid, and phocid species and are often not associated with any recognized clinical signs. Successful treatment has been reported in an adult California sea lion with myositis using ponazuril (10 mg/kg/day, P●) for 28 days and prednisolone in the first 5 days of therapy.

Toxoplasmosis: *Toxoplasma gondii* is known to infect the California population of sea otters, causing disease that ranges from asymptomatic infection to severe encephalitis. Fatal meningoencephalitis due to *T. gondii* has also been reported in a Florida manatee and disseminated disease in Antillean manatees. *Toxoplasma* spp encephalitis is also reported in harbor seals and Northern fur seals. Disseminated toxoplasmosis is reported in California sea lions. *T. gondii* is reported from Atlantic bottlenose, Risso's (*Grampus griseus*), striped (*Stenella coeruleoalba*), and spinner dolphins, and serologic evidence of toxoplasmosis is being discovered in an ever-widening array of marine mammal hosts, including polar bears. No successful treatment has been reported. Transplacental transmission has been reported in a Risso's dolphin.

VIRAL DISEASES

Adenovirus: Adenovirus has been isolated from a sei whale (*Balaenoptera borealis*), beluga whale, and bowhead whales (*Balaena mysticetus*). A novel otarine adenovirus 1 has been isolated from California sea lions affected with hepatic disease, and adenovirus particles have been reported in walrus and fur seals. Fatal disease associated with adenovirus infection has been reported in California sea lions, South African fur seals, and South American sea lions. No disease was noted in the cetaceans.

The most prominent histologic lesion in all cases was hepatic necrosis. Massive coagulation necrosis without apparent zonal distribution was seen in some animals. Basophilic intranuclear inclusions in hepatocytes or granular amphophilic intranuclear inclusions in Kupffer cells were seen. No evidence of adenovirus was detected in the lungs. Adenovirus from California sea lions is not known to cause disease in people.

Caliciviruses (San Miguel Sea Lion Virus): Caliciviruses have been isolated from otarid seals, walrus, Atlantic bottlenose dolphins, and opaleye fish

(*Girella nigricans*). The marine caliciviruses appear to be serotypes of vesicular exanthema of swine virus (VESV, *see* p 738). Several species of mysticete cetaceans have antibodies to different serotypes of VESV. By 4 mo of age, most California sea lions have neutralizing antibodies to one or more of the serotypes. Opaleye fish are probably responsible for the endemic status of caliciviruses in marine mammals that inhabit the coastal waters of California. To date, infections have not been diagnosed in marine mammals in the Atlantic Ocean.

The most consistent lesion in marine mammals is skin vesicles. In pinnipeds, the vesicles are most prevalent on the dorsal surfaces of the fore flippers. In dolphins, vesicular lesions have been seen in association with "tattoo" lesions and old scars. Vesicles are 1 mm to 3 cm in diameter. They usually erode and leave shallow, fast-healing ulcers, but occasionally vesicles regress and leave plaque-like lesions. Treatment is supportive only; skin lesions usually resolve without treatment. Infection may cause premature parturition in pinnipeds. Affected pups have interstitial pneumonitis and encephalitis and fail to thrive.

Inoculation of marine caliciviruses into pigs causes vesicular lesions identical to those seen in vesicular exanthema. In people, heavy exposure to marine caliciviruses can result in neutralizing antibodies. Localized lesions in an accidental laboratory exposure as well as isolation of calicivirus from a clinically ill primate indicate that these viruses should be handled carefully.

Herpesvirus: Herpesviruses isolated from pinnipeds include phocid herpesvirus 1 (PhHV-1), an alpha herpesvirus, and four gamma herpesviruses, phocid herpesvirus 2 (PhHV-2), Hawaiian monk seal herpesvirus, Otariid herpesvirus 1, and Northern elephant seal herpesvirus. Herpesviruses have been identified in a wide range of cetaceans, some associated with encephalitis and others with various skin lesions.

Young harbor seals from Atlantic waters infected with PhHV-1 develop nasal discharge, inflammation of the oral mucosa, vomiting, diarrhea, and fever, followed by coughing, pneumonia, anorexia, and lethargy that can result in death in 1–6 days. Morbidity can approach 100% in stressed seals in crowded conditions; mortality is ~50%. The incubation period appears to be 10–14 days. Pacific harbor seals with PhHV-1 tend to develop signs related to adrenal and hepatic dysfunction.

PhHV-2 has been associated with recurring circumscribed areas of alopecia ~0.5 cm in diameter in gray seals. Herpetic lesions in beluga whales are generally circular, as much as 2 cm in diameter, and may appear slightly depressed with a target appearance or be raised and proliferative. The centers of some lesions are necrotic or may contain verrucous growths. Systemic infections have not been documented in the cetaceans.

Diagnosis is often made at necropsy or by clinical signs and observation of characteristic intranuclear inclusion bodies in biopsies of early skin lesions. In seals, interstitial pneumonia caused by herpesvirus must be distinguished from bronchial pneumonia caused by influenza virus.

In systemic herpesvirus infection, therapy is supportive. In a documented epidemic, oral acyclovir did not eliminate the infection but appeared to significantly shorten clinical signs in primary infections. Vaccination with 1 mL of trivalent poliovirus vaccine to control recrudescence of suspected herpesvirus lesions has been used with some success; although it reduced the severity of recrudescence in seals, there is a potential public health risk because live poliovirus may be shed after vaccination. Stress and immunosuppression are associated with recrudescence of latent infections. There is no evidence that the herpesviruses of pinnipeds or cetaceans are zoonotic.

Influenza Virus: Four different influenza A viruses have been isolated from harbor seals and two other subtypes from a stranded pilot whale. H1N1 has been isolated from a northern elephant seal. Serologic evidence of exposure to influenza virus exists for a wide range of marine mammals. Infection is probably common. Only nonspecific clinical signs were reported in the stranded pilot whale, which had difficulty maneuvering, was emaciated, and was sloughing skin. Disease due to influenza virus in seals is better characterized. Even well-fed captive animals become weak, incoordinated, and dyspneic. Swollen necks due to fascial trapping of air escaping through the thoracic inlet is reported. Occasionally, white or bloody nasal discharge is evident. The incubation period during epidemics in harbor seals is ≤ 3 days. Many factors probably contribute to the explosive nature of the reported epidemics. High population densities and unseasonably warm temperatures contribute to high mortality.

In harbor seals, influenza pneumonia is characterized by necrotizing bronchitis and bronchiolitis and hemorrhagic alveolitis. In the pilot whale, the lungs were hemorrhagic and a hilar node was greatly enlarged. For differential diagnosis, see *HERPESVIRUS*, above.

The virulence of epidemics has precluded attempts at intensive supportive care. People whose eyes were contaminated while doing necropsies, or by being sneezed on by affected seals, have developed keratoconjunctivitis within 2–3 days, and identical virus has been recovered. All affected people have recovered completely within 7 days without developing any antibody titers, which suggests that the reaction is local, as occurs with Newcastle disease virus.

Morbillivirus: Phocid seals are susceptible to canine distemper virus (see p 777) and to a closely related but distinct morbillivirus (phocine distemper virus [PDV]). Generally, young seals are affected and show depression, anorexia, crusting conjunctivitis, nasal discharge, and dyspnea. Pneumonia develops, and mortality can be high in previously unexposed animals. Outbreaks in wild harbor seals have been extensive in the North Sea. Seals vaccinated with canine distemper vaccine have been rendered immune to challenge with the virus (suspension of organ material) obtained from dead wild seals.

A delphinoid distemper virus (cetacean morbillivirus [CMV]), closely related to rinderpest (see p 771) and peste des petits ruminants (see p 766), has been implicated in the deaths of harbour porpoises and common dolphins off the coast of the UK, striped dolphins in the Mediterranean, and bottlenose dolphins in the western Atlantic and Gulf of Mexico. Pilot whale calves, white-beaked dolphins (*Laegorhynchus albirostris*), harp seals, hooded seals (*Cystophora cristata*), and Mediterranean monk seals (*Monachus monachus*) have been affected by PDV and/or CMV infections. In the wild, harp seals and pilot whales have been incriminated as apparent reservoirs of PDV and CMV, respectively.

Therapy is supportive. Mortality in naive populations is high, often due to secondary infections facilitated by the immunosuppressive impact of active morbillivirus infection. Vaccination with a subunit vaccine is practiced in European rescue centers and appears to be protective, but this approach has not been applied in North

America, in large part due to lack of availability of the appropriate vaccine.

Poxvirus: Poxvirus has been identified morphologically in skin lesions of both captive and free-ranging pinnipeds and cetaceans of a wide range of species. Lesions in California sea lions, harbor seals, and gray seals are probably due to parapoxviruses; lesions in South American sea lions (*Otaria byronia*) and Northern fur seals are probably not. An orthopox virus has been isolated from pox-like lesions on a gray seal. Poxvirus has also been associated with skin lesions in Atlantic bottlenose dolphins, Atlantic white-sided dolphins, killer whales, dusky dolphins, long-beaked common dolphins (*Delphinus capensis*), Hector's dolphins (*Cephalorhynchus hectori*), and Burmeister's porpoises (*Phocoena spinipinnis*), among others.

Outbreaks typically occur in postweanling pinnipeds recently introduced into captivity. The incubation period is 3–5 wk. A break in the epithelial surface may be required to start an infection. Lesions can recur. Small, cutaneous, raised nodules (0.5–1 cm in diameter) occur on the head, neck, and flippers of affected pinnipeds. These may increase to 1.5–3 cm in diameter during the first week and may ulcerate or develop satellite lesions during the second week. After the fourth week, lesions begin to regress, although nodules are reported to persist as long as 15–18 wk. Areas of alopecia and scar tissue may remain after resolution.

Cutaneous poxvirus infections in cetaceans can develop on any part of the body, but lesions are most common on the head, pectoral flippers, dorsal fin, and tail fluke. They range from ring or pinhole lesions to black, punctiform, stippled patterns ("tattoo" lesions). Ring or pinhole lesions appear as solitary, 0.5–3 cm, round or elliptical blemishes, which sometimes coalesce. They are usually light gray and may have a dark gray border, although the reverse color pattern is also seen. Lesions may persist for months or years without apparent ill effects.

Major differential diagnoses include cutaneous streptothricosis and calicivirus. Diagnosis is based on the presence of eosinophilic, intracytoplasmic inclusion bodies in lesion biopsies and is confirmed by identification of typical poxvirus particles by electron microscopy.

Poxviruses of marine mammals do not appear to cause systemic infections. Although animals with cutaneous poxvirus lesions have died, other factors were

responsible. Therapy to control secondary bacterial infections is indicated only when skin lesions suppurate. The parapoxviruses of pinnipeds can cause isolated lesions on the hands of people not wearing gloves during contact with infected animals.

Miscellaneous Viral Diseases: A ringed seal (*Phoca hispida*) in Norway was diagnosed with rabies, which was confirmed by immunofluorescent examination of the brain. At the time, there was an epidemic of rabies in foxes in the area. Other rhabdoviruses isolated from cetaceans, which are not recognized by antisera to representatives of the *Lyssavirus*, *Ephemerovirus*, or *Vesiculovirus* genera, may be related to rhabdoviruses of fish.

Papillomavirus infections have been reported in a wide range of cetaceans, including narwhals (*Monodon monoceros*) and several species of mysticete whale. Lesions are typical of those found in terrestrial species. No therapy is known. Lesions are usually self-limiting.

Hepadnavirus infection with a hepatitis B-like agent has been documented in a Pacific white-sided dolphin with a long history of recurrent illness in captivity. No evidence of zoonotic transmission was identified.

Endogenous gamma retroviruses have been identified in the genome of killer whale, bottlenose dolphin, Atlantic white-sided dolphin, long-finned pilot whale, striped dolphin, short-beaked

common dolphin, Risso's dolphin, harbour porpoise, and white-beaked dolphin. The only retrovirus cultured and characterized to date in a marine mammal was a spumavirus isolated from recurring skin lesions in a California sea lion that subsequently died of *Pasteurella* pneumonia complicated with herpesvirus.

Coronavirus infections have been associated with pneumonia epizootics in wild Pacific harbor seals. A coronavirus has also been identified in a beluga whale.

An enterovirus of unknown pathogenicity isolated from a rectal swab of a California gray whale has been reclassified as a calicivirus. Antibodies, unassociated with disease, against human influenza virus (after challenge) and poliomyelitis virus were found in bottlenose dolphins. Enterovirus has been found associated with tongue lesions in bottlenose dolphins.

Severe enteritis and vomiting that rapidly led to death in a captive beluga whale were suggestive of parvovirus enteritis, but no virus was isolated.

NEOPLASTIC DISEASES

Tumors in marine mammals are infrequent, although a wide variety has been reported. They are of little consequence except for malignant lymphoma in harbor seals, in which horizontal transmission can occur in a closed population, and transmissible venereal tumor of California sea lions.

MINK

MANAGEMENT

Mink (*Mustela vison*) are housed individually in raised, wire mesh pens. A nest box with a hole for entry is attached outside or placed within the pen. Wood used for the nest box should not be painted or treated with wood preservatives. Soft, awn-free marsh hay, clean straw, untreated dry wood shavings, or fine wood-wool make suitable nest material. Nest boxes should be cleaned and nest material replaced as required, especially before whelping. Sheds are used throughout the year and should admit natural daylight. There should be plenty of

air circulation and shade in the warmer months.

Mink feed may be supplied as a wet gruel placed on top of the wire mesh or as a commercially prepared, dry, pelleted ration placed in feed hoppers. During the weaning and postweaning periods, food is supplied on feeding trays or placed on an adjustable wire nest box cover for small kits that cannot reach the top of the pen. Fresh water should always be available. Watering cups fastened to the outside of the pen with a lip protruding inside are used. Automatic, heated, recirculating watering systems with individual nipples are most commonly used in sheds.

Cold storage facilities are necessary to freeze and store the meat portion of the ration. A day's supply of fish and meat by-products is thawed, commercial cereal and vitamins added, and the combined ration mixed with water to a consistency that will remain on the wire of the pen without dropping through. Ready-mixed feeds may be delivered daily, either ready to feed or in frozen blocks that are thawed as required. Dry pelleted diets are used on some ranches for part or all of the year.

Ranchers usually keep one male for each five female breeders. Mink are seasonal breeders, with reproductive activity controlled by increasing periods of daylight. Artificial lights in the sheds must be used with caution, because they may adversely affect photoperiod and interfere with the normal reproductive cycle. In the northern hemisphere, the breeding season begins in late February or early March and lasts ~4 wk. Mating should occur within 1 hr after the female is placed in the male's pen. If fighting ensues, they should be separated. Ovulation is induced by mating. Females mated before mid-March are usually mated again after 7–8 days, often with an additional mating the following day; thus, individual females may be mated two or three times. Ova from two matings have been known to develop in the same litter. Implantation of the fertilized ova is delayed, so the apparent gestation period is 40–75 days. The implantation period can be altered by using artificial light after breeding.

Mink have one annual litter of 1 to 12 kits (average 5). Most kits are born during the last week in April and the first 2 wk in May. Kits are blind, hairless, and weigh ~10 g when born but grow rapidly throughout the summer to reach a weight of ~1,200 g (females) or 2,600 g (males) by October. Kits are weaned at ~6–8 wk of age and may be separated shortly thereafter and housed in single pens. Adult mink are extremely agile, strong, and vicious. Handling requires the use of special leather gloves or wire catching cages.

Mink kits are vaccinated when at least 6–8 wk old with a 3-way vaccine containing *Pseudomonas* bacterin, botulism, and mink enteritis virus, and again when at least 10 wk old with a modified-live distemper vaccine. Breeders should be revaccinated in December or January before the breeding season.

Pelt collection usually is done in November or December. The most humane way to kill mink is with pure cooled carbon monoxide in cylinders. In the USA, mink farms are certified under the strict criteria

for the humane treatment of animals by the Fur Commission USA.

BACTERIAL DISEASES

Botulism: Botulism (see p 605) occasionally causes heavy losses in unvaccinated mink that consume feed containing type C toxin. Usually, many mink are found dead within 24 hr of exposure to the toxin, while others show varying degrees of paralysis and dyspnea. Necropsy findings are nonspecific and related to death from respiratory paralysis. Diagnosis is confirmed by inoculation of serum or filtered tissue from affected mink into mice. The immunotype of the botulism toxin is type C in almost all outbreaks.

Toxic feed should be removed and sampled for testing, and stored feed or ingredients tested for the toxin. Recovered mink are not immune to further challenge. Annual vaccination of kits (at 6–8 wk) and breeders with vaccines containing type C botulism toxoid, *Pseudomonas* bacterin, distemper, and mink virus enteritis vaccines is highly recommended.

Hemorrhagic Pneumonia: *Pseudomonas aeruginosa* may result in serious losses. Mink of all ages are affected, particularly during the stress of fall molt. Mink are usually found dead with no prodromal signs. A bloody nasal exudate may be seen at the time of death. Gross lesions include a severe hemorrhagic pneumonia with swelling and consolidation of one or more lung lobes. Treatment involves immediate vaccination of the entire herd. A *Pseudomonas* bacterin is included in the recommended 3-way vaccine (see above).

Escherichia coli has become the more common cause of hemorrhagic pneumonia in mink as a result of vaccination against *Pseudomonas*. Gross and clinical signs are indistinguishable from those of *Pseudomonas*. Bacterial culture is the only way to determine which pathogen is present. Exposure to *E. coli* most frequently comes from contaminated water, but it may also be feedborne. Underlying viral infections such as influenza, Aleutian disease, and distemper must be excluded. Antibiotic sensitivities are a must to assist with treatment selection, because sensitivity patterns for *E. coli* in mink vary greatly.

Urinary Infections and Urolithiasis:

Urinary tract infections, commonly called "plum bladders," cause serious losses in

females in late spring (during pregnancy and lactation) and in males in late summer and autumn (during the rapid growth and furring period). Several predisposing factors have been suggested, including contamination of food, cages, or nest boxes by pathogenic bacteria; decreased water intake; or increased ash intake.

Mink may die without showing signs, but a large, distended bladder can be palpated grossly, or they may have difficulty in urinating or dribble urine. Occasionally, hematuria may be seen. Necropsy findings include acute hemorrhagic cystitis or pyelonephritis, usually associated with calculi (magnesium ammonium phosphate) in the bladder or kidneys. Various organisms, including staphylococci, coliforms, and *Proteus* sp, have been isolated.

In severe outbreaks, culture and antibiotic sensitivity tests should be done, and medication added to the feed. Good sanitation to reduce environmental contamination and increasing the water supply help prevent the condition. When a continual problem exists (with magnesium ammonium phosphate calculi), feed-grade (75%) phosphoric acid may be added to the feed (0.8 lb/100 lb [8 g/kg] of wet mixed feed), from March to early June and from mid-July to October, to reduce the urine pH. Feed and urine pH should be monitored to keep urine pH at ≤ 6 . Feed pH should not be < 5.1 .

Mastitis: A variety of bacteria, mainly staphylococci, streptococci, and *Escherichia coli*, are involved in mastitis in mink. Staphylococcal mastitis typically results in abscessation of affected glands or subclinical disease evidenced only by mild diarrhea in the kits. *E. coli* causes a peracute, necrotizing mastitis similar to that seen in dairy cattle. Predisposing factors include poor nest box and cage sanitation, rough or sharp edges to the entrance of nestboxes, and high bacterial contamination of feed. Treatment and prevention involve improving management and treating individual animals or the herd with appropriate antibiotics based on sensitivity testing.

Miscellaneous Bacterial Diseases:

Various diseases or signs of disease, including septicemia, pneumonia, purulent pleuritis, abortions, abscesses, cellulitis, and enteritis, occur sporadically; occasionally, they may become herd problems. Many bacteria, including *Proteus*, *Klebsiella*, and *Campylobacter* spp, coliforms, streptococci, staphylococci, and salmonellae, have been isolated.

Treatment should be based on antibacterial sensitivity tests. Drugs may be administered parenterally or in the feed or water. Dosage can be estimated on the basis of body wt; female mink weigh ~ 2 –3 lb (0.9–1.4 kg), and males ~ 5 –6 lb (2.3–2.8 kg). Dosages recommended for cats should be used and adjusted for weight. However, some sulfonamides (eg, sulfaquinoxaline and sulfamethazine) and streptomycin should not be used in mink. Trimethoprim/sulfadiazine causes abortions in pregnant female mink.

The source of infection should be determined and eliminated. Enteritis often is caused by contaminated or spoiled feed and dirty nest boxes. Abscesses are often caused by injury from wire or splintered wood in the pens, awns in hay or straw used for bedding, or spicules of bone in the feed. Outbreaks of tularemia, anthrax, brucellosis, tuberculosis, and clostridial infections have been caused by feed contaminated with tissue of animals that have died or are carriers of these infections. Careful selection of feed ingredients and disinfection of equipment and pens are important in prevention and control of many infections. Dead stock should not be used as mink feed.

VIRAL DISEASES

Aleutian Disease (Plasmacytosis):

Aleutian disease is a parvovirus infection characterized by poor reproduction, gradual weight loss, oral and GI bleeding, renal failure and uremia, and high mortality. All color phases of mink may be infected, but light color phases genetically derived from the Aleutian color phase are most susceptible. The causative parvovirus is not related to mink viral enteritis (see below). Transmission occurs in utero and by direct or indirect contact with infected mink.

After infection, immunoglobulin levels frequently increase markedly. Immunoglobulins are unable to neutralize the virus; immune complexes form and deposit in various tissues, resulting in immune-complex glomerulonephritis and arteritis. Gross pathologic changes include splenomegaly, renal changes (varying from swelling and petechiation to atrophy and pitting), and enlargement of mesenteric lymph nodes. Histologic lesions include plasma cell infiltration in the kidneys, liver, spleen, lymph nodes, and bone marrow; bile duct proliferation; membranous glomerulonephritis; and fibrinoid arteritis. Kits from dams negative for Aleutian disease virus may die from acute interstitial pneumonia.

Aleutian disease is controlled through a test and slaughter program. Positive mink are identified by blood testing for specific antibody by counterimmunoelectrophoresis or lateral flow ELISA. All positive mink should be culled. Mink to be kept for breeding stock should be tested in late fall (before selection of breeding stock and pelting) and in January or February (before breeding). New introductions to the herd should be tested.

Genetic selection of resistant mink using a quantitative ELISA and/or iodine agglutination test is being used to increase survivability and reproduction. These tests identify mink with hypergammaglobulinemia for culling. The quantitative ELISA identifies overall antibody levels to Aleutian virus, allowing mink with lower antibody levels to be selected for breeding.

There is no vaccination or effective treatment. The virus is present in the saliva, urine, feces, and blood of infected mink. Pens should be steam cleaned and dipped in or sprayed with 2% sodium hydroxide. Equipment should be disinfected after handling, vaccinating, or testing mink on infected farms. Raccoons and flies may serve as vectors, and their control is essential.

Distemper: Mink of all ages are susceptible to canine distemper virus (*see* p 777). The incubation period is 9–14 days. The virus may be recovered from infected mink 5 days before clinical signs appear. Recovered mink may continue to shed the virus for several weeks. Transmission may be direct (through contact or aerosol) or indirect.

Clinical signs include nasal and ocular discharge; hyperemia, thickening, and crustiness of the skin on the muzzle, feet,

and ventral abdominal wall; neurologic signs (convulsions and “screaming fits”); or a combination of these. Histologic ELISA, immunohistochemistry, or fluorescent antibody examination may reveal intracytoplasmic or intranuclear inclusions or distemper antigen in epithelial cells of the bladder, kidneys, bile ducts, intestine, lungs, trachea, and occasionally brain. Recent outbreaks have required PCR confirmation, because immunohistochemistry testing was negative.

In outbreaks, affected mink should be culled, and the balance of the herd vaccinated as soon as possible. Deaths from neurotropic distemper may occur until 12 wk after vaccination. Kits should be vaccinated prophylactically when 11–12 wk old with a modified-live vaccine. Ordinarily, adults are vaccinated at the same time.

Mink Viral Enteritis: Mink viral enteritis is a highly contagious disease caused by a parvovirus related to, but not identical with, that of feline panleukopenia (*see* p 796). All ages are susceptible, but the disease is most serious in kits. Transmission usually occurs by the fecal/oral route; the incubation period is 4–8 days.

Clinical signs include sudden anorexia; depression; watery, mucoid, blood-tinged diarrhea; dehydration; and death. Characteristic gross lesions include a flaccid, dilated, hyperemic small intestine with liquid fetid contents. Some mink may die suddenly with no gross lesions. Intestinal lesions are characterized by erosion of surface mucosa, blunting and attenuation of villi, and dilation of crypts. Ballooned epithelial cells may contain inclusion bodies similar to those of feline panleukopenia. A fluorescent antibody procedure is used to confirm the diagnosis. Splenic and lymph node lesions include lymphoid depletion and necrosis.

Early in an outbreak, all mink showing signs should be culled or isolated, and all clinically healthy mink should be vaccinated immediately. Affected mink can be treated PO with a mixture of kaolin, pectin, and neomycin. Mink viral enteritis can be prevented by vaccination. All mink should be vaccinated when they reach at least 6–8 wk old with a combination 3-way vaccine containing mink viral enteritis, botulism, and *Pseudomonas*. Annual vaccination is recommended.

Influenza: The first case of influenza was identified in the USA in mink in October 2010. Since then, it has become a

Mink kit showing signs of canine distemper, including heavy nasal and ocular discharge with eyelids that are swollen and sealed shut. Courtesy of Dr. John Gorham.

frequent cause of disease on mink ranches. Influenza usually presents with coughing and sneezing heard in areas of the ranch. Losses usually increase due to secondary bacterial infections. Influenza has also affected newborn kits, presenting as increased respiration and significant death losses. Exposure to influenza can come from multiple sources. Raw pork, poultry products, and sick employees may all be avenues for virus introduction. Treatment consists of treating secondary infections to mitigate losses. Spread across the ranch usually takes 2–6 wk. After the disease runs its course, >90% of mink have been shown to be antibody positive.

Aujeszky Disease (Pseudorabies):

Aujeszky disease occurs occasionally in mink fed pork products contaminated with pseudorabies virus (*see* p 1300). Mortality may be high, and clinical signs are referable to the CNS (tonic and clonic convulsions, excitement alternating with depression, and self-mutilation in some cases). Diagnosis is confirmed by virus isolation or serology. Because contaminated pork is the usual source of infection, all pork products should be cooked before being fed to mink.

Astrovirus (Shaky Mink Syndrome):

Astrovirus infection is a self-limiting neurologic disease seen sporadically in mink kits from mid June to mid July. Usually, the condition is limited to one kit per litter, with an incidence of 0.1%–2%. Higher incidence has been reported on a European ranch. Kits have tremors, and histopathology shows meningoencephalitis. Mortality is low and appears to be caused by inability of the mink to eat or drink because of the shaking. Early in the disease, astrovirus can be identified, but later the mink clear the virus and are negative. Lesions and clinical signs do not improve, and euthanasia of affected mink is warranted for welfare concerns.

Epizootic Catarrhal Gastroenteritis:

Millions of mink have been affected by an agent (most likely a coronavirus) that causes an acute catarrhal gastroenteritis. The disease usually occurs in adult dark mink. Outbreaks occur most frequently during times of stress, eg, early fall molting, spring mating, and whelping seasons. Clinical signs (mucus in the feces and partial anorexia) rarely last longer than 5–6 days. Death may occur if the affected mink are immunosuppressed by Aleutian

disease virus. There are no commercially available vaccines. Treatment is symptomatic and of questionable value. It is important to differentiate this condition from mink viral enteritis.

PRION DISEASE

Transmissible Mink Encephalopathy:

This progressive neurologic disease of mink is rare, but mortality may reach 60%–90% of the ranch population. The incubation period is 8–12 mo. Mink usually bite compulsively, are incoordinated and somnolent, scatter feces in the pen, and flip their tails up over their backs (like squirrels). Histologic lesions of the brain are spongiform changes of the gray matter, astrogliosis, and neuronal vacuolation. The demonstration of disease-specific prion protein in nervous tissues aids in the diagnosis. Although the means of transmission is unknown, “downer” cattle are suspected to be the source of the agent. There are no vaccines or treatment.

NUTRITIONAL DISEASES

Steatitis or myositis (yellow fat disease, *see* p 1200) occurs in young, rapidly growing mink as a result of excessive, rancid, unsaturated fatty acids and a deficiency of vitamin E in the diet. Affected mink may be found dead, or they may exhibit slight locomotor disturbances followed by death. Necropsy findings include yellow, edematous internal or subcutaneous fat that contains an acid-fast pigment. It is more common to find myoglobinuria and dark red bladders (resembling plum bladder). Histopathology shows myositis and cardiomyopathy. Hepatic vitamin E levels <15 mcg/g can lead to acute death. Control consists of removal of the source of the rancid fats and polyunsaturated oils and proper storage of feed. Stabilized vitamin E may be administered in the feed (15 mg/mink) for 4 wk, and affected kits should be injected parenterally with 10–20 mg of vitamin E for several days. Feeding a nutritionally sound diet with added vitamin E is preventive.

Chastek paralysis (thiamine deficiency) results from feeding certain raw fish that contain the enzyme thiaminase. These include whitefish, freshwater smelt, carp, goldfish, creek chub, fathead minnow, buckeye shiner, sucker, channel catfish, bullhead, minnow, white bass, sauger pike, burbot, and saltwater herring. Affected mink gradually become anorectic, lose

weight, and die after terminal convulsions and paralysis. Fish that contain high levels of thiaminase should be thoroughly cooked at 181°F (83°C) for 25 min, or fed raw as a portion of the diet only on alternate days. Mink injected with thiamine hydrochloride, 50 mg, SC, recover rapidly. Adequate thiamine (brewer's yeast) should be included in the ration.

Rickets occurs due to the rapid growth rate of kits when rations are deficient in vitamin D, calcium, or phosphorus. Affected kits usually crawl unsteadily in a frog-like posture, have rubbery bones, and are smaller than normal. The diet should be supplemented as required, and severely affected kits may be treated individually. (See also p 1051.)

Nursing disease is a metabolic disease that affects lactating mink ~40 days after whelping. It is characterized by rapid dehydration, serum electrolyte imbalances, renal shutdown, and death. Treatment can be successful if affected females are identified as soon as they begin refusing feed and rehydrated with IP or SC sterile fluids. The disease is multifactorial; although there appears to be a genetic predisposition in certain light color mutations, it is more severe in females with large litters and during hot weather. Often, affected females have concurrent subclinical mastitis. Adequate water, environmental cooling systems, fostering kits from large litters to make litter size more manageable for the female, and early weaning help prevent this condition.

Cotton underfur usually indicates anemia and may be caused by feeding certain fish (Pacific hake, coalfish, whiting) that interfere with iron metabolism in mink, which affects melanin pigment formation. Thoroughly cooking the offending fish at 181°F (83°C) for 25 min or feeding it on alternate days prevents the condition.

Biotin deficiency, which can cause gray underfur and loss of guard hair, is seen when high levels of uncooked eggs, particularly turkey eggs, are fed. Avidin, a factor present in eggs, inactivates biotin, a vitamin required for pigmentation and hair growth. Affected mink may be injected with 1 mg biotin twice weekly for 4 wk, and biotin may be added to the ration. Biotin deficiency can be prevented by cooking eggs at 196°F (91°C) for 5 min.

POISONING

Lead poisoning (see p 3078) may be seen in mink that have ingested lead-containing paint from wire or other equipment. Affected mink gradually lose weight and die

within 1–2 mo with clinical signs consistent with either gastroenteritis or CNS disturbance. Individual mink may be treated with calcium edetate as a chelating agent. All sources of lead should be removed.

Insecticides other than pyrethrum, piperonyl butoxide, and rotenone may be highly toxic to mink. Even these insecticides should not be used on mink <8 wk old, or where such mink can contact them (eg, nest boxes). Other insecticides should be avoided whenever possible. (See also p 3058.)

Wood preservatives (chlorinated phenols, cresols) can cause death of kits in the first 3 wk of life and occasionally of older mink. They should not be used where mink can chew on treated wood (pens, nest boxes, or nest litter). Shavings used as nest-box litter should not contain wood preservatives.

Diethylstilbestrol causes reproductive failure and a high incidence of urinary tract infections in mink and should not be included in the ration. Similarly, thyroid and parathyroid glands included in meat trimmings fed to mink may result in reproductive failure if present at high levels.

Chlorinated hydrocarbons and **polychlorinated biphenyls** contained in the ration can cause reproductive failure. Mink appear to be exquisitely sensitive to **polybrominated biphenyls**; 1 ppm in the ration has caused litter size and offspring viability to decrease. (See also p 3056.)

Dimethylnitrosamine (DMNA) is hepatotoxic in mink. In the past, addition of sodium nitrate as a preservative to herring meal resulted in formation of DMNA, which causes hepatic degeneration, ascites, and extensive internal hemorrhage.

Sulfaquinoxaline upsets normal blood-clotting mechanisms of mink and causes extensive internal hemorrhage. **Streptomycin** is toxic to mink.

Salt toxicity is seen in young kits starting on solid food. Affected kits become dehydrated and show CNS signs such as tremors or seizures. The most common cause is increased salt levels in feedstuffs. By-product from the cheese, poultry, fish, and processed sandwich meat industries contain higher than expected salt concentrations. Prevention is accomplished by testing feed and ingredients for salt levels and removing ingredients with high salt concentrations and supplemental salt.

MISCELLANEOUS DISEASES

Fur clipping and tail biting are common in mink and may be caused by captivity. Fur clipping decreases the value of the pelt, and tail biting frequently results in fatal

hemorrhage. There is no effective treatment. All mink demonstrating these behaviors should be culled.

Urinary incontinence (wet belly disease) is a nonfatal condition that usually affects obese males in the late summer and autumn. It is characterized by dribbling of urine and staining of the pelt around the urinary orifice. Because affected areas of the pelt must be discarded, the condition is of economic importance. The cause is unknown, but genetic strain, high dietary fat level, and obesity appear to have the greatest influence on incidence. Affected mink should have an ample water supply.

Starvation and chilling cause death in mink fed inadequate fat or provided with too little feed during the winter and early spring. Affected mink are thin and may run until they collapse and die, or they may be found dead in their cages. Such deaths usually occur after the environmental temperature decreases suddenly, especially in the early spring when mink are being brought into breeding condition. Necropsy reveals emaciation and an absence of body fat, in some cases accompanied by hepatic lipidosis and gastric ulceration. This results from improper management and must be differentiated from infectious diseases.

Gray diarrhea in mink clinically resembles chronic pancreatic necrosis in dogs and is characterized by a ravenous appetite and passage of large amounts of gray, fetid feces. Affected mink appear to die of starvation. No pancreatic abnormalities, viruses, bacteria, or parasites have been demonstrated to be causes. Treatment is of questionable value.

Gastric ulcers and hepatic and renal lipidosis are common in mink and usually are associated with high levels of dietary fat or with other diseases or stresses that result in several days of inappetence (eg, during late gestation, the period of weaning kits, or the fall period of furring up). Renal lipidosis is commonly seen in mink implanted with melatonin. Treatment involves B vitamins (either feeding or via injection) and increasing the protein quality of the feed.

Hereditary diseases such as hydrocephalus, hairlessness, "screw neck," "bobbed tails," Ehlers-Danlos syndrome, hemivertebrae, and tyrosinemia occur occasionally. Culling the sire, dam, and littermates of affected mink is necessary for control.

Coccidiosis (see p 203) occasionally causes losses in young mink. Affected mink have diarrhea, blood-tinged feces, dehydration, and weight loss. Coccidiostats may be used to control outbreaks. Coccidiosis can be prevented through good sanitation and regular manure removal.

Myiasis develops in mink when flies of *Wohlfahrtia* spp lay maggots directly on the skin of kits. The larvae penetrate the skin and produce inflammation and lesions that resemble abscesses. Affected kits become restless, lose condition, and may die. Malathion dust (5%) placed beneath the litter in the nest boxes beginning a few days before the flies appear may help prevent infestation. It should not be used before whelping or until the kits are 1 wk old. Treatment may be repeated once after a 2-wk interval. (See also CUTEREBRA INFESTATION IN SMALL ANIMALS, p 879.)

NONHUMAN PRIMATES

This overview presents a working knowledge of the common families of nonhuman primates maintained in captivity. More species than ever are now promulgated and maintained in captivity, and many are kept in private facilities. Prosimians such as *Lemur catta* (ring-tailed lemur) and New World monkeys such as *Cebus albifrons* (white-fronted capuchin) are commonly encountered in practice. The nonhuman primate species most widely used in research are the macaques, *Macaca mulatta* (rhesus monkey), *M fascicularis* (cynomolgus monkey), and *M nemestrina*

(pig-tailed monkey); some African species, primarily *Chlorocebus aethiops* (African green monkey, vervet) and *Papio* spp (baboons); and some of South American origin, *Saimiri sciureus* (squirrel monkey) and *Aotus trivirgatus* (owl monkey). *Saguinus* spp (marmosets) and *Callithrix* spp (tamarins, marmosets), also of South American origin, have had more limited use in research but are common in the pet trade.

Increased restrictions on exportation or reduced availability of nonhuman primates from countries of origin have led to decreased importation. Importation of

nonhuman primates into the USA is prohibited except for scientific, educational, and exhibition purposes.

Nonhuman primates are natural hosts for a variety of infectious agents, many of which are zoonoses, and are also susceptible to many human infectious diseases, such as measles and tuberculosis. Consequently, newly acquired nonhuman primates should be quarantined for 1–3 mo before research use or introduction into established colonies, to permit adequate evaluation of their health status and to allow adaptation to the laboratory environment. The basic principle of quarantine is to completely isolate each group of animals and not mix animals from different shipments or sources without restarting the quarantine period. Nonhuman primates imported into the USA must undergo a 31-day minimum primary import quarantine

in a facility registered with the CDC. Imported animals that die or become severely ill and require euthanasia during this quarantine period must be necropsied and the deaths reported to the CDC, Division of Quarantine. In clinical practice, any new nonhuman primate should be tested for tuberculosis, and a routine fecal examination and trichrome stain should be done. Depending on the species, routine tests such as those for cytomegalovirus, herpes simiae, and herpes simplex (1, 2, etc) also can be run at this time. Many of the nonhuman primates seen in clinical practice are infants and are immunocompromised; they are highly susceptible to common cold and influenza viruses as well as streptococcal infections and should be isolated from people with upper respiratory signs.

For nonhuman primate therapeutics, see TABLE 13.

TABLE 13 NONHUMAN PRIMATE THERAPEUTICS^a

ANTIBIOTICS	
Amoxicillin	11 mg/kg/day, IM or SC; 11 mg/kg, PO, bid; 62.5 mg, PO, bid (lemurs)
Metronidazole	25–50 mg/kg, PO, bid for 10 days (gastroenteritis and inflammatory bowel disease)
Azithromycin	40 mg/kg, PO, once, then 20 mg/kg/day, PO, for 5 days
Cefazolin	25 mg/kg, IM or IV, bid for 10 days
Ceftriaxone	50–100 mg/kg, IM or IV, bid
Doxycycline	2.5 mg/kg, PO, bid for one day, then 2.5 mg/kg/day, PO
Minocycline	2–15 mg/kg/day, PO
Enrofloxacin	5 mg/kg, IM or PO, once to twice daily for 10 days
Erythromycin	30–50 mg/kg, IM or PO, bid–tid
Gentamicin	3–5 mg/kg, IM or IV, bid for 5–7 days
Penicillin G potassium + penicillin G benzathine	20,000–60,000 U/kg, IM, once to twice daily (higher dosage in lemurs)
Trimethoprim-sulfamethoxazole	15–50 mg/kg, PO or IM, bid; sulfamethoxazole at 20 mg/kg, PO, bid (higher dosages for lemurs)
PARASITICIDES	
Fenbendazole	50 mg/kg/day, PO, for 5 days, repeated in 2 wk
Ivermectin	200–300 mcg/kg, SC, IM, or PO, repeated in 14 days
Mebendazole	22 mg/kg/day, PO, for 3 days, repeated in 14 days (for <i>Giardia</i> sp)
Metronidazole	30–50 mg/kg, PO, bid for 5–10 days

TABLE 13 NONHUMAN PRIMATE THERAPEUTICS^a (continued)

Praziquantel	5 mg/kg, IM, PO, or SC, once (15–20 mg/kg, PO or IM, for some cestodes; 40 mg/kg, PO or IM, for trematodes)
Thiabendazole	100 mg/kg, PO, once, repeated in 14 days (owl monkeys); 50 mg/kg/day, PO, for 2 days (<i>Strongyloides</i>); 75–100 mg/kg/day, PO, for 10 days (<i>Entamoeba</i> , <i>Balantidium</i>) in great apes
ANESTHETICS AND ANALGESICS	
Ketamine hydrochloride	10–15 mg/kg, IM, for restraint only; ketamine (15 mg/kg) with diazepam (1 mg/kg), IM, or ketamine (8 mg/kg) with midazolam (0.2–1 mg/kg), IM, for additional muscle relaxation
Ketoprofen	2 mg/kg/day, IV or IM
Inhalant gas (isoflurane, halothane)	1%–2%; maintenance of surgical plane of anesthesia
Flunixin meglumine (analgesic)	0.5–2 mg/kg, IV, IM, or SC, bid
Buprenorphine	0.005–0.01 mg/kg, SC, IM, or IV, bid-qid (great apes) 0.015–0.02 mg/kg, IM, SC, tid-qid (New World primates)
Butorphanol tartrate	0.02 mg/kg, SC, qid (New World primates); 0.02 mg/kg (not to exceed 0.3 mg total), IM (chimpanzees); may cause profound respiratory depression
Dexmedetomidine	40 mcg/kg, IM, for anesthesia in combination with ketamine at 20–30 mcg/kg, IM (lemurs) or at 2–6 mg/kg, IM (macaques and baboons)
Midazolam	0.05–0.1 mg/kg, IV (slow) or IM; 0.1–0.5 mg/kg, IM (with ketamine helps prevent seizures in lemurs); 5 mg/animal, IM (chimpanzees)
Oxymorphone (opioid analgesic)	0.025–0.075 mg/kg, IM or IV, every 4–6 hr (New World primates); 0.15 mg/kg, SC, IM, or IV, every 4–6 hr (Old World primates); 1–1.5 mg/animal, SC or IM, every 4 hr (chimpanzees)
Propofol	2.5–5 mg/kg, IV bolus induction, 0.3–0.4 mg/kg/min constant-rate infusion (baboons and macaques); 7–8 mg/kg, IV bolus (marmosets, larger nonhuman primates); 1–2 mg/kg, IV bolus (chimpanzees), followed by infusion to effect; oxygen support always available
Tiletamine-zolazepam	3–5 mg/kg, IM, for restraint only (great apes), severe ataxia noted during recovery: 1–2.5 mg/kg, IM (New World primates); 1.5–3 mg/kg, IM (macaques)

^a All are extra-label uses.

BACTERIAL DISEASES

Gastrointestinal Diseases: The bacteria most commonly associated with GI disease in nonhuman primates are *Campylobacter jejuni* and *Shigella* spp. Occasionally, enterotoxigenic *Escherichia coli*, *Pseudomonas aeruginosa*, *Yersinia* spp, *Lawsonia intracellularis*, *Salmonella* spp, *Aerobacter aerogenes*, and *Aerobacter*

hydrophila are implicated. Nonhuman primates may be intermittent, asymptomatic carriers of any of these organisms. *Helicobacter* spp have been implicated as a cause of gastritis, anorexia, and vomiting.

GI diseases may be major problems in captive nonhuman primates. Clinical signs include watery or mucoid, blood-tinged feces, rapid dehydration, emaciation, and prostration. Smaller primates will dehydrate

and become hypoglycemic very rapidly. In many privately owned nonhuman primates, dietary indiscretion is common, and the owner should be asked about irregular feeding habits. Rectal prolapse is an occasional sequela. Helminths or pathogenic protozoa may be a complicating factor. Fecal assays and trichrome stains should be done, and appropriate anthelmintics administered. Mortality can be extremely high in acute outbreaks unless treatment is instituted promptly to restore and maintain normal fluid and electrolyte balance. The most common lesions at necropsy are hemorrhagic enteritis, enterocolitis, colonic ulcers, or simply colitis.

Severe clinical signs and death are generally due to dehydration, hypokalemia, and metabolic acidosis. Hydration should be restored and maintained with parenteral electrolyte solutions. Although medications may often be easily administered parenterally, potassium, B vitamins, electrolytes, bismuth subsalicylate, and antibacterial agents can be administered PO or by nasogastric tube in most nonhuman primates. Culture and identification of the infecting organisms and assessment of antibiotic sensitivity may be needed for effective therapy. Metronidazole at 25–50 mg/kg, PO, bid, may be instituted until culture results are obtained. Enrofloxacin (5 mg/kg/day) or the combination of trimethoprim (4 mg/kg) and sulfamethoxazole (20 mg/kg), administered as a total daily oral dosage for 10 days, is useful to treat shigellosis. Azithromycin (30–50 mg/kg, IM, bid for 7–14 days) is recommended to treat *Campylobacter*-associated diarrhea.

Pneumonia: Upper respiratory diseases of bacterial origin can cause widespread illness, and bacterial pneumonia is associated with increased mortality, particularly in newly imported or immature nonhuman primates. Causative agents include *Streptococcus pneumoniae*, *Klebsiella pneumoniae*, *Bordetella bronchiseptica*, *Haemophilus influenzae*, and various species of streptococci, staphylococci, and pasteurellae. Both New World and Old World infant primates are highly susceptible to cross-species transfer from people. Many times, caretakers have had a history of an upper respiratory infection, so adequate history on presentation is important. Infants that are handreared frequently present with aspiration pneumonia from bottle feeding, and appropriate cultures and radiographs will be needed.

Pneumonia may accompany or follow other primary diseases (eg, dysentery or

respiratory viral infection). Clinical signs may include coughing, sneezing, dyspnea, mucoid or mucopurulent nasal discharge, pyrexia, lethargy, anorexia, and weight loss. The principal lesions seen at necropsy are those of bronchopneumonia or lobar pneumonia. Empiric antibiotic therapy with azithromycin, trimethoprim/sulfamethoxazole, penicillin, or cephalosporin (either of the latter two in combination with an aminoglycoside) generally is indicated. Cultures from pharyngeal swabs or transtracheal lavage are useful to isolate the causative agent and determine the specific antibiotic sensitivity. Intensive nursing and other supportive therapy, such as fluid and oxygen administration, may also aid recovery in select cases.

Tuberculosis: All nonhuman primates are susceptible to tuberculosis, although major differences exist in the prevalence of cases in different species. Most cases of tuberculosis in nonhuman primates have been reported in Old World primate species such as rhesus monkeys. Reports in New World species such as squirrel monkeys are much less frequent. The incidence of tuberculosis is <1% among quarantined Old World primates, but 45% of cases (especially cynomolgus monkeys) may not be diagnosed until after the first 30 days of quarantine. Clinical signs are not a reliable indication of the severity of tuberculosis in monkeys. A monkey that appears healthy may have extensive miliary disease involving thoracic and abdominal organs; signs of debilitation may appear only shortly before death. However, advanced tuberculosis should be suspected in animals that cough; lose appetite or weight; and/or have enlarged or draining lymph nodes, skin wounds that fail to heal, or abdominal masses. A testing program is mandatory; a tuberculin skin test (intradermal tuberculin skin test), using mammalian old tuberculin (MOT) is the only USDA-approved tuberculin test for nonhuman primates and is the primary diagnostic method for routine surveillance. Intradermal injection of 0.1 mL of MOT using a 26-gauge needle in the palpebrae is an approved USDA method; 0.5 mL may be used in marmosets and tamarins. The injection sites are observed at 24, 48, and 72 hr after injection. Grading systems can be found in the Guidelines for the Prevention and Control of Tuberculosis in Nonhuman Primates on the National Institutes of Health Web site. If palpebral swelling is present with a lid droop, this may be interpreted as positive. Tuberculin tests should be done on all nonhuman primates on arrival at the

facility and at 2-wk intervals thereafter until at least three consecutive negative tests have been recorded for the entire group. The last test should be administered within 14 days of the release from quarantine and introduction into an established colony.

The time from initial infection to skin test conversion depends on the route of exposure, the infecting inoculum, and the strain of organism, but usually occurs within 3–4 wk in rhesus monkeys. Late in the disease, anergy can result in a negative skin test. Anergy may also be induced by concurrent viral infection, such as measles, or immunosuppressive disease. Infected nonhuman primates may also develop latent tuberculosis. These animals appear healthy, are not infectious, and are often skin-test negative. Latent tuberculosis may be reactivated in response to environmental stressors or other immune modulation, leading to active disease and potential transmission.

After their release from quarantine, all nonhuman primates should be skin-tested at least semiannually, and quarterly testing is recommended for research animals. Captive animals in private settings and New World primates may be tested annually. Radiographic examination of the chest may aid diagnosis in well-established cases but is unreliable because lesions rarely calcify or cavitate as they do in people. Additional diagnostic tests, such as culture, PCR, and staining of a gastric lavage or transtracheal wash sample, ELISA, and comparative abdominal skin testing with avian and atypical tuberculin, may aid in diagnosis. Biopsies of positive or suspicious abdominal tests may be useful in identifying true delayed-type hypersensitivity reactions. Because of the public health risk, euthanasia is recommended for all positive reactors. Tuberculosis should then be confirmed at necropsy. When a positive case is identified, the entire group of exposed nonhuman primates in a maintenance colony should be quarantined, and skin testing at 2-wk intervals implemented. Privately owned animals should be quarantined away from small children and untrained personnel. For animals in quarantine, the period should be restarted and testing should be continued. All personnel working with any nonhuman primates or in primate facilities should have regular skin tests.

MYCOTIC DISEASES

See also FUNGAL INFECTIONS, p 632.

Microsporium spp and *Trichophyton* spp rarely infect institutional nonhuman primates. In clinical practice with privately

owned nonhuman primates, it is more common. Topical treatment of ringworm with undecylenic acid ointment or 1% tolnaftate cream, bid for 2–3 wk, may help, but nonhuman primates often orally remove any topical medications, making treatment ineffective. Administration of griseofulvin at 25 mg/kg/day, PO; ketoconazole at 5–10 mg/kg, PO, bid for 30 days; or fluconazole at 2–3 mg/kg/day, PO, for 30 days is also very effective. *Candida* spp are common saprophytes of the skin, GI tract, and reproductive tract; they act as facultative pathogens in debilitated nonhuman primates. Ulcers or white, raised plaques may be seen on the tongue or mouth; the fungus may also attack fingernails. Oral lesions must be differentiated from those of trauma, monkeypox, or herpesvirus infections. A topical cream containing nystatin is effective in superficial infections. Oral nystatin (200,000 U, qid, continued for 48 hr after clinical recovery) is effective for candidiasis of the GI tract. *Dermatophilus congolensis* infection has been reported in owl monkeys. Papillomatous lesions are seen on the face and extremities. The infection is transmissible to people. Aspergillosis may develop in various nonhuman primate species, and the organism usually is a facultative pathogen in immunocompromised hosts. Treatment with voriconazole or terbinafine is empirical. In endemic regions of the western and southwestern USA, *Coccidioides immitis* has been associated with fungal pneumonia and disseminated mycosis ("valley fever") in monkeys and apes after exposure to airborne spores of this soil fungus.

PARASITIC DISEASES

Newly imported nonhuman primates harbor numerous parasites. Some are commensal; others can be made self-limiting by strict sanitation and good husbandry. However, some can cause serious diseases or debilitation and should be removed by specific treatment. Captive-raised New World primates housed indoors (ie, with their caretakers) are rarely found to have intestinal parasites; however, this may not be the case when they associate with sandboxes and various outdoor enclosures. Fecal examinations should be part of the routine clinical annual examination.

Arthropods: Pulmonary acariasis (*Pneumonyssus* spp) is common in wild-caught Asian and African primates, particularly rhesus monkeys and baboons.

Infection is rare in laboratory-raised or captive, privately raised nonhuman primates. The life cycle of *Pneumonyssus* spp is not well understood. Infestations usually do not produce serious symptomatic disease, although they may cause sneezing and coughing. Lesions include dilation and focal chronic inflammation of terminal bronchioles. The gross lesions may occasionally be confused with tuberculous granulomas. Ivermectin (200 mcg/kg, SC, PO, IM, repeated in 14 days) has been used for treatment in closed breeding colonies.

Mange mites (*Psorergates* spp, *Sarcop-tes scabiei*) or sucking lice (*Pedicinus obtusus*) are seen occasionally, particularly in feral animals, and may produce dermatoses. Systemic treatment with ivermectin, 200 mcg/kg, PO, SC, IM, repeated every 3 wk, or topical treatment with pyrethrin, repeated after 3 days if necessary, is recommended. Use of more toxic topical parasiticides should be avoided because of the possibility of ingestion during grooming. Fleas are commonly seen in New World primates that are associated with dogs or cats in the environment. Premise control measures must be instituted, and baths with a pyrethrin-based shampoo will temporarily remove fleas from the animal's haircoat.

Helminths: *Oesophagostomum* may cause characteristic granulomatous nodules in the large bowel associated with development of the worms and with an immune reaction of the host. The nodules may rupture and cause peritonitis. *Strongyloides* and *Trichostrongylus* are invasive—adults may cause enteritis and diarrhea, larvae may cause pulmonary lesions during migration. These helminths, as well as *Trichuris*, can be treated effectively with thiabendazole at 100 mg/kg, administered PO at intervals of 2–4 wk; ivermectin at 200 mcg/kg, SC, repeated in 14 days; or febendazole at 50 mg/kg/day, PO, for 3 days and repeated in 14 days. The effectiveness of anthelmintic treatment is enhanced by aggressive environmental hygiene practices. *Prosthenorchis* is an acanthocephalan, common in Central and South American nonhuman primates, that burrows into the mucosa of the ileocecal junction and sometimes perforates the bowel or causes obstruction when present in large numbers. Cockroaches are intermediate hosts, and their elimination, along with strict sanitation, is essential for control of infection. *Dipetalonema* and

Tetrapetalonema are filarid worms found in the peritoneal cavity of New World species; large numbers may be present with very limited host reaction. Lungworms such as *Filaroides* are commonly found in many South American monkeys.

Cestodes: *Bertiella studeri* and other enteric cestodes may be found in animals of feral origin and are treated effectively with praziquantel (5 mg/kg, IM, PO, or SC, once). For some cestodes, 15–20 mg/kg, PO or IM, once, will be needed. Somatic larval (cystic) cestodiasis has been reported. Flukes may cause respiratory, GI, and hematologic signs. *Schistosoma* sp is a blood fluke, whereas *Fasciola* sp infect the liver and may cause hepatic disease and abscessation (more common in Old World primates). The intermediate hosts are snails and crustaceans, which are ingested through contaminated water or food. This is of zoonotic concern. Praziquantel at 40 mg/kg, PO or IM, in a single dose has been effective.

Protozoa: Nonhuman primates may serve as hosts of various intestinal amebae. *Entamoeba histolytica* is the principal pathogenic form in nonhuman primates (as in people). It has only rarely been reported as pathogenic in monkeys, mostly in South American spider and woolly monkeys. However, it can be a serious infection in marmosets and has caused serious enteritis in great apes. In a heavy infection, it may cause severe enteritis and diarrhea, and cysts may be demonstrated in the feces in large numbers. The fecal trichrome stain is a useful tool to diagnose these types of infections, which are often overlooked in a direct or flotation fecal examination. *Giardia* inhabit the upper small intestine and may cause watery diarrhea. Treatment with metronidazole (50 mg/kg/day, PO, for 5–10 days) is recommended. *Cryptosporidium parvum* may also cause diarrhea in nonhuman primates, mainly in young animals. Successful treatment in marmosets with paromomycin has been reported. This infection is usually self-limiting in immunocompetent hosts.

Blood parasites, such as *Plasmodium*, *Leishmania*, and *Trypanosoma* spp, are also found. Generally, there is an equilibrium between the parasite and the natural host, with infections rarely causing overt clinical disease. Transmission of simian malaras to people, although rare, has occurred in areas where the appropriate mosquito vectors are present. Some nonhuman primate species (eg, owl

monkeys) are excellent models for malarial research.

Naturally occurring toxoplasmosis (*Toxoplasma gondii*) has been reported in Central and South American primates. Clinical signs of infection tend to be nonspecific (lethargy, anorexia, diarrhea). Hepatic focal necrosis and fibrinous pneumonia with edema are common histologic findings. *Toxoplasma* can be demonstrated in blood smears in acute cases. (See also p 685.)

VIRAL DISEASES

A number of herpesviruses affect nonhuman primates; many exist as latent or subclinical infections in reservoir hosts but cause severe disease or death when transmitted naturally to other hosts. All macaques are considered to be potential shedders of Cercopithecine herpesvirus type 1 (Herpesvirus simiae, B virus). The infection is generally subclinical or mild (conjunctivitis or oral vesicles) in *Macaca* spp but usually causes a fatal encephalitis and encephalomyelitis in people. Transmission may occur via a bite, scratch, or contamination of a superficial wound or mucous membranes (eg, conjunctiva) with infectious saliva, conjunctival secretion, or genitourinary secretions. Human fatalities due to B virus encephalitis illustrate the importance of using appropriate precautions and personal protective equipment to prevent direct or indirect contact with macaque secretions and body fluids. Captive-born and raised animals should still be screened when first presented in a clinical setting and subsequently every year afterward in a private facility.

Saimiriine herpesvirus type 1 (herpesvirus T) causes mild herpetic lingual ulcers and stomatitis in squirrel monkeys, but fatal epizootics have followed natural transmission to owl monkeys and marmosets. The human herpesvirus, herpes simplex virus type 1, causes a mild infection in people and certain other primates, but owl monkeys, gibbons, capuchins, and tree shrews (*Tupaia glis*) are highly susceptible and may die; signs may include ulcerations of the mucous membrane or skin, conjunctivitis, meningitis, or encephalitis. Human caretakers with oral lesions should be replaced until the infection regresses, and any interaction with the public should be discouraged.

Naturally occurring, clinically silent infections of hepatitis A virus (enterically transmitted hepatitis virus) have been seen

in chimpanzees (*Pan troglodytes*) and monkeys. Increased AST and ALT values are of diagnostic significance in nonhuman primates. Human infections have been contracted from chimpanzees.

Because some vaccines are not available to protect nonhuman primate colony personnel or the primates against herpes and some viral hepatitis infections, exposure should be prevented. This is best accomplished by carefully training personnel in the handling of nonhuman primates, using personal protective equipment (clothing, face masks, goggles or shields, and gloves), separating primates in species-specific rooms, and paying strict attention to hygienic standards. In private facilities, prescreening the primates by serologic and PCR testing is recommended.

Several other viruses commonly produce clinical disease in newly imported primates. Rubella infection (measles) acquired via human contact can assume epizootic proportions. The virus causes a nonpruritic, exanthematous rash on the face, chest, and lower portions of the body; it may also cause interstitial giant-cell pneumonia, rhinitis, conjunctivitis, and, particularly in New World monkeys, gastroenteritis. Marmosets are extremely susceptible, and children, especially, should not be encouraged to interact with this species. There is no specific treatment. Vaccination of infant rhesus monkeys and other macaques with human measles vaccine is recommended. Modified-live measles vaccine can cause disease in marmosets and is *not* recommended. Monkeypox and other poxvirus infections may be seen in primate colonies. Monkeypox is a reportable, zoonotic disease characterized by a maculopapular rash and variolous pustules (see p 2419). Affected monkeys usually survive; after recovery, they are immune to challenge.

Immunosuppressive disease in nonhuman primates may be caused by a number of retroviruses, including several orthoretroviruses formerly called type C and type D oncornaviruses, and several simian immunodeficiency viruses (SIVs). The SIVs are lentiviruses closely related to human immunodeficiency virus 1 (HIV-1) and HIV-2. Unique isolates have been found in different species of nonhuman primates. SIVs are of low pathogenicity in the natural hosts, African species, and infections are often clinically silent but may cause devastating disease similar to AIDS in macaques after cross-species transmission. SIV has been demonstrated

to infect people, although the longterm consequences of infection are unknown. Infection with orthoretroviruses in the genus *Betaretrovirus* (formerly the type D retroviruses SRV, 5 serotypes) may cause an immunodeficiency predisposing to a complex of diseases such as fibromatosis, atypical mycobacteriosis, intestinal cryptosporidiosis, pneumocystic pneumonia, disseminated cytomegalovirus infection, and candidiasis in colonies of macaques. Infection with oncornaviruses in the genus *Deltaretrovirus* (formerly type C retrovirus) results primarily in lymphoproliferative disease, and rarely T-cell lymphoma, in Old World monkeys and apes. There is great host-interspecies variation in clinical signs and susceptibility from virus to virus. Transmission between nonhuman primates is via direct or indirect contact with infected blood and other body fluids or from dam to offspring.

Hemorrhagic viral zoonoses, such as Ebola, Marburg, and mosquito-borne yellow fever, are risks with wild-caught animals. An important differential diagnosis for these zoonoses is simian hemorrhagic fever. This *Arterivirus* infection is subclinical in African monkeys but is highly contagious and fatal for Asian species. Hemorrhagic necrosis of the proximal duodenum is a pathognomonic lesion. Captive populations that ultimately are housed in private facilities are a low risk.

NUTRITIONAL DISEASES

See also NUTRITION: EXOTIC AND ZOO ANIMALS, p 2287.

All laboratory nonhuman primates are susceptible to vitamin C deficiency. Hypovitaminosis C may cause immunosuppression and increase susceptibility to infectious diseases before clinical signs of the deficiency appear. Commercial monkey diets contain vitamin C that is stable for 3 mo after the diet is milled and packaged, if properly stored. Supplemental sources are green leafy vegetables and citrus fruits. Orally administered human pediatric vitamin preparations that contain ascorbic acid are readily accepted. Daily intake of vitamin C at 3–6 mg/kg prevents scurvy. Scurvy should be treated with ascorbic acid at dosages of 25–50 mg/kg/day until clinical signs resolve and dietary consumption of adequate vitamin C is restored. Primates require vitamin D to prevent rickets and osteomalacia. Asian and African primates can use provitamin D₂ (in plant materials);

Central and South American primates (New World) cannot and require provitamin D₃. Commercial diets specifically formulated for New World primates should be the main component of the diet of these animals. Fish-liver oils provide an adequate source of D₃, or as little as 1.25 IU/g of diet can be added to the ration. Exposure of monkeys to sunlight facilitates conversion of vitamin D to active forms. Without adequate D₃, New World primates may develop secondary nutritional hyperparathyroidism (see p 1054).

MISCELLANEOUS CONDITIONS

Diabetes: Diabetes is frequently seen in clinical practice. The genus *Cebus* is overrepresented. Causes of diabetes vary from obesity (carbohydrate overload), genetic predisposition, and overall poor dietary choices. The animal should be brought to the hospital fasting; laboratory tests should include a CBC, serum chemistries, a urinalysis, levels of insulin and fructosamine, and a glycosylated hemoglobin. The caretaker should be educated on dietary restrictions and the availability of newer commercial diets for these animals. Blood glucose readings can be obtained at home by the caretaker, and both oral and parental medications administered with little effort.

Acute Gastric Dilatation: Life-threatening bloat occurs sporadically in captive nonhuman primates and may be associated with feeding after a prolonged fast or periods of water restriction or accidental overfeeding. Etiologic factors include intragastric fermentation associated with *Clostridium perfringens* and abnormal gastric function. Monkeys become acutely ill, with clinical findings similar to those seen in small animals (see p 384). Acute gastric dilatation is often fatal without emergency treatment. The stomach must be evacuated and fluids replaced, in like volume, with electrolyte solution given parenterally. Shock and dehydration usually occur and require prompt treatment. Periodic evacuation of the stomach may be necessary for several days until GI function is normal. Metabolic alkalosis may result from continued loss of hydrochloric acid. Adequate sodium, chloride, and potassium must be provided via parenteral fluid therapy.

Tetanus: Infection with *Clostridium tetani* is a risk with free-ranging and outdoor-housed monkeys, particularly as

a consequence of fighting, parturition, frostbite, and other forms of skin trauma. Immunization with tetanus toxoid should be considered for populations at risk. Marmosets are routinely vaccinated with adsorbed human product or equine product at 0.25 mg, IM, every 5 yr. (See also TETANUS, p 611.)

Intestinal Adenocarcinoma: The number of aged nonhuman primates maintained in captivity has increased in recent years, primarily due to improvements in husbandry, nutrition, and veterinary care, but also because of an emphasis on animal models for aging research. This increase in the aged nonhuman primate population, particularly macaques, has been associated with an increase in the incidence of intestinal adenocarcinoma, which may exceed 20% in animals >30 yr old in some colonies. Decreased appetite, weight loss, anemia, and a palpable abdominal mass are common clinical findings. Tests for fecal occult blood are often positive. Radiographic examination may show changes associated with partial obstruction. Surgical biopsy is diagnostic for adenocarcinoma. The location of these tumors is most commonly the ileoceccocolic junction, rarely in the small intestine. Histologic lesions include a thickened intestinal wall and constriction of the lumen (so-called "napkin ring" lesion), with variable signs of hemorrhage and ulceration. Metastatic lesions are uncommon, and some animals respond favorably to surgical excision.

Trauma: Trauma from cagemate aggression or self-mutilation (biting or hair pulling) may occur occasionally, as may thinning of the hair due to self-induced alopecia. Trauma is also very common in captive nonhuman primates in clinical practice. Animals that live with other species in the domestic environment may be subjected to wounds inflicted by dogs and cats. Massive soft-tissue injury, such as that which occurs from these attacks, may cause increased loads of bacteria into the bloodstream, as well as acute blood loss and shock causing coagulopathy and endothelial disruption. This complicated chain of events causes hypothermia, acidemia, and inflammation and should be treated as a life-threatening emergency. Rapid control of hemorrhage, correcting the hypothermia, early blood component administration, and high-volume fluid therapy are indicated to avert continued ischemia and renal

shutdown; antibiotics should be given to prevent infection and sepsis. Measures should be taken to enhance the psychologic well-being of nonhuman primates (eg, group housing, exercise pens, shelters, foraging activities, and cage toys), and animals in social groups should also be provided facilities for refuge and escape.

PSYCHOLOGICAL WELL-BEING AND ENVIRONMENTAL ENRICHMENT

Providing for the psychological as well as the physical well-being of nonhuman primates maintained in captivity is a high priority. Psychological well-being is enhanced by appropriate social companionship (ie, compatible conspecifics); opportunities to engage in behavior related to foraging, exploration, and other activities appropriate to the species, age, gender, and physical condition of the animal; and housing that allows typical movement and resting postures. When home cages are of the minimum legal size, enlargements or added exercise areas should be encouraged. Interactions with human caretakers should be generally positive and not a source of undue stress. Well-designed and implemented environmental enrichment programs should meet these basic requirements, with the objective of minimizing traumatic injuries due to aggressive interactions, reducing the incidence of stereotypic and self-injurious behaviors, and ameliorating preexisting abnormal behaviors. Results of attempts to manage self-injurious behavior (eg, self-biting, hair plucking) with drugs such as benzodiazepines or haloperidol have been inconsistent, and long-term management is generally unrewarding. Socialization, which may involve visual and auditory stimuli as well as physical contact, appears to provide substantial benefit to most species of nonhuman primates, and should be provided within the constraints of research protocols and daily management practices. Additional enrichment options include forage boards or other food-related enrichment devices, manipulation mirrors, and a variety of cage toys provided on a rotating schedule to maintain novelty. Animal behavioral assessments as well as periodic review and evaluation of the effectiveness of enrichment program components should be performed by appropriately trained individuals.

PET BIRDS

Advances in avian medicine have changed the emphasis from infectious diseases and emergency medicine to wellness care. Nutrition and behavior are important components of the health of psittacine birds and play a major role in pet bird wellness programs. Mass importation of wild-caught psittacine birds was curtailed in the mid-1980s, and the current pet bird population is comprised primarily of captive-bred parrots. This has resulted in novel medical concerns and unique behavioral challenges. The knowledge base regarding psittacine and other pet bird diets and husbandry continues to increase, as does the importance of providing a psychologically suitable environment for these complex animals. Pet birds are intelligent and social animals adapted for flight. Keeping solitary pet birds in small indoor cages, with limited opportunity for exercise, has both physical and psychological consequences.

Veterinarians have a responsibility not only to diagnose and treat disease but also to educate bird owners on how to provide the best care for and prevent disease in their bird. Preventing disease entails providing a proper diet, an appropriate size cage and perches, proper sanitation, and environmental enrichment (ie, toys, foraging opportunities, social interaction).

A cage provides living space as well as protection and security. It should be large enough to not only house the bird and provide ample room for climbing and playing but also to accommodate toys, foraging opportunities, and multiple perches of different sizes and textures. Owners should purchase the largest cage

possible (considering space and cost), while following minimum size recommendations (TABLE 14). Cages must be large enough to accommodate multiple perches and ensure that birds will have adequate room to move around and exercise.

MANAGEMENT

Managing pet birds in the clinical setting can be challenging. The ability to “mask” clinical signs of illness until late in the disease process often results in birds presenting much sicker than owners realize. Because of this, birds are also riskier patients to evaluate. Birds have a much higher metabolism than mammals, and oxygen deprivation can occur during restraint, treatment, or diagnostic sampling. Owners should be informed of the risks of handling and sampling and the need for a step-by-step approach through the physical examination and diagnostic testing. Placing severely debilitated birds in a warm oxygen incubator or cage while obtaining the history and before physical examination may be warranted. In all avian examinations and diagnostic procedures, being prepared with all needed items for examination, sample collection, and treatments before restraining the bird is important. This includes a light source, oral speculum, gram scale, stethoscope, syringe and needle for venipuncture, blood tubes, and fluids for administration. If a bird is extremely stressed, in pain, or not used to handling, sedation before diagnostic testing may be warranted.

TABLE 14 MINIMUM CAGE SIZE AND BAR SPACING RECOMMENDATIONS

Bird	Cage Size (inches [length × width × height])	Bar Spacing (inches)
Budgerigar, cockatiel, lovebird, parrotlet	20 × 20 × 30	0.5
Conure, <i>Poicephalus</i> spp, caique, miniature macaw	36 × 24 × 48	0.75
African grey parrot, Amazon parrot, small cockatoo	40 × 30 × 60	0.751
Macaw, large cockatoo	48 × 36 × 66	1.5

History: Having the owners bring a pet bird in its own cage for examination is desirable but often impractical. Alternatively, owners can be asked to bring photos or videos of the cage set-up, as well as recent papers from the cage floor so the droppings can be examined. The history should include the type and size of cage, cage bar size and spacing, type of substrate and how often it is changed, frequency of cleaning food and water bowls, where the cage is located in the home, and temperature and humidity of the cage environment. The diet that is offered, the foods that are actually eaten, and any recent changes in diet or appetite should be noted. A complete history also should include the source of the bird and whether it was hand or parent raised; exposure to other birds or pets, including client-owned birds and birds outside the home; length of ownership and history of previous owners; how much time the bird is outside of its cage and if it is monitored during this time; exposure to outdoors; and time spent in interaction with people or other birds in the household.

The length of time a bird has been in the household is usually inversely proportional to the probability that illness will be caused by a primary infectious disease. Newly acquired birds or those exposed to other birds outside the household via bird shows or pet store visits are most likely to be affected by contagious diseases. Chronic malnutrition and secondary infections are more common in birds without recent exposure to potentially infectious birds. Malnutrition is a major cause of subclinical disease in birds, which often becomes clinical when a secondary infection occurs.

Clinical signs of illness can be difficult to detect in birds. However, astute owners may recognize minor behavioral differences in their bird, such as not vocalizing in the morning or decreased interaction with family members. These changes should be considered potential signs of illness. Owners with less experience or less interaction with their birds are less likely to notice these early signs. Feathers can effectively mask even severe emaciation or abdominal distention. Owners may also notice other signs of illness, such as changes in droppings or vocalizations, or if the bird appears to be sleeping more. Veterinarians who see avian patients should be able to identify common species of pet birds (cockatoos, Amazon parrots, macaws, conures, etc) and be familiar with normal species-specific behaviors. For example, parrots of *Pionus* spp often make rapid sniffing noises when stressed that can be mistaken for respiratory distress.

Physical Examination: The bird should be observed in the cage or carrier before manual restraint. Observation should be done from a nonthreatening distance (several feet away). The bird's stance and breathing pattern should be noted. Is it perching and standing on both legs? Is it alert? Are the eyes open or closed? Are the feathers fluffed or sleek? Is there a wing droop? Is the tail bobbing up and down (a sign of increased respiratory effort)? Is the bird open-mouth breathing? A respiratory rate should be obtained at this time. The normal resting respiratory rate for pet birds varies with size and species, with the rate ranging in smaller birds (<300 g) from 30–60 beats/min and in larger birds (400–1,000 g) from 15–30 beats/min. If the bird is showing signs of respiratory distress, it should be placed in a warm, oxygenated incubator before restraint.

Birds should be restrained in a manner that minimizes stress and does not cause undue fear. If the bird is used to being handled, often a towel can be slowly and gently placed over the bird. If an owner has worked with the bird at home with a towel, the veterinarian may ask the owner to towel the bird and then hand it off for examination or testing. Minimizing restraint time, talking to the bird in a quiet voice, and moving slowly can help with many birds. Baby birds or hand-raised cockatoos often can be examined with minimal to no restraint. Many pet birds will step out of the cage or on to a hand and can be gently towed. Some nervous birds may benefit from sedation for examination and diagnostic testing. Birds that are not handled routinely (breeding or aviary birds) may have to be gently towed directly from the cage or carrier.

Restraint of psittacine birds involves immobilizing the head, generally with a thumb on one side of the mandible and the

Restrainted Quaker parakeet. Courtesy of the Schubot Exotic Bird Health Center.

Skeleton of a budgerigar. Illustration by Dr. Gheorghe Constantinescu.

index or middle finger on the other. The feet and the distal remiges (primary wing feathers), if not trimmed, are held by the opposite hand in medium to large parrots. This leaves the thorax and abdomen free to expand with respiration. If the primary wing feathers have been trimmed, a towel may be useful to prevent the wings from flapping during restraint. Birds should be observed closely during restraint; all birds can become stressed, and obese birds can overheat, especially when held in a towel. If respirations become increased or labored, or if the bird becomes weak, the bird should be returned to its cage.

As soon as the bird has been restrained, the crop should be palpated to determine whether food or fluids are present. If the crop is full, the holder should monitor for any signs of regurgitation during restraint. Diagnostic procedures may need to be delayed until the crop empties. An accurate weight is critical to monitor health, body condition, and recovery from illness and to determine fluid therapy, nutritional needs, and medication dosages. Ears, eyes, nares, and oral cavity should all be examined and appear clean, with no exudate, masses, or swellings. The choana on the roof of the oral cavity should have intact sharp papilla.

Exudate around the nares can indicate respiratory or sinus infection, and debris on the feathers of the head or face can indicate vomiting or regurgitation. The condition of the feathers and skin should be noted, including the symmetry and integrity of the beak and nails. Overgrown beak and nails can indicate poor husbandry, nutrition, or liver disease. The integument of the feet should be intact, without excessive wear, callous, or ulceration. Excessive wear of the plantar surface of the feet can indicate inadequate perching or poor nutrition. Excessive wear or callous unilaterally may indicate a problem with the contralateral foot.

Body condition can be determined by palpating the pectoral muscles. A keel scoring system from 1–5 is often used, with 1 as very thin, 5 as obese, and 3 as an appropriate score for most pet birds. Severely obese birds may deposit fat over the neck, thighs, and abdominal cavity. Wings and legs should extend and flex fully, and grip strength should be symmetrical.

Respiratory rate should be monitored throughout the examination; respirations may increase with hyperthermia, stress, or obesity. Respirations should normalize within 3–4 min after the bird has been released. Heart rate is rapid in restrained

birds; typically, a large parrot will have a heart rate of >250 beats/min when restrained. Arrhythmias may occur but can be difficult to categorize because of the rapid heart rate. The cloaca should have sufficient tone to provide tight closure, the skin should be moist, and the feathers around the vent should be clean.

Routine Grooming Procedures: Wing clipping

is frequently requested by owners. Communication with owners about wing trims is vital and should include the degree and purpose of the wing trim. Owners may assume that a wing trim is required at regular intervals. In captivity, however, the frequency at which feathers are molted varies widely based on nutrition, exposure to natural sunlight, photoperiod, and humidity. The fact that a wing trim is a deterrent to flight, but not a guarantee, should be emphasized. A bird that can only glide to the ground indoors may be able to fly outdoors on a windy day. The basic types of wing trims are: 1) Removing 4–7 of the distal primary flight feathers from both wings, below the level of the coverts. The number of feathers that must be removed is inversely proportional to the bird's weight. 2) Leaving 1–4 distal primary feathers and removing the remainder of the primaries from both wings. This clip has fallen out of favor, but some owners have used it for many years. If it has worked well for their bird, it may be wise to continue its use. 3) Removing a variable number of primary feathers from just one wing. This clip is unnecessarily severe and not recom-

mended. Some smaller birds are able to compensate by holding their tails to the side and are still able to fly even with all primary remiges trimmed.

Excessively aggressive wing trims, especially when performed at the same time as a nail trim, can cause both physical and psychological damage to birds. The sudden lack of stability and lift can cause birds to fall, possibly injuring either the carina of the keel or the beak. This lack of stability can lead to serious behavioral problems, especially when it occurs in a young bird that is learning to fly.

Nail trimming is often requested, frequently for the owner's comfort and not because of true overgrowth of the nails. However, nail trimming decreases the bird's stability and increases the chance it will fall from its perch. Generally, a compromise can be reached by blunting the needle-like tip while still leaving sufficient nail to allow a stable grip.

Various types of equipment can be used for nail trims, depending on the size of the bird. Human fingernail trimmers work well to remove the tips of the nails from very small birds. Cat claw trimmers, White's nail trimmers, and hobby drills with sanding bits are all useful. Sanding tools are also excellent to remove excess keratin that can accumulate on the lateral surfaces of the beak. **Beak trimming** is sometimes necessary because of an overgrown upper or lower beak. Birds with beak deformities often have underlying nutritional deficiencies, disease, or previous trauma. Healthy birds provided adequate environmental abrasive surfaces rarely require beak trims.

Viscera, budgerigar. Illustration by Dr. Gheorghe Constantinescu.

Concrete (cement) perches are available in various sizes and textures. These can work well for medium-sized psittacine birds (~250–700 g) when a suitable size is selected and properly placed in the cage. These perches can eliminate the need for both nail trimming and removal of excess keratin from the beak. The perch should be placed where the bird is forced to stand for brief periods (eg, in front of a food bowl or treat cup). To avoid irritation to the plantar surfaces of the feet, the concrete perch should not be the main perch on which the bird sits to preen or sleep.

In previous decades when parrots were widely imported, open-rolled steel bands were used to identify the location at which they were quarantined. Now most birds are **leg banded** (using closed bands) as chicks for individual identification. Bands present certain hazards to the bird, but removal also entails some risk if the proper equipment is not available. The open (gap present), rolled, steel quarantine bands are extremely strong and require removal by a full-size bolt cutter with sharp edges. The closed aluminum bands placed on young, captive-raised birds must be stabilized to prevent twisting while being cut. These bands require two cuts to remove; a sharp, properly designed instrument for removal decreases the danger of leg trauma. Full-circle plastic bands can be removed in the same manner. **Microchipping** is replacing or augmenting banding as a means of identification. The standard for placement of these chips in psittacine birds is in the left pectoral muscles. Adverse reactions or failures in birds have been infrequent; the intramuscular placement reduces the risk of microchip migration. Although microchipping is relatively safe in large parrots with good breast muscle (>150 g), it is riskier in smaller birds. Microchipping small birds (<150 g) has resulted in bleeding and death.

Clinical Pathology: Hematologic testing and plasma biochemical analysis are especially important in birds, because physical examination tends to be less revealing than in other animals. The quantity of blood that can be drawn depends on the weight and health of the bird. Blood collection should be limited to 1% of body wt. Blood is usually collected from the right jugular vein, which is larger than the left. The basilic (wing) vein can also be used but is prone to hematoma formation. In medium to large psittacine birds, seabirds, and poultry, the medial metatarsal vein can also be used. Coating a syringe with an anticoagulant before collection may be helpful in smaller species in which sample collection may take longer

but can cause artifacts in the blood smear, affecting the differential cell count.

The normal PCV varies between psittacine species. For example, cockatiels normally have a higher PCV than many other species, averaging 50%–55%. Cockatoos (*Cacatua* spp), however, often have a PCV in the 40%–45% range.

Anemia can be a result of blood loss or decreased production. Blood loss can occur in cases of trauma or severe organ disease or in idiopathic cases such as conure bleeding syndrome. Response to blood loss anemia may include the presence of immature erythrocytes and anisocytosis along with increased polychromasia. Decreased RBC production can occur with any chronic disease, and the anemia is often nonregenerative. Toxins such as lead or oil ingestion can result in hemolytic anemia.

Polycythemia is rare in birds and is defined as a PCV >70%. It has been reported in birds with chronic respiratory diseases and in macaws with pulmonary hypersensitivity syndrome, a condition that occurs in macaws housed in poorly ventilated areas with birds that produce large amounts of powder down such as cockatoos, cockatiels, and African grey parrots.

Avian RBCs are nucleated, so traditional mammalian methods of WBC determination are not adequate. Various diluents (eg, Eosinophil Unopette®, Natt-Herrick's® solution) are available to enable accurate WBC determinations. Estimated WBC counts are less accurate but can be useful when the individual performing the estimate produces blood smears of consistent quality and thickness. Normal total WBC counts vary with species and age (see TABLE 15). Adult cockatiels often have total WBC counts of 4,000–7,000 × 10³/μL. Adult macaws are usually at the high end of the normal avian range (12,000–15,000 × 10³/μL).

For many avian species, reference values for WBC counts are still being determined. A leukocytosis, and the differential or type(s) of WBCs that are increased, can identify underlying disease and give an indication of the most likely causes. The differential count in birds can be affected by bacterial, fungal, and viral diseases, as well as toxins. The types of avian WBCs are the heterophil, eosinophil, monocyte, and basophil.

Heterophils are equivalent to mammalian neutrophils, with much the same function. Avian heterophils contain lysosomal enzymes and are bactericidal and phagocytic. They are the first cells to respond to any infectious or inflammatory disease process. Instead of forming a liquid purulent material, avian heterophils form an inspissated, caseous material. This caseous material is

then walled off by macrophages and fibrous tissue to form a granuloma. Heterophilia can occur during infection or from stress. Heteropenia is often associated with an overwhelming infection or viral disease.

Lymphocytes function in antibody and antigen production and cellular and humoral immune reactions. Lymphocytosis may occur in chronic infections (chlamydial, fungal, mycobacterial) or with lymphoid neoplasia. In some species (eg, canaries and Amazon parrots), up to 70% of the WBCs are normally lymphocytes. Lymphopenia is often associated with viral diseases (eg, circovirus or polyomavirus) or sepsis.

Monocytosis is often associated with chronic granulomatous diseases such as chlamydial, fungal, or mycobacterial infection. Eosinophilia has been reported with parasitic diseases and has also been associated with delayed hypersensitivity reactions. Basophilia can occur during inflammatory conditions and chronic infection.

Physiologic differences in birds create variations from accepted mammalian normal values for many **biochemical measurements**. Because of the excretion of uric acid rather than urea as the primary product of protein metabolism, uric acid levels are significantly higher in birds than in mammals, whereas BUN is significantly lower. Uric acid may be increased in severe renal disease or with articular gout (see p 1926). Severe dehydration may increase uric acid levels, but levels return to normal with rehydration.

No reliable biochemical indicator is currently available to detect early renal impairment.

Serum or plasma glucose is higher in birds than in mammals, with levels of 250–400 g/dL common, depending on species. Levels that indicate diabetes also vary with species and individuals but often are >700–800 g/dL (see p 1925).

Hepatic enzymes measured commonly include AST and LDH, which have normal values several times those of mammals (AST, 10–400 U/L; LDH, 75–450 U/L). Measurement of CK is often performed concurrently to differentiate increased values of AST due to muscle necrosis from those due to hepatic damage. LDH is a short-lived enzyme of limited usefulness in detection of hepatic necrosis. ALT levels are very low compared with those in mammals (5–15 U/L); however, increased levels can indicate hepatocellular necrosis. Birds have low bilirubin reductase levels; therefore, total bilirubin is normally also very low, and increases with hepatic disease are not consistent (total bilirubin range 0–0.1 mg/dL). Birds also do not become icteric with hepatic disease as do mammals; they excrete biliverdin through their kidneys, resulting in yellow or lime-green urates. Bile acid measurements are useful indicators of hepatic function, with levels <100 μ mol/L considered normal for most avian species (depending on the laboratory). Establishing reference values for different avian species will enhance the usefulness of bile acid assays.

TABLE 15 NORMAL HEMATOLOGIC VALUES IN SELECTED PET BIRD SPECIES

Bird	Sample Size (n)	WBC $\times 10^3/\mu$ L	PCV
African grey parrots (<i>Psittacus erithacus</i>)	176	8–11	42–50
Amazon parrots (<i>Amazona</i> spp)	155	7.5–12.5	44–49
Budgerigars (<i>Melopsittacus undulates</i>)	57	2.5–6.5	42–53
Cockatiels (<i>Nymphicus hollandicus</i>)	212	3.0–7.8	45–57
Cockatoos, umbrella (<i>Catua alba</i>)	115	5–13	38–48
Conures (<i>Aratinga</i> spp)	62	7.5–11.5	42–49
Eclectus parrots (<i>Eclectus roratus</i>)	44	7.0–11.7	41–49
Lovebirds (<i>Agapornis</i> spp)	31	4.5–9.0	39–51
Macaws (<i>Arara</i> spp)	146	8.5–15.5	41–52
Pionus parrots (<i>Pionus</i> spp)	28	7.0–11.5	44–51
Quaker/monk parrots (<i>Myiopsitta monachus</i>)	62	5.5–12.5	38–48
Senegal parrots (<i>Poicephalus senegalus</i>)	26	6.5–12.0	37–49

Note: Samples were obtained at wellness examination. No other concurrent disease was detected or treated, except for behavioral concerns.

Calcium and phosphorus values are similar to those found in mammals. These levels may increase up to 3-fold in hens in preparation for egg laying (ie, calcium ~30 mg/dL and phosphorus >10 mg/dL), usually with a relatively normal ratio of these minerals. Total solids as measured via refractometer are significantly lower in birds than in mammals, with levels of 3–5.5 g/dL normal for most species. Total solids can also increase in reproductively active hens.

Cholesterol and triglyceride reference ranges are still being evaluated, but reference values are ~180–250 mg/dL for cholesterol and 51–200 mg/dL for triglycerides. Increased levels of both triglycerides and cholesterol have been reported in birds fed a high-fat diet. High levels can also be seen in reproductively active females and may be a risk factor in birds that develop atherosclerosis. Omega-3 fatty acids added to the diet as well as dietary restriction and conversion to a pelleted diet have been shown to reduce hypertriglyceridemia and hypercholesterolemia.

Hematology and Plasma Biochemistry of the Neonate: Neonates have some important differences from mature birds in their hematologic and biochemical parameters. Neonates have a lower PCV (20%–30%). The normal adult range is present beginning at 10–12 wk in most species. Neonates have a lower total protein (1–3 mg/dL) and concomitant lower plasma albumin concentrations than adults. A high WBC count (20,000–40,000 cells/uL) is common in neonates; the normal adult range is present at 9–11 wk of age. Neonates also have lower uric acid values and higher alkaline phosphatase and CK concentrations than adults.

Routine Medical Procedures: Injections can be given by several routes. SC injections are used for fluid administration, some vaccinations, and many routine medications such as antibiotics. Preliminary studies show that the SC route may be as effective as IM injections for most medications, without the associated muscle necrosis. To ensure that the medication or fluid being injected is actually deposited subcutaneously, the skin must be clearly visualized; use of alcohol to wet the skin and feathers is recommended to aid in visualization. Insulin syringes (50 U or 0.5 mL) with 27-gauge needles are invaluable for accurate dosing when small quantities must be administered. SC fluids are often used in birds. To maximize their absorption and minimize discomfort, fluids should be

warmed to 102°–106°F. Sites of administration are the lateral flank, the inguinal web, and the back. Maintenance fluids are estimated at 50 mL/kg divided bid-tid. In dehydrated birds, 50% of the total daily maintenance can be administered SC (25 mL/kg) and repeated every 6–8 hr until hydration is reestablished.

IM injections are given into the pectoral muscles in most pet birds; leg muscles are also used in some species, particularly raptors. The muscle fibers of birds are more vascular and tightly packed than those of mammals, making both muscle necrosis and inadvertent IV injection more likely.

IV injections are occasionally indicated in birds. Common medications administered IV are some antibiotics, amphotericin B, chemotherapeutic drugs, contrast media, and fluids.

Indwelling catheters can be placed in the jugular, basilic, or medial metatarsal veins for constant-rate infusions or intermittent fluid administration. Intraosseous (IO) catheters can also be inserted, generally in the proximal tibiotarsal bone or distal ulna. A standard hypodermic needle may be used (usually 25-gauge for initial entry, followed by a second 22-gauge needle sutured in place), or a spinal needle with stylet may be used for large birds. Without a stylet or second needle, a bone plug may obstruct the needle. The IO or IV catheter is intermittently flushed with warm saline whenever fluids are not being infused. Maintaining an IV catheter in an avian patient can be challenging, and IO catheters are often preferable for long-term fluid therapy. However, fluid therapy via IO catheters can be painful to the bird, especially after 1–2 days.

Crop (gavage) feeding may be used to meet caloric needs in anorectic birds. Commercial formulas are available and convenient to use. Adequate hydration and normal body temperature (103°–106°F [39°–41°C]) must be established before initiating crop feeding to prevent desiccation of the crop food and GI stasis. In adult birds, generally 30 mL/kg can be administered tid-qid. Baby birds have a much more distensible crop and will hold ~10% of their body weight per feeding (100 mL/kg). Oral medications may be added to the crop feeding or given directly by mouth. The technique of holding the bird so that the medication is administered into the commissure of the mouth and rolls onto the tongue will minimize stress, loss of medication, and the danger of aspiration. Medicating birds can be quite difficult for owners; wrapping the bird in a towel for

administration of medication can be stressful for both the bird and the owner and, in some cases, adversely affect the human-bird bond. Compounding medications to make them more palatable and in a smaller volume can be very helpful in using oral medications. Mixing the flavored medication with favorite foods, juice, or baby food can also help ensure compliance. Medications administered in the water are indicated only in special circumstances such as small flocks of birds or aviary birds not used to handling and would require daily netting and restraint, or in special cases in which an owner cannot handle a bird. Enrofloxacin and doxycycline in drinking water generally provide adequate blood levels for efficacy. However, lack of accurate dosing, stability of the medication, and palatability make this route undesirable in most cases.

Sedation is sometimes desirable for diagnostic or treatment procedures to reduce stress and minimize fear. Midazolam administered at 0.5–1 mg/kg, IM, or 1–2 mg/kg intranasally (IN) is a safe and effective sedation protocol in most pet birds; flumazenil (0.02–0.1 mg/kg, IM or IN) may be given to reverse the effects. If the bird is thought to be in pain or discomfort, butorphanol (0.5–3 mg/kg, IM or IN, depending on species) may be given alone or with midazolam. Amazon parrots often require the higher dosage (2–3 mg/kg) of butorphanol, whereas raptors require the lower dosage (0.5 mg/kg). Isoflurane or sevoflurane anesthesia delivered by face mask can also be used alone or in conjunction with sedation for more prolonged procedures or painful treatments.

Intubation in birds is relatively easy, because the absence of an epiglottis facilitates visibility of the tracheal opening and arytenoids. Fasting before anesthesia should be of minimal duration; fasts of 4–6 hr are typical. Regardless of the duration of the fast, the crop should be palpated for the presence of food or fluid before anesthesia. Delayed crop emptying is common in clinically ill birds. If anesthesia must be administered to a bird with food or water still in the crop, fluid should be removed by a feeding tube if possible, and the head should be elevated for the duration of anesthesia, regardless of whether the bird is intubated. Endotracheal tubes should be uncuffed, because the absence of a tracheal ligament increases the risk of tracheal necrosis if a cuff is overinflated. Even an uncuffed tube can cause tracheal damage or necrosis; therefore, after the bird is intubated, head movement should be

minimized. A small animal ventilator can be used for most birds as small as 100 g and can greatly improve ventilation during anesthesia. If a mechanical ventilator is not available, manual intermittent positive-pressure ventilation will increase oxygenation in anesthetized birds. A capnograph, pulse oximeter, and Doppler are also useful for anesthetic monitoring. The normal body temperature of most psittacines is 103°–106°F (39°–41°C). Birds tend to lose body heat rapidly when anesthetized, and maintaining body temperature during prolonged anesthesia or surgery is crucial for recovery. Birds with feather loss are more at risk of hypothermia. Water warming blankets under the bird or Bair Huggers™ can be used effectively to maintain body temperature. An emergency drug sheet and emergency drugs should be readily available whenever a bird is anesthetized.

Environmental management is very important; severely ill birds benefit greatly from increased environmental temperature and humidity (eg, use of commercial incubators with temperature and humidity controls). For at-home emergencies, a warm environment can be created by wrapping clear plastic wrap around three sides of the cage and placing an electric heating pad on the remaining side, being sure the bird cannot reach the pad. Digital thermometers with remote probes can provide accurate monitoring of environmental temperatures. A quiet location, away from the sound of barking dogs and other excessive activity, will decrease stress.

The cage arrangement can be critical for ill birds. If a perch is supplied, the food and water must be elevated so that the bird has ready access without having to climb down from the perch. Often, it is best to remove perches entirely from the cage of an ill bird and place the food and water container on the cage floor so that the bird has easy access and does not expend energy simply trying to maintain a perched position.

PEDIATRIC DISEASES

Birds are classified by their maturity level at hatching. Parrots, doves, and finches are altricial, hatched without feathers, with eyes closed, and helpless. Poultry, ratiates, and waterfowl are born precocial, with down feathers, open eyes, and the ability to walk and feed themselves at hatching. Psittacine neonates are completely dependent on the parent birds for warmth and food; they also lack a functional immune system and are more susceptible to disease. Because of these characteristics,

proper husbandry and nutrition of the chick and parents is critical for their health and survival.

Today, chicks are either parent raised (most small parrots such as budgerigars and lovebirds) or hand raised (large parrots). There are advantages and disadvantages with both methods. Most aviculturists believe that hand-raised parrots make better pets and that incubator hatching and hand raising reduces the incidence of some infectious diseases. Disadvantages of hand raising can include stunting and an increase in husbandry-related diseases such as crop stasis or aspiration pneumonia. Many avian veterinarians and behaviorists also believe that hand raising may lead to behavioral issues because chicks cannot learn species-specific behaviors from parent birds and become imprinted on people.

The health of a chick depends on many factors, such as the health of the parents, genetics, the incubation process, nutrition (type of food, temperature, and consistency), environment (humidity, warmth, and cleanliness), and exposure to infectious diseases. When an ill neonate is presented, the history of not only the chick, but also of its parents, the aviary, and the nursery are important. Is the chick being hand fed or parent fed? Is the chick incubator hatched? How old is the chick? Is the nursery closed, or are chicks taken in from other facilities? What is the temperature and humidity of the nursery? What is the type of food fed, its consistency, temperature, amount fed, and frequency of feedings? What are the cleaning practices?

General environmental temperature guidelines are for newly hatched psittacine chicks, 92°–94°F; unfeathered chicks, 90°–92°F; pin-feathered chicks, 85°–90°F; and fully-feathered and weaned chicks, 75°–80°F.

A diet of 25%–30% solids should be fed to chicks >2 days old (more dilute formula for newly hatched), with the environmental temperature between 102°–106°F. Most medical issues arise in young birds in the first week of life, at fledging, or at weaning.

Physical examination of the chick can typically be done with minimal restraint, and the chick should be kept warm throughout the examination. The crop should be palpated at the beginning of the examination. Birds with food in their crop should be handled carefully to reduce the risk of regurgitation and/or aspiration. Mentation and body weight (a growth chart should be requested from the breeder if possible) should be noted. Before they fledge, chicks have little musculature over

their keel bone; therefore, the muscle and subcutaneous fat over the hips, elbows, and toes should be evaluated. It should be determined whether the ears and eyes are open, or when they opened, if known.

The skin, feather quality, and distribution of the feathers should be examined. Healthy chicks have yellowish pink skin, and feathers first appear on the head, wing, and tail. Abnormal feather growth or delayed or abnormal opening of eyes can be a sign of stunting. Stress bars (lucent areas across the vane of the feathers) indicate a period of stress when that portion of the feather was forming. These are common during weaning, so a few stress bars are not uncommon. A large number of stress bars may indicate an underlying illness or condition.

The oral cavity should be moist with no plaques or lesions, and the choana should be examined for blunting of the choanal papilla, which can indicate hypovitaminosis A or chronic respiratory disease. The crop may be quite full in a neonate. The veterinarian should observe for crop contractions and ask when the chick was last fed and how much was fed, to determine whether the crop is emptying normally. Nestlings have a normally distended abdomen because of an enlarged proventriculus and ventriculus from being fed large amounts of formula. Chicks should be handled carefully to avoid placing excess pressure over their abdomen.

The spine, neck, wings, legs, and feet should be examined for abnormal curvature or weakness and evaluated for normal posture. The vent should be clean of debris.

Aspiration Pneumonia: Aspiration pneumonia is one of the most common causes of respiratory disease in hand-fed psittacine birds. Chicks can aspirate while being fed large quantities of liquid formula, especially when being fed by an inexperienced person. Aspiration often occurs as birds begin to wean.

Clinical signs include increased respiration, respiratory distress, poor feeding response, and depression. Depending on the age and size of the chick, a CBC and radiographs may aid in the diagnosis; however, diagnosis is often based on history and physical examination findings.

Treatment consists of oxygen therapy, nebulization, antibiotics, antifungals, warmth, supplemental fluids, and anti-inflammatory drugs. Prognosis is guarded.

Bacterial Disease: The normal gut microflora in chicks is primarily gram-positive

bacteria. The presence of large numbers of gram-negative bacteria or budding yeast indicates infection. Bacterial infections can occur from multiple sources: an unsanitary environment, inappropriate storage of formula, and use of unclean feeding utensils.

Clinical signs can include crop stasis, poor feeding response, regurgitation, depression, and dehydration. Diagnosis is based on clinical signs and results of a fecal or crop Gram stain, CBC (leukocytosis, monocytosis), and culture and sensitivity testing.

Treatment is with antibiotics, based on culture and sensitivity results if available, and supportive care. Neonates on antibiotics often develop secondary yeast infections; therefore, prophylactic treatment with an antifungal drug such as nystatin or fluconazole may be warranted (see TABLE 18, p 1901).

Yeast Infection: *Candida albicans* can be present in low numbers in a healthy chick but may proliferate in the presence of antibiotic treatment, malnutrition, stress, or immunosuppression. It is the most common fungal infection in young birds and can result in thickening of the crop mucosa, which may be palpable externally and has been described as "Turkish towel in appearance."

Clinical signs are crop stasis, poor feeding response, and depression. There may be lesions or plaques in the oral cavity. Intestinal or gastric candidiasis can result in malabsorption. Diagnosis is with fecal or crop cytology revealing large numbers of budding yeasts.

Treatment is with antifungal medications. Antifungals should be given to baby birds prophylactically when on antibiotic therapy to prevent yeast overgrowth (see p 1899).

Viral Disease: The most common viral diseases in psittacine chicks are polyoma virus, avian bornavirus, proventricular dilatation disease and circovirus, and psittacine beak and feather disease (see p 1908).

Foreign Bodies: Foreign bodies can be found in young birds, including ingestion of substrate, toys, or feeding tubes. Diagnosis is based on clinical signs, history, and radiographs or CAT scan results. Treatment may require an ingluviotomy to gain access to the mucosal surface and lumen of the crop, proventriculus, or ventriculus. Removal of a foreign body, such as a feeding tube, is the most common indication for this procedure in pediatric birds. In larger or

older birds, a rigid endoscope may be necessary to visualize and extract upper GI foreign bodies. The endoscope may be used either orally or through an ingluviotomy incision, depending on the accessibility of the foreign body.

Crop Stasis: Crop stasis, defined as the inability of the crop to empty in a normal time frame, is a common condition in hand-fed chicks. Crop stasis can occur due to poor husbandry and nutritional practices or primary disease. Environmental temperatures that are too cold or inadequate humidity can lead to crop stasis, as can feeding formula that is too cold or thick. All aspects of the nursery and feeding practices should be evaluated.

Clinical signs include a distended crop, dehydration, poor feeding response, regurgitation, and depression. Diagnosis is based on physical examination findings, palpation of the crop, and cytology and/or culture of the crop contents.

Treatment may include physically emptying the crop, fluid therapy, antibiotics and/or antifungals, and providing smaller, more dilute, and more frequent feedings once the crop is emptying.

Crop Burns: Crop burns result from feeding baby bird formula that is too hot. This can occur when a microwave oven is used to heat the formula (not recommended because of the formation of hot spots within the formula). Mild cases may result in red and inflamed skin in the area of the crop. Second- and third-degree burns will be acutely inflamed and blistered and may lead to tissue necrosis and fistula formation. In subacute cases, birds may be presented with food draining from a fistula through the crop wall and skin. Diagnosis is based on history, clinical signs, and physical examination findings. Treatment includes antibiotics, supplemental fluids, anti-inflammatory drugs, and nutritional support. Surgical repair is often required but should be postponed until the burned area is well demarcated (usually several days); repair involves debriding devitalized tissues, separating the crop wall from overlying skin, and closing the two layers separately. Prognosis is good if the remaining crop wall is sufficient for closure and the esophagus is intact.

Esophageal and Pharyngeal Trauma: Esophageal and pharyngeal trauma occurs from improper hand-feeding technique, either with the syringe tip or a rigid feeding

tube. This leads to tissue trauma, cellulitis, and distribution of food into subcutaneous tissues. Birds may present depressed, anorexic, cold, and dehydrated, with poor feeding response. Swelling may be palpable in the neck area. Diagnosis is based on the history of hand feeding and oral or endoscopic examination to identify the puncture site.

Surgically opening the pockets, flushing the wounds, and allowing for drainage is important in treatment, along with antibiotics, analgesics, anti-inflammatory drugs, and supportive care. Prognosis depends on severity of the lesion, amount of food deposited in the tissues, and how quickly the lesion is detected and treated. In severely traumatized cases, prognosis is guarded to poor.

Hepatic Lipidosis: The liver relative to total body weight is typically larger in neonates than in adult birds, so some degree of hepatomegaly is normal in chicks. However, neonates with hepatic lipidosis typically have the following characteristics: 1) they are usually still being hand fed, often with a commercial formula to which the owners have added peanut butter, oil, or some other high-fat food, and 2) they are usually heavy for their age and exhibit severe respiratory distress. These birds must be handled gently and minimally. Cool oxygenation is the best first step. They have virtually no air sac capacity, and the stress of feeding and breathing at the same time may exceed their oxygen reserves. Drastically reducing the quantity of crop food per feeding, adjusting the content of the formula, and adding lactulose to the formula are the general nutritional changes required. Parenteral fluid supplementation will help keep the initially hyperthermic bird hydrated. When possible, blood samples should be submitted to check for concurrent infection or other diseases.

Failure to Thrive: Hereditary, congenital, and husbandry issues may affect the growth of young birds. Stunted chicks are thin, and the head is disproportionately large. Toes, wings, and hips are thin; eye and ear openings may be delayed. The skin may be dry and without adequate subcutaneous fat. Abnormal feather patterns (swirls) may develop on the head of a stunted chick. Stunting can develop early, in the first 30 days, or shortly after purchase from the breeder. Usually stunting is caused by husbandry and nutritional issues, often

because of handlers inexperienced at hand feeding. Inappropriate quantities of hand feeding formula, incorrect temperature, and incorrect consistency of the formula cause reduced feeding response and/or GI stasis. Birds purchased soon after arriving at the pet store are often mistakenly labeled as "weaned." In nature, these birds would be eating partially on their own but still receiving supplementation from their parents. When such a bird is sold to an uninformed owner, it usually takes a few days to a few weeks for the bird's insufficient food intake to create noticeable debilitation and weakness. These birds may also have underlying problems, eg, decreased hepatic function or immunosuppression.

Diagnosis is based on the history and physical examination findings. Treatment is supportive (fluids, nutritional support, and warmth). Antibiotics or antifungal drugs may or may not be needed, based on diagnostic test results. Some of these birds will survive, but many will not.

Splayleg or Rotational Leg Deformity:

The term splayleg is a catchall for deformities of the legs in young birds. Often, there are laxities of the ligaments of the stifle and/or angular deformities of the femur, tibiotarsus, and tarsometatarsus. Causes are poorly documented, but risk factors include nutritional deficiencies (consistent with those of metabolic bone disease, *see* p 1917) and insufficient support or substrate in the enclosure.

Various methods of external coaptation have been devised and are most successful when the bird is young. Placing the chick in a deep enclosure with a suspensory device or cloth that allows the leg to be directed vertically or taping the legs together in a "hobble" may be corrective if implemented early. Stifle subluxation can develop because of disruption of the cruciate and/or collateral ligaments. Surgery (osteotomy and external skeletal fixator) may be used for rotational deformities.

Beak Deformities: Mandibular

prognathism commonly occurs in several birds from the same clutch and is seen most commonly in cockatoos. If detected early, the hand feeder may be able to correct prognathism by pulling the beak upward and out for several minutes, several times a day. In older chicks, the condition may require a prosthetic that pulls the upper beak out and over the lower beak. This can

be cumbersome and painful, and the prosthetic often needs to be reapplied. Trans-sinus pinning is a more recent and more reliable method of correction but carries some risk.

Scissor beak is a lateral deviation of the upper or lower beak. This may be caused by improper incubation temperature or possibly genetic factors in some chicks. If detected early, mild scissor beak can be corrected by manually placing a counter force on the beak for several minutes 2–3 times daily. More severe defects may require placing a beak prosthetic.

Constricted Toe Syndrome: Constricted toe syndrome is fairly common in neonates, often affecting more than one digit. An annular band of fibrous tissue forms at a joint of the digit, impeding circulation. The cause is unknown, although either excessively low or high humidity and septicemia have been proposed. This syndrome is most common in *Eclectus* parrots and macaws, usually in chicks housed in environments with inadequate humidity.

When detected early, debriding the annular band and applying a moist dressing is often effective. In more severe cases, small longitudinal incisions can be made on the medial and lateral surfaces of the affected toe to allow for swelling and to promote circulation. If circulation loss is severe and necrosis is apparent, amputation may be necessary. NSAIDs can be used to reduce inflammation and pain. A bandage will protect the site from contamination and secondary infection. Early detection and intervention is critical in successful treatment.

Toe Malposition: Toe malposition usually involves the lateral or fourth toe, which points forward instead of backward. If discovered early, malposition is easily corrected by taping the toe in a normal position. In young birds, the foot can be bandaged with the toe pointing backward in the normal position for several days. Older chicks may need prolonged bandaging.

Cryptophthalmia (Eyelid Atresia): Cryptophthalmia is most commonly seen in cockatiels and is often observed in clutch mates. The condition is usually bilateral. The eyelids, if present, are generally normal in conformation but greatly reduced in length, leading to small to nonexistent palpebral fissures. If the palpebral fissure is sufficient to allow functional vision, no

correction is needed or recommended. Extending the palpebral fissure by conjunctival eversion can be performed with modest success when the palpebral aperture is absent or reduced and functional vision is compromised.

"Lockjaw": *Bordetella avium* is the causative agent of a syndrome that can appear in clutch mates, most commonly in cockatiels. Bacterial invasion from the sinuses progresses to the skeletal muscle of the mandible, resulting in a myositis and "lockjaw." Treatment is antibiotics and supportive care. Manually opening the beak can be difficult, so feeding and medicating the bird can be challenging. Prognosis is guarded to grave.

Choanal Atresia: Choanal atresia is seen most commonly in African grey parrots but has also been documented in other species. With choanal atresia, the communication between the nares, infraorbital sinus, and the choana is incomplete or absent. Clinical signs are increased mucus accumulation and possible infection in the nares and sinuses. Blunted choanal papilla may be detected on oral examination. Diagnosis is by endoscopic examination of the choana.

Atresia can be treated by creating an opening in the choana through the nares with an intramedullary pin. A red rubber feeding tube is then threaded through the nares, out the choana, and back behind the head of the bird and is left in place for 2–3 wk. This procedure is usually performed in stages, beginning with a small tube first and following with a larger tube.

BACTERIAL DISEASES

Bacterial diseases are common in pet birds and should be considered in the differential list of any sick bird. Inappropriate husbandry and nutrition are often contributing factors. Neonates and young birds are especially susceptible. GI and respiratory infections are most common and can lead to systemic disease.

Normal bacterial flora of companion birds include *Lactobacillus*, *Corynebacterium*, nonhemolytic *Streptococcus*, *Micrococcus* spp, and *Staphylococcus epidermidis*.

The most commonly reported pathogens are gram-negative bacteria (*Klebsiella*, *Pseudomonas*, *Aeromonas*, *Enterobacter*, *Proteus*, and *Citrobacter* spp, *Escherichia coli*, and *Serratia marcescens*). *Pasteurella*

spp have been reported as possible septicemic agents in birds attacked by pet cats or rats. *Mycobacterium* and *Chlamydia* are common intracellular bacterial pathogens. Infections with *Salmonella* spp are occasionally seen.

The most common gram-positive bacterial pathogens are *Staphylococcus aureus*, *S. intermedius*, *Clostridium*, *Enterococcus*, *Streptococcus*, and other *Staphylococcus* spp. Methicillin-resistant *S. aureus* (MRSA) is rare but has been documented. *Mycoplasma* spp have been implicated in chronic sinusitis, often found in cockatiels. This organism is difficult to culture, and the true incidence is unknown. Staphylococci and streptococci (especially hemolytic strains) and *Bacillus* spp are thought to be responsible for several dermatologic conditions in psittacine birds. Staphylococci are often isolated from lesions of pododermatitis (bumblefoot) in many avian species.

Clostridial organisms are common secondary invaders of damaged cloacal tissue in birds with cloacal prolapse or papillomatosis. Several specific syndromes of birds can arise from various species of clostridia. A Gram stain or anaerobic culture is necessary to identify these organisms.

Diagnosis is based on clinical signs and results of cytologic examination and culture of tissue or swab samples. A Gram stain is used to identify normal flora, yeast, and spore-forming bacteria. Culture is needed to identify specific organisms and their sensitivity to antibiotics. Samples can be obtained from the respiratory, GI, urinary, and reproductive tracts. Sample sites for culture and cytology include the choanal slit, sinus, cloaca, wounds, conjunctiva, internal organs (via ultrasound-guided fine-needle aspirates, endoscopic examination, or surgery), and blood.

Treatment is based on location of infection and results of culture and sensitivity testing. See TABLE 16 for a partial list of frequently recommended antimicrobials.

Chlamydiosis

(Psittacosis, Ornithosis)

Chlamydia psittaci is an obligate intracellular bacterium that can infect all companion birds but is especially common in cockatiels, budgerigars, and parrots. Current state and federal regulations governing the testing, reporting, treatment, and quarantine for *Chlamydia* should be followed.

TABLE 16 ANTIMICROBIALS USED IN PET BIRDS

Antimicrobial ^a	Dose, Route, and Frequency ^b
Amikacin sulfate	15 mg/kg, IM, bid
Amoxicillin/clavulanate	125 mg/kg, PO, tid
Azithromycin	50 mg/kg/day, PO
Ceftazidime sodium	75 mg/kg, IM, tid
Ciprofloxacin	25 mg/kg, PO, bid
Clindamycin	100 mg/kg, PO, bid for 5 days to treat <i>Clostridium</i>
Doxycycline	25 mg/kg, PO, bid for 45 days ^c
Doxycycline injectable, 20 mg/mL	75–100 mg/kg, IM or SC, every 5 days, then weekly for six treatments ^c
Enrofloxacin	15–20 mg/kg, PO or IM, bid
Metronidazole	25 mg/kg, PO, bid for 14 days for <i>Giardia</i> , <i>Clostridium</i>
Marbofloxacin	2.5 mg/kg/day, PO
Trimethoprim/sulfamethoxazole	50–100 mg/kg, PO, bid

^a Most are unapproved for use in birds, and caution is indicated.

^b May vary with etiology and species treated

^c Duration and dosage for treatment of *Chlamydia*

The incubation period of *C psittaci* is from 3 days to several weeks. The organism is excreted in the feces and in nasal and ocular discharge of infected birds. Although labile in the environment, the organism can remain infectious in organic debris for >1 mo.

Clinical signs range from asymptomatic carriers to severe disease and may include ocular, nasal, or conjunctival irritation and discharge; anorexia; dyspnea; depression; dehydration; polyuria; biliverdinuria; and diarrhea. Clinically ill birds may have a leukocytosis, monocytosis, and increased AST and bile acid concentrations. Radiographs may reveal hepatomegaly, splenomegaly, or airsacculitis.

Diagnosis of *C psittaci* can be challenging, especially in the absence of clinical signs. Few laboratories will culture the organism. Various antibody and antigen tests are available, but these have limitations. Serologic tests available include indirect fluorescent antibody, complement fixation, ELISA, and fluorescent antibody. A positive serologic test result is evidence that a bird has been infected but might not indicate active infection. Exposed but clinically normal birds may produce appreciable antibody titers. Acutely ill birds may not mount an antibody response, also yielding false-negative results. These factors make an antibody test an insufficient screening tool for chlamydiosis in birds when used alone. Because of the intracellular nature of *Chlamydia* and the reduction in numbers of organisms that accompanies antibiotic use, false-negative results of antigen tests are common. With the advent of PCR testing, diagnosis of *Chlamydia* is more readily accomplished, and attempts to culture the organism or identify elementary bodies in tissue specimens are rarely done. Laboratories should be consulted before shipment to identify appropriate samples and shipping methods. Because of the difficulty in diagnosing *Chlamydia*, a single test method may not be adequate, and a PCR assay of a combined conjunctival, choanal, and cloacal swab sample, in conjunction with a serologic test, is recommended.

Doxycycline is commonly used for treatment of *Chlamydia* infection. Because the treatment period required to eliminate the organism is uncertain, treatment for 45 days is recommended. Dietary calcium sources should be reduced if doxycycline is administered orally. Clinically ill birds should be treated with oral or injectable doxycycline initially to establish therapeutic drug levels quickly. Formulations of doxycycline in the food or water and

chlortetracycline-impregnated seeds or other foods are available or can be manufactured to treat infected flocks. A doxycycline-medicated feed for budgerigars can be created by combining 300 mg of doxycycline hyclate (from capsules) with 1 kg of a mixture of oats, millet, and sunflower oil (1 part cracked steel oats is mixed with 3 parts hulled millet; add 5–6 mL of sunflower oil per kg of the oat/seed mixture). Fresh medicated mix should be made daily and fed as the sole diet for 30 days. Doxycycline may also be added to the water for cockatiels (200–400 mg doxycycline hyclate/L of water), Goffin's cockatoos (400–600 mg/L), and African grey parrots (800 mg/L). A doxycycline syrup, using a monohydrate- or calcium-syrup formulation, can be given at 40–50 mg/kg/day, PO, to cockatiels, Senegal parrots, and blue-fronted and orange-winged Amazon parrots; in African grey parrots, Goffin's cockatoos, blue and gold macaws, and green-winged macaws, the recommended dosage is 25 mg/kg/day, PO. These indirect modes of antibiotic administration depend on ingesting sufficient quantities of antibiotics to maintain effective blood levels, which may not always occur. Only certain formulations of doxycycline can be given IM or SC. Doxycycline injectable has been successful at 75–100 mg/kg every 5–7 days for 6 wk.

Because *C psittaci* is transmissible to people, the zoonotic risk must be considered when designing the diagnostic and therapeutic plan. Current state and federal regulations governing the testing, reporting, treatment, and quarantine for birds infected with *Chlamydia* should be followed. A compendium of control measures is available at www.nasphv.org/documents/Compendia-Psittacosis.html.

Avian Mycobacteriosis

Avian mycobacteriosis infections are usually caused by *Mycobacterium avium* and *M. genavense*. *Mycobacterium intracellulare*, *M. bovis*, and *M. tuberculosis* are less commonly reported. Psittacine birds most commonly infected are brotogeris parakeets and Amazon parrots. Avian mycobacteriosis is a chronic progressive disease affecting the liver and GI tract. Clinical signs include anorexia, weight loss, depression, and diarrhea. Birds with early infections may show few clinical signs.

Diagnosis of mycobacterial infection can be challenging and is most reliably done by acid-fast staining, culture, and/or DNA probe of a biopsy specimen. Biopsy of the

liver, intestines, spleen, or a suspected mass is recommended; however, PCR testing of ultrasound-guided fine-needle aspirates of the liver may be diagnostic. Avian mycobacteria are difficult to culture, so a negative culture result does not exclude infection. A fecal acid-fast stain has poor sensitivity but may identify birds shedding large numbers of organisms; PCR testing of a fecal sample is a more sensitive test method. Most birds will have a significant leukocytosis with a monocytosis. Radiographs may reveal hepatomegaly and splenomegaly. Granulomas may occur that may be confused with tumors.

If infected birds are in a multiple bird collection, determining whether other birds are infected can be difficult. Husbandry and sanitation should be assessed. High-risk birds should be isolated and monitored by serial examinations (weights), CBCs, and fecal acid-fast stains or PCR testing.

Treatment involves combination antibiotic therapy for 6–12 mo or longer. Owner compliance is critical and should be discussed at length before beginning treatment. Use of multiple antibiotics (typically three) is recommended, because mycobacterial organisms are prone to developing antibiotic resistance. Antibiotics in differing combinations that have been used successfully are rifabutin (45 mg/kg), clarithromycin (60–85 mg/kg), ethambutol (30 mg/kg), and enrofloxacin (20–30 mg/kg). All combinations are used daily.

Birds with advanced disease and granuloma formation have a poor prognosis. Although human infection has not been associated with exposure to birds, precautions should be taken for zoonotic risk, especially in immunocompromised people.

MYCOTIC DISEASES

Fungal diseases are common in companion birds. Often, they are a secondary infection in an already ill or immunocompromised bird. The most common fungal diseases are respiratory tract infections caused by *Aspergillus* spp and GI tract infections caused by *Candida* spp. *Macrorhabdus* is an unusual fungus that affects the GI tract and occurs most commonly in small pet birds (budgerigars, lovebirds, finches, parrotlets, and cockatiels).

Candidiasis

Candidiasis is a common fungal disease seen in pet birds. The etiologic agent is the opportunistic yeast *Candida albicans*,

which commonly affects the GI tract. Although *C. albicans* is the most common isolate, others including *C. tropicalis*, *C. parapsilosis*, *C. glabrata*, and *Hansenula* spp may also be found and may be refractory to treatment.

C. albicans is not generally considered a primary pathogen. Small numbers of *Candida* are commonly found in the GI tract of birds and may become pathogenic when normal digestive flora are disrupted by immunosuppression. (See also CANDIDIASIS, p 2791.)

Candidiasis most commonly affects unweaned chicks. Those on broad-spectrum antibiotics are most at risk. Neonatal cockatiels are considered most susceptible. Infection may be endogenous, because of yeast overgrowth, or caused by oral inoculation of large numbers of *Candida*, either by parental feeding or by hand feeding with utensils that are inadequately cleaned.

Clinical signs in adult birds are typically mild and may include mild weight loss, lethargy, and dull plumage. Young birds may have more severe disease, especially if they are immunocompromised. Clinical signs in juvenile birds include anorexia, crop stasis, white plaques in the oral cavity, regurgitation, and weight loss. Localized infections in the oral cavity can lead to difficulty swallowing or halitosis. With severe infections, there may be complete crop and GI stasis. Thickening of the crop may develop (Turkish-towel appearance). Infection of the proventriculus and ventriculus can also occur and may lead to more severe clinical signs such as weight loss, regurgitation, diarrhea, and depression. See TABLE 17 for differential diagnoses for regurgitation in birds.

Diagnosis of candidiasis is by identifying *Candida* spp on a Gram, Romanowsky-type, or new methylene blue stain of the feces, crop contents, or regurgitated material. Scrapings or impression smears may also be performed to diagnose suspected yeast infections of the skin. In severe cases, when tissue invasion has occurred, the budding yeast will produce hyphae that can be seen in scrapings obtained from the crop or pharynx, or from the feces.

Often candidiasis is secondary to poor husbandry and an unclean environment. If a reservoir of exogenous *Candida* is present (eg, poor nest box or feeding tube hygiene), then eliminating the source of the *Candida* is critical. In neonates with crop stasis, the crop must be emptied and smaller amounts fed until the crop stasis has resolved. Metoclopramide may help

TABLE 17 DIFFERENTIAL DIAGNOSES FOR REGURGITATION IN PET BIRDS

Problem	Species Commonly Affected	Common Agents (if known)	Typical Signs
Toxicosis	Various	Lead, zinc, pesticides, medications	Vomiting, abnormal droppings, lethargy, possible CNS signs
Oral upper GI irritation	Cockatiels, various	Plants (<i>Pothos</i> , <i>Philodendron</i>), various medications, other caustic materials	Lethargy, ptialism, passive regurgitation of water, erythema of tongue and pharynx
Proventricular dilatation syndrome	Macaws, miniature macaws, African grey parrots, cockatoos, others	Avian bornavirus	Weight loss, vomiting, seeds in feces, possible CNS signs
Bacterial GI infections	Various	Gram-negative bacteria	Vomiting, watery droppings, lethargy
Candidiasis	Cockatiels, lovebirds, others	<i>Candida</i> spp	Regurgitation, crop distention, oropharyngeal and crop lesions
Trichomoniasis	Budgerigars, cockatiels, doves, others	<i>Trichomonas</i> spp	Regurgitation, mouth and crop lesions (white matter), mucus in crop
Ventricular, proventricular, or crop obstruction	Cockatoos, macaws, <i>Electus</i> parrots, cockatiels, others	Wood shavings, corn cob bedding, other bedding, fibers, foreign bodies, ascarids	Vomiting, depression, weight loss
Proventricular adenocarcinoma	Various	Neoplasm	Vomiting, weight loss, lethargy, severe pain, sudden death
Internal papillomatosis	Amazons, macaws	Psittacine herpesvirus 1	Vomiting, straining to defecate, secondary cloacal and choanal infections
Abdominal mass	Budgerigars	Renal or gonadal mass—usually neoplasia	Weight loss, lameness, vomiting
Behavioral	Various	Courtship behavior	Regurgitation on mirror, owner, toy, or cagemate

crop motility and prevent regurgitation. After identifying and resolving any predisposing factors, treatment with nystatin or fluconazole should be initiated. Nystatin (300,000 IU/kg, PO, bid) is commonly used for treatment because of its low cost and low toxicity. Disadvantages are poor taste and large volume required. Because it is fungistatic and not absorbed

from the GI tract, it is only effective when in direct contact with infected tissue, so it is often administered tid before feeding. If the yeast is resistant to nystatin or the bird is difficult to medicate, then fluconazole (20 mg/kg, PO, every 48 hr) is available for systemic treatment.

Flock treatment has historically been accomplished with use of chlorhexidine at

10 mL/gal. of drinking water for 1–3 wk. Because chlorhexidine is a disinfectant, its use will also deplete the normal digestive flora. Acidification of the upper GI tract by use of apple cider vinegar has also been reported to resolve *Candida* overgrowth.

See TABLE 18 for some antifungal drugs used in pet birds.

Aspergillosis

Aspergillosis is an opportunistic infection that typically occurs in immunocompromised hosts (malnutrition, especially vitamin A deficiency) or when birds are

exposed to large numbers of aerosolized spores. It is not transmitted bird-to-bird. *Aspergillus fumigatus* is the most common species isolated; *A. flavus* and *A. niger* are also found. *Rhizopus*, *Penicillium*, *Mucor*, and *Scedosporium apiospermum* can cause similar signs and are more difficult to diagnose and treat. Predisposing factors for developing infection include species predilection (African grey parrots, Amazon parrots, cockatiels, and macaws), aspiration of food or medications, immunosuppression (underlying disease), moldy bedding or feed, and use of corticosteroids. Poor hygiene and inadequate ventilation,

TABLE 18 ANTIFUNGALS USED IN PET BIRDS

Antifungal ^a	Dosage	Route, Frequency
Amphotericin B	1 mg/kg intratracheal; 0.25–1 mg/mL sterile water for nebulization	Given intratracheally once daily; nebulized 10–20 min, bid
	1.5 mg/kg	IV, tid
Amphotericin B suspension	100 mg/kg	PO, bid × 30 days
Clotrimazole	2 mg/kg	Given intratracheally, once daily × 5 days
	10 mg/mL (1%)	Nasal flush; nebulized for 30 min bid
Enilconazole	1 mg (0.05 mL/kg of a 1:10 dilution)	Given intratracheally, once daily × 7–14 days
	0.1 mL/kg in 5 mL sterile water	Nebulize for 30 min, 5 days × on, 2 days off
Fluconazole	5–15 mg/kg	PO, bid
	20 mg/kg	PO, every 48 hr × 3 treatments
Griseofulvin	10 mg/kg	PO, bid
5-Flucytosine	20–75 mg/kg	PO, bid
F-10 ^b (quaternary ammonium disinfectant)	1.5/400 mL distilled water	Nebulization for cutaneous and possibly respiratory fungus
Itraconazole	5–10 mg/kg	PO, once to twice daily (lower dosage, and use cautiously in African grey parrots)
Ketoconazole	10–30 mg/kg	PO, bid
Terbinafine	10–15 mg/kg 1 mg/mL solution	PO, bid Nebulization for 30 min
Nystatin oral suspension (100,000 U/mL)	300,000–600,000 U/kg	PO, bid
Voriconazole	12–18 mg/kg	PO, bid

^a Most are unapproved for use in birds, and caution is indicated.

^b Quaternary ammonium and biguanidine compound; nontoxic, ampholytic surfactant

especially in warm, humid climates, can also increase the incidence of disease.

Clinical Findings: Clinical signs depend on the site of infection. Most infections occur in the upper respiratory tract, air sacs, lungs, trachea, and syrinx. Systemic infections occur when the infection spreads to internal organs, including bone, liver, kidneys, or brain. Eye and skin infections can also occur. Anorexia and weight loss are often present. Respiratory signs may include dyspnea, tail bobbing, exercise intolerance, and voice change. Rhinitis caused by *Aspergillus* appears similar to bacterial rhinitis or sinusitis. A Gram stain or modified Wright's stain of lesions or debris often demonstrates fungal hyphae. Infraorbital sinusitis caused by aspergillosis often must be surgically debrided before therapy is effective. Extensive or chronic fungal sinusitis may lead to osseous changes and permanent malformation of the upper respiratory architecture. Extension of infection to the brain can cause CNS signs.

Tracheitis due to aspergillosis can occur in immunocompromised birds. *Aspergillus* granulomas often form in the syrinx of psittacine birds and raptors and are particularly challenging to treat. Changes in vocalization may occur before dyspnea is observed, and often these birds will stretch out their necks while breathing. Lower respiratory disease, including airsacculitis, often involves invasion by *Aspergillus* spp. Granulomas of the air sacs or the coelomic cavity are also common, usually in the caudal thoracic or abdominal air sacs. These lesions may require surgical resection.

Diagnosis: Diagnosis can be challenging but should be pursued because treatment is longterm and costly. Aspergillosis should be considered in any pet bird presenting with signs of upper or lower respiratory disease, wasting disease, or marked leukocytosis/monocytosis. A leukocytosis/monocytosis combined with clinical signs and radiographic findings can provide a strong presumptive diagnosis in suspect cases. Often birds with chronic disease will be anemic. A radiograph may reveal airsacculitis, granulomas, or severe pulmonary disease. A CT scan or MRI is more likely to reveal more subtle or diffuse disease. Serologic testing is of limited use; antibody and antigen titers, including galactomannan antigen testing, often result in false-negative or false-positive results. A false-negative often occurs because of immunosuppres-

sion, so consultation with the laboratory regarding interpretation is important. PCR testing to detect specific *Aspergillus* DNA is a much more sensitive method to confirm infection and is more suitable for immunocompromised birds because detection of antibodies is not involved. Plasma protein electrophoresis showing increased β -globulin levels is consistent with aspergillosis. Definitive diagnosis may require direct visualization of lesions either by surgery or endoscopy and confirmation by biopsy, cytology, and/or fungal culture of lesions. Low fungal viability may yield a negative culture despite confirmation by cytologic results.

Treatment: Treatment varies depending on the site of infection. An acute tracheal infection with obstruction by an aspergilloma is an emergency that may require placing an air sac tube. After tube placement, syringeal or tracheal plaques are removed with a rigid endoscope. Amphoterin B can then be instilled intratracheally at 1 mg/kg through the glottis, and treatment with systemic antifungals and nebulization should be started. Amphoterin B is the only fungicidal agent available and can be used in nebulization, as a nasal flush, intratracheally, and in IV administration. For nebulization, a concentration of 0.25–1 mg/mL of sterile water can be used. Nasal and sinus flushes are generally more dilute at 0.05 mg/mL of sterile water. Amphoterin should not be diluted with saline, because this decreases its potency.

Flushing the nares and sinus with unmedicated sterile water or saline before medicating may allow samples to be obtained for cytologic examination and culture. Several flushes of unmedicated warm isotonic saline or sterile water should be done before a final infusion of the medicated mixture. Care must be exercised to maintain the bird's head in a downward position to avoid the potential for aspiration of the infected debris into the lower respiratory tract.

Itraconazole (5–10 mg/kg, PO, once to twice daily) is the most commonly used azole for systemic infection. African grey parrots are more sensitive to adverse effects of itraconazole, especially regurgitation and anorexia, and should be dosed at 5 mg/kg/day, PO. Terbinafine (10–15 mg/kg, PO, bid) can be used in lieu of or in conjunction with itraconazole. Clotrimazole can be used for nebulization in conjunction with systemic therapy (10 mg/mL, nebulized 15–30 min

2–4 times/day). Voriconazole (12–18 mg/kg, PO, bid) is being used for resistant strains of *Aspergillus*.

If fungal granulomas are identified and the lesions are accessible, debulking endosurgically or treating the lesions topically with amphotericin B may improve the outcome. Birds undergoing treatment should be monitored closely for adverse effects of many antifungal drugs, which can include depression, anorexia, and liver dysfunction. Hepatic enzyme, bile acids, and uric acid concentrations should be monitored every 4 wk during treatment. Treatment success may be difficult to determine, but serial CBCs and radiographs may be helpful. Treatment with oral drugs should be continued for 2–4 wk after clinical signs have resolved. Birds with aspergillosis often have underlying disease problems and may be immunocompromised, which may affect treatment and recovery. Thickened and scarred air sacs that develop during and persist after infection can provide an ideal environment for disease recurrence.

Macrorhabdus ornithogaster Infection

(Macrorhabdosis, Megabacteria, Avian gastric yeast)

Macrorhabdus ornithogaster most often affects the proventriculus and ventriculus of smaller companion birds (eg, budgerigars, parrotlets, lovebirds, cockatiels, and finches). Previously described as a bacterium, this organism has a worldwide distribution and varies widely in pathogenicity.

Clinical Findings and Diagnosis:

Clinical signs of infection are weight loss, regurgitation, lethargy, passage of undigested food, and diarrhea. These clinical signs may mimic proventricular dilatation disease. Mortality may be high, but birds may recover. In birds that recover, relapses and potential shedding of the organism in the feces are likely. This disease is often seen in conjunction with immunosuppression (eg, polyomavirus and circovirus infection, or associated with poor husbandry). Asymptomatic infection is common.

Diagnosis is made by examining a wet mount of a fresh dropping at 10–50× magnification with the stage condenser mostly closed to increase contrast. The large, rod-shaped organisms are approximately 2–4 µm wide and 60–90 µm long. Many birds are asymptomatic and shed low

numbers of organisms, whereas sick birds tend to shed large numbers. Birds may shed the organism intermittently, so a negative fecal examination does not exclude infection. Wet mount, modified Wright's, or Gram stain of a fecal sample often reveal organisms. *M. ornithogaster* appears as a large, gram-positive rod, with mottling or stippling throughout its length. Although the size and length may vary, organisms recovered from the droppings are generally several magnitudes larger than the normal digestive bacilli found in birds. Selected veterinary laboratories offer both visual identification and PCR testing. *M. ornithogaster* does not grow on conventional fungal media. Radiographs may reveal a dilated proventriculus. Necropsy lesions may include thinning of the isthmus, proventricular dilation and ulceration, thickening of the proventricular wall, mucus production, and softening of the koilin layer of the ventriculus.

Treatment and Control: The goals of treatment are to reduce the number of organisms and improve the general health and immunocompetence of the bird. Amphotericin (100 mg/kg, PO, bid for 30 days) has had the highest treatment success rate, but failures are common, especially with a shorter duration of treatment. Acidification of the proventriculus (apple cider vinegar, vitamin C) has been reported to create an environment less conducive to proliferation of *Macrorhabdus*. Voriconazole has been successful (anecdotal) at 10 mg/kg, PO, bid.

Treatment with sodium benzoate in the drinking water has been anecdotally reported to be successful but still experimental. Sodium benzoate at 1 tsp/L water for 5 wk cleared the infection in nonbreeding budgerigars, but in budgerigars that were rearing chicks in high environmental temperatures >90°F, treatment with ½ tsp/L water resulted in neurologic signs and death of the adult budgerigars because of their increased water intake. The current recommendation for treatment of *Macrorhabdus* with sodium benzoate is ½ tsp (2.5 g) of sodium benzoate powder/L of water (used as only water source and made fresh daily). If the birds are not drinking the medicated water, the dose should be decreased to ¼ tsp (1.25 g)/L of water, and slowly increased back to ½ tsp over the next few days. Feces should be rechecked at 14 days; if *Macrorhabdus* organisms are still present, the dose should be increased over several days to 1 tsp (5 g)/L. Feces should be rechecked at 30 days. The lower dose of ¼ to ½ tsp powder/L of water should be used

in birds housed outdoors in summer (temperatures $>90^{\circ}\text{F}$ [32.2°C]) and in birds feeding chicks. Gloves should be worn when handling medication.

Asymptomatic carriers are common. Artificial incubation of eggs and hand feeding nestlings can help establish a pathogen-free flock.

Malassezia spp

Malassezia spp have been reported in birds with feather picking and dermatologic conditions. In suspect cases, biopsy or cytology should be performed. Culture is often unrewarding. The recommended treatment is fluconazole at 5–10 mg/kg, PO, once to twice daily. Topical therapy with either dilute chlorhexidine 0.1% spray or clotrimazole may be used alone or in conjunction with systemic treatment.

Cryptococcus neoformans

Cryptococcosis is worldwide in occurrence and caused by a saprophytic fungus, *Cryptococcus neoformans*. This fungus is uncommon in avian species, but it has been isolated from the fecal droppings of wild birds, particularly pigeons, and from feces of canaries and psittacine birds. *C. neoformans* infection has been reported in Columbiformes, a Moluccan cockatoo, a thick-billed parrot, a green-wing macaw, and an African grey parrot. Veterinarians should be aware that not only can birds be carriers of the disease and become ill but also that *C. neoformans* is zoonotic. Most human infections with *C. neoformans* occur in immunocompromised individuals and are associated with environmental exposure, although cases have been reported in which contact with a pet bird appeared to be the source of infection.

Clinical signs of *Cryptococcus* infection include weakness, lethargy, anorexia, diarrhea, and dyspnea. With CNS involvement, neurologic signs such as blindness and paralysis may occur. Clinical diagnosis can be difficult. A definitive diagnosis requires demonstrating the organism on cytologic or histologic examination or culture. The organism is a round to oval yeast with a mucopolysaccharide capsule. A mucoid gelatinous exudate may be noted within the respiratory tract, coelomic cavity, sinuses, brain, or within the long bones.

Treatment recommendations for birds include amphotericin B, itraconazole, ketoconazole, fluconazole, or voriconazole. Fluconazole or voriconazole are the drugs of choice for CNS or ocular infections.

Rhodotorula mucilaginosis

Rhodotorula mucilaginosis is a yeast occasionally seen in skin infection in raptors (falcons). It causes yellowish brown crusty areas of the skin in the axillary or inguinal areas. Untreated lesions may develop into hyperkeratotic proliferative growths. Diagnosis is based on physical examination findings and results of cytologic or histopathologic examination and culture of infected tissues.

Treatment involves excision of proliferative lesions and topical antifungal therapy. Antibiotics may be necessary to prevent secondary infections, and analgesics or anti-inflammatory drugs may be warranted for pain.

Miscellaneous Mycoses

Dermatophytosis, including *Trichophyton* and *Microsporum* spp is occasionally reported in pet birds. Treatment protocols for dogs and cats are used (see p 874). Histoplasmosis and mucormycosis are also occasionally reported in pet birds.

PARASITIC DISEASES

See also POULTRY, p 2780 et seq.

Parasitic disease has become less common in captive parrots throughout the past 20 yr with the restrictions against importation of wild-caught birds; many pet birds now are incubator hatched, hand raised, and have little to no access to the outdoors or to other birds. Commonly reported parasitic diseases include protozoal infections such as giardiasis in cockatiels, sarcocystis in larger parrots, and mites in budgerigars and passerines.

Parasites of the Circulatory System

See also BLOODBORNE ORGANISMS, POULTRY, p 2780.

Protozoa: *Haemoproteus* was previously documented with great frequency in imported *Cacatua* spp. *Leucocytozoon*, *Plasmodium*, and *Atoxoplasma* spp are all seen occasionally in various species, most commonly in raptors, canaries, and Columbiformes, and are currently not of major significance in psittacines. Atoxoplasmosis is still diagnosed in canaries.

Parasites of the Gastrointestinal System

Giardiasis: Giardiasis has been reported in many species of birds but is most commonly seen in cockatiels. Adult birds may be latent

carriers. Transmission is presumably direct (ingestion of infective cysts). Affected cockatiels occasionally exhibit feather pulling in the axillary and inner thigh regions, along with vocalization. A true causal relationship between giardiasis and these clinical signs has not been proved. Droppings of affected cockatiels may be voluminous and aerated (a "popcorn" appearance).

There are several ways to diagnose *Giardia* spp infection: the zinc sulfate flotation test of feces to detect cysts, the direct saline smear of fresh feces to detect motile trophozoites, and an ELISA test for *Giardia* spp antigen in feces. Because the presence of cysts is variable, serial tests may be needed. The accuracy of the *Giardia* spp SNAP test designed for people is unknown.

Metronidazole (50 mg/kg/day, for 5–7 days) or carnidazole (20 mg/kg/day, PO, for 1–2 days) is the recommended treatment. In cockatiels, treatment of giardiasis with fenbendazole at dosages extrapolated from dogs has been anecdotally reported to cause death.

Trichomoniasis: Trichomoniasis has been reported in many orders of birds, including Columbiformes, Galliformes, Falconiformes, Psittaciformes, and Passeriformes. *Trichomonas gallinae* (called frounce in birds of prey and canker in Columbiformes) is occasionally seen in pet birds, notably budgerigars. Clinical signs may include anorexia, dysphagia, weight loss, and dyspnea. Whitish yellow, caseous lesions adherent to the mucosa of the oropharynx, crop, and esophagus may be seen in raptors and Columbiformes. Budgerigars generally do not have grossly visible oral lesions but do have increased salivation and regurgitation. Transmission is by direct (parents feeding young) or indirect (ingestion of contaminated food and water) contact; raptors may become infected by ingesting infected pigeons or doves.

Microscopic examination of a warm saline mount of material from the oral cavity may reveal the flagellated organism. Treatment protocols include carnidazole (20 mg/kg, PO, once), ronidazole (6–10 mg/kg/day, PO, for 14 days), or metronidazole (50 mg/kg/day, PO, for 5 days).

Other Protozoal Diseases: Other protozoan parasites such as coccidia are much more common in gallinaceous or Columbiforme birds, although coccidial oocysts are seen occasionally in psittacine and passerine birds.

Cryptosporidiosis has been seen in a variety of avian species but is thought to be a secondary rather than a primary pathogen. Transmission of *Cryptosporidium* spp is through ingestion or inhalation of sporulated oocysts. Because of the small size and low shedding rate of *Cryptosporidium* spp, diagnosis can be difficult, but a Sheather's sugar flotation test is best. An acid-fast stain can also be used to detect the organism. Clinical signs may involve the GI, respiratory, or urinary tract, especially in immunosuppressed birds. Treatment for cryptosporidiosis in birds is not described.

Plasmodium spp infection (malaria) is highly pathogenic in gyrfalcons, canaries, and penguins. *Plasmodium* is spread by mosquitoes. Clinical signs may be none to weakness and death. Treatment for malaria, if needed, is with chloroquine.

Atoxoplasmosis is a highly pathogenic protozoal disease that causes hepatomegaly and splenomegaly in canaries, with coccidia-like oocysts shed in the feces. The host becomes infected by ingesting the oocysts. Infected birds may be asymptomatic or exhibit anorexia, weight loss, diarrhea, and depression. Clinical disease is typically more severe in fledgling birds, whereas adults are often asymptomatic. Diagnosis is made by fecal flotation (best in adults), buffy coat smear with Romanowsky stain, liver impression smear, or PCR testing of feces. Treatment options are toltrazuril (12.5 mg/kg/day, PO, $\times$ 14 days) or sulfa-chlorpyridazine (150–300 mg/L drinking water, 5 days/wk $\times$ 2–3 wk).

Other protozoan parasites such as **coccidia** are much more common in gallinaceous or Columbiforme birds, although coccidial oocysts are seen occasionally in psittacine and passerine birds.

Roundworms: Various genera and species of roundworms infect pet birds, and wild birds may transmit nematodes to captive parrots housed outdoors. Transmission is direct by ingestion of embryonated ova. Clinical findings include loss of condition, weakness, emaciation, and death; intestinal obstruction is common in heavy infections. Diagnosis of intestinal nematode infection is by fecal flotation, although shedding of ova may be intermittent. Ivermectin (0.2 mg/kg, PO, SC, or IM, repeated in 10–14 days), pyrantel pamoate (4.5 mg/kg, PO, repeated in 10–14 days), or fenbendazole (20–50 mg/kg, PO, repeated in 14 days) are generally effective. In warm climates where exposure via outdoor aviaries is likely, routine deworming

(every 6 mo) with one of these anthelmintics is often practiced.

Cestodes: Cestodes are uncommon in domestically bred birds. The most common pet birds infected with tapeworms are cockatoos, African grey parrots, and finches. Intermediate hosts are most likely insects and arachnids of various types, earthworms, and slugs. Infected birds are asymptomatic or are unthrifty, with or without diarrhea. Diagnosis is based on visualization of eggs on a fecal flotation.

Praziquantel (5–10 mg/kg, PO or IM, once) is the recommended treatment. Recurrence is rare in cases in which the intermediate host is not indigenous to the area where the bird is housed.

Parasites of the Integumentary System

Scaly Face (Leg) Mite: *Knemidocoptes pilae* (also *Cnemidocoptes pilae*) is common in budgerigars and rare in all other psittacine species. In budgerigars, white, porous, proliferative encrustations involving the corners of the mouth, cere, beak, and occasionally the periorbital area, legs, or vent are typical. In passerine birds (particularly canaries and European goldfinches), crusts form on the legs and surfaces of the digits (“tassel foot”). The mites can be recovered from facial scrapings of budgerigars, although the clinical appearance is generally pathognomonic. In passerines affected with *Knemidocoptes*, skin scrapings of the legs often result in hemorrhage and are generally not recommended. Ivermectin (0.2 mg/kg, PO or IM) or moxidectin (0.2 mg/kg, PO or topically) is generally effective. The treatment is repeated in 2 wk.

Feather Mites: Psittacine birds are seldom affected by feather mites. Occasionally, infestation with the red mite (*Dermanyssus gallinae*) may be found in outdoor aviaries, especially in nest boxes. A causative relationship between mites and feather picking is often assumed by owners of feather-picking birds, although this is rarely the case. More commonly, behavioral, husbandry, and/or systemic factors are linked to feather loss (see p 1927).

Mite-infested birds may be treated with pyrethrin sprays, 5% carbaryl powder, or ivermectin (0.2 mg/kg, PO or IM) repeated in 2 wk. Nest box treatment includes mixing 5% carbaryl powder into the nest box substrate. Cages should be cleaned thoroughly, and wooden nest boxes should be discarded and replaced.

Parasites of the Respiratory System

Air Sac Mites: *Sternostoma tracheacolum* parasitizes the entire respiratory tract, most frequently of canaries and gouldian finches. The mites are found in the trachea, syrinx, lungs, and air sacs. All stages of the mite are found within the respiratory tissues. The life cycle is poorly understood.

In mild infections, birds are usually asymptomatic; in heavy infections, audible dyspnea (high-pitched noises and clicking), sneezing, tail bobbing, and open-mouthed breathing are noted. Copious amounts of saliva are seen in the oropharynx, and ptialism may be present. Signs are exacerbated by handling, exercise, and other stresses. Mortality can be high. Transillumination of the trachea in a darkened room occasionally reveals the mite. Response to treatment can help reach a diagnosis.

When the recovery of an individual bird is paramount, treatments should be administered quickly and with minimal handling. Ivermectin (0.2–0.4 mg/kg, PO or IM) repeated in 2 wk or moxidectin (0.2 mg/kg, PO or topically) repeated in 2 wk may be administered.

Sarcocystosis: Sarcocystosis is a major cause of mortality in parrots housed outdoors in the southern USA. In severely affected areas, even indoor birds can be infected via contaminated food. The oocysts of this protozoan parasite are passed from infected opossum feces by insects (eg, flies, cockroaches) or mice and rats into the feed cups or enclosure of the birds. The feces of these transport hosts are then consumed by the birds, and a rapidly fatal disease can develop. Old World species are immunologically naive to this disease, and a high mortality rate is observed in untreated birds such as cockatoos, African grey parrots, and *Eclectus* parrots. Cockatiels are also susceptible, and renal as well as pneumonic lesions are often noted at necropsy in this species. Although not contagious, cases tend to occur in clusters because the infected opossum feces are spread via insects around the aviary grounds. Large die-offs have been documented.

Clinical signs are lethargy, passive regurgitation of water, respiratory distress, weakness, ataxia, and anemia. In Old World parrots (eg, cockatoos, African grey parrots), disease occurs in the early stages of infection as the parasite is undergoing schizogony or merogony (asexual reproduction) in the lung. This causes lung damage, and the birds die

acutely with or without signs of respiratory distress. In New World parrots (eg, macaws, conures), the organism encysts in the muscle or CNS, causing weakness, ataxia, or neurologic signs. The disease can manifest as an asymptomatic or clinically apparent muscular disease, cardiac disease, acute pulmonary disease, or encephalitis. Encephalitis (paresis, intention tremors, and head tilt) has been seen in psittacines and raptors.

No specific diagnostic test is available, although results of plasma protein electrophoresis may indicate infection (marked increase in β -globulin concentrations with or without a marked increase in gamma globulin concentrations). An indirect immunofluorescence antibody (IFA) test has been developed that may aid in antemortem diagnosis of the nonperacute form of sarcocystosis in psittacine birds. The sensitivity and specificity of the IFA test ranges from 83%–86%. Results of muscle biopsy may be conclusive for the encysted stages but is not commonly performed. When a muscle biopsy is done, the quadriceps muscle has been reported to be a better biopsy site than the pectoral muscle. Increases in enzyme activities of LDH, AST, and CK have been reported.

Protracted treatment with trimethoprim/sulfa (30 mg/kg, bid) and pyrimethamine (0.5 mg/kg, PO, bid) has had limited success. Response to treatment is generally monitored by serial PCV sampling. Newer drugs used to treat infection by the related protozoa, *Sarcocystis neurona*, that affects horses have not yet been evaluated for treatment in birds.

Gross necropsy findings include increased lung density, hemorrhage, and renal lesions. Clinical signs may also reflect CNS involvement. Histopathologic samples should include lung, kidney, muscle, and CNS tissue if neurologic signs are apparent.

VIRAL DISEASES

Avian Polyomavirus

(Papovavirus, Budgerigar fledgling disease, Psittacine polyomavirus)

Avian polyomavirus (APV) primarily affects young birds. There are two primary forms of the disease based on species affected: budgerigar fledgling disease and a nonbudgerigar polyoma infection. Both are characterized by peracute to acute death of preweaned neonates. Adult birds typically are resistant to infection; they will seroconvert and shed the virus for up to 90 days, then clear the infection. The incubation period is 7–10 days.

The typical presentation of budgerigar fledgling disease is a well-fleshed juvenile, just before fledgling age, with acute onset of lethargy, crop stasis, and death within 24–48 hr. Other clinical signs are cutaneous hemorrhage, abdominal distention, and feather abnormalities. Surviving budgerigars >3 wk old often exhibit feather dystrophy (French molt or feather dusters). In other species of psittacines <4 mo old, the infection is also often fatal. Older nonbudgerigar psittacines may have subclinical disease or hemorrhages and coagulopathies. Prevalence of the virus in adult psittacines, including budgerigars, is thought to be high.

Antemortem diagnosis is accomplished with DNA probes of cloacal swab and blood samples and virus-neutralizing antibody tests of blood samples to identify birds with previous viral exposure. Diagnosis in a flock setting is typically based on clinical signs, signalment, and necropsy findings.

Gross necropsy findings in deceased chicks often include pale skeletal musculature and subcutaneous ecchymotic hemorrhages. The kidneys and liver are enlarged and may be pale, congested, and mottled, or have pinpoint, white foci. Petechial or ecchymotic hemorrhages may also be present on viscera, particularly the heart. The heart is sometimes enlarged and may show hydropericardium. Intranuclear inclusion bodies are often seen in the liver, kidneys, heart, spleen, bone marrow, uropygial gland, skin, feather follicles, etc.

Aviary control methods include avoiding the housing of budgerigars or lovebirds on premises where other species are bred, adhering to standard hygiene procedures, preventing access to the nursery by visitors, and not introducing birds into the aviary without 90 days quarantine and testing. Eliminating APV infection from an infected budgerigar aviary is challenging. First, all breeding must be stopped for 6 mo. The presence of infected neonates, fledglings, and adults propagates the disease. During this time, adult birds are moved to a noninfected area while the entire aviary is disinfected. Nest boxes should be disinfected or discarded and replaced. After 6 mo, adult breeding birds can be returned to a clean aviary and breeding resumed.

Pet store prevention should include separating neonates from different sources, purchasing birds from sources where polyomavirus testing and vaccination are performed, and ideally, not purchasing or selling unweaned birds.

Treatment is supportive care. A vaccine is available. For breeding birds, two doses of the vaccine are administered at a 2-wk interval; this should be done off-season. The manufacturer recommends administration of the first dose when the chick is >35 days old, with a booster vaccination in 2–3 wk.

Psittacine Beak and Feather Disease

Psittacine beak and feather disease (PBFD) is caused by a psittacine circovirus. The virus was first recognized in the 1970s in cockatoos with beak and feather lesions. Since then, it has been recognized in most species of parrots and also in Passeriformes and Columbiformes. Infected birds shed virus in their feathers, feather dander, feces, and oral secretions. Transmission occurs by inhalation and/or ingestion of the virus and can occur vertically. The virus is very stable in the environment, so fomites can be a significant source of infection. The name is not as representative of the current typical clinical presentation, which often does not include beak abnormalities and is less likely to have the severe, classic feather abnormalities seen in cockatoos when the disease was first documented. Use of screening PCR tests has greatly decreased the prevalence of the virus in captive bred *Cacatua* spp. However, disease is still seen in African grey parrots, *Eclectus* parrots, lovebirds (*Agapornis*), lorikeets, and other species, but is rare. The natural infection appears to occur primarily in juvenile birds, with few instances of clinical infection seen in birds >3 yr old.

In the classic PBFD infection, the first indication of the presence of disease is a lack of powder down on the beak. The virus causes abnormal formation of growing feathers and immunosuppression. Feathers are pinched or clubbed at their base and may have hemorrhage within the developing shaft. The feathers fall out easily and grow back slowly or not at all. The distribution of affected feathers depends on the age of the bird and the stage of the molt when infected. Pigment loss may occur in colored feathers. The bird may live with these lesions for months to years. As the disease progresses, the immune system is affected, and most birds die of secondary infections. A peracute form of the disease occurs in young birds, which develop enteritis and pneumonia, lose weight, and die. African grey parrots may develop a pancytopenia, because the virus attacks the bone marrow. These birds die suddenly with viral inclusions in the thymus, bursa, and bone marrow.

Diagnosis is based on clinical appearance; results of PCR testing of feces, feather dander, or blood; and biopsy of affected feather follicles showing basophilic intracytoplasmic inclusions. Testing by PCR may detect infection in birds that still appear healthy. These birds may subsequently become ill or may mount an effective response to the virus. Because of the stability of the virus, PCR analysis can also be used for environmental testing. Quarantine and retesting are recommended for PCR-positive, asymptomatic birds. At necropsy, affected birds often have no gross lesions internally, but intranuclear or intracytoplasmic inclusions may be seen histologically in the feathers, bursa, thymus, liver, or other organs.

There is no specific treatment for PBFD, and treatment of infected birds is supportive. The contagious nature of PBFD and its generally terminal outcome in clinically affected birds warrant isolation and eventual euthanasia in most clinical cases. Strict hygiene with attention to dust control, screening protocols including PCR testing of both birds and the environment, and lengthy quarantines are highly recommended in breeding facilities with susceptible species. All new susceptible birds should be tested before introduction to the aviary. In infected breeding colonies, removing all eggs for cleaning and artificial incubation may also be required. Since the development of a PCR-based assay, prevalence of the disease has decreased.

Pacheco's Disease

(Pacheco's herpesvirus)

Psittacine herpesvirus is an alpha herpesvirus that is the causative agent of Pacheco's disease and internal papillomatosis in parrots. Pacheco's disease causes a viral hepatitis seen predominantly in New World species (Amazon parrots, macaws, and conures). Internal papillomatosis occurs in parrots that have survived Pacheco's disease. Papillomatosis is most commonly observed in macaws, Amazon parrots, conures, and hawk-headed parrots. Disease is associated with stress, which can cause clinically healthy carriers to shed virus and initiate infection in susceptible birds, as often occurs during introduction of new birds, relocation, or in those with underlying illness or during breeding. It is spread by direct contact, aerosol, or fecal contamination of food or water, with an incubation period of 3–14 days. The outcome of the infection depends on the genotype of the

virus, the species of bird infected, and the bird's overall health. Infected birds become chronic carriers and will remain persistently infected and intermittently shed the virus throughout their lives. Old World species are less likely to be either inapparent carriers or clinically susceptible. Patagonian species and some *Aratinga* spp may be natural hosts in the wild, and some individuals of these species may asymptotically shed virus when stressed. Other species can also act as carriers.

Terminal signs include acute death in well-fleshed birds and bright yellow urates with scant feces. Other clinical signs are diarrhea, green urates, lethargy, regurgitation, weakness, and depression. Diagnosis in the live bird can be done by DNA probes of combined oral and cloacal swabs or blood samples. Increases in plasma AST activity and marked leukopenia have been reported.

Because of the acute nature of the disease, gross histologic lesions may not be evident. However, most affected birds will have hepatomegaly, splenomegaly, and renomegaly. The liver may be mottled or grossly discolored. Ecchymotic and petechial hemorrhages may be present on the pericardium and within the mesenteric fat. Intranuclear inclusions are seen histologically in the liver, spleen, intestinal epithelium, and pancreas. Primary differential diagnoses for Pacheco's disease include acute salmonellosis, polyomavirus, and psittacine reovirus. Acyclovir (80 mg/kg, tid, or 400 mg/kg in feed) can be used during an outbreak; however, the risk of increased transmission because of handling is great. Autogenous vaccines have been developed during outbreaks and have effectively decreased morbidity and mortality. An inactivated vaccine is available.

Cloacal papilloma, gross lesion, in a blue-fronted Amazon parrot. A red proliferative mass commonly originates from just inside the rim of the cloacal opening. Courtesy of Dr. Louise Bauck.

The lesions of **papillomatosis** are predominantly present in the oral and cloacal mucosa but may also be found internally in the intestinal tract, or less commonly, in the conjunctiva or bursa. Owners usually first notice blood from a papilloma in the droppings, and/or the papilloma prolapses through the cloaca. Lesions may be mild or severe (ulcerated and bleeding) and often wax and wane. Ulcerated lesions may need to be cauterized or surgically removed, although they typically recur. Treatment is supportive, such as analgesics, cautery, and antibiotics to prevent secondary infection. Antiherpetic drugs are not curative and do not appear to impact the course of disease.

Other Herpesvirus Infections:

Amazon tracheitis is also caused by a herpesvirus, although the incidence of this infection is low. Other clinically significant herpesviruses include the strain responsible for papillomatous foot lesions in *Cacatua* spp and the depigmentation lesions noted on the feet of macaws.

Avian Bornavirus/Proventricular Dilatation Disease

(Macaw wasting disease)

Proventricular dilatation disease (PDD), also known as macaw wasting disease, neuropathic ganglioneuritis, lymphoplasmacytic ganglioneuritis, psittacine encephalomyelitis, and most recently avian bornavirus (ABV), was first recognized in the late 1970s in macaws imported into the USA and Germany. The disease primarily affects macaws, conures, and African grey parrots, although all parrots are probably susceptible. The causative agent of this disease is avian bornavirus.

The common presentation of affected birds is chronic weight loss (often following an initial increase in appetite), passage of undigested food (most easily recognized when whole seeds are found in the droppings), and regurgitation. A dilated proventriculus may be seen radiographically. Neurologic signs (convulsions, tremors, weakness, ataxia, blindness) may occur in some species, with or without concurrent GI signs. Clinical signs may be slowly progressive or develop acutely. Outbreaks are sporadic, with a low morbidity and a high mortality.

Before the discovery of ABV as the causative agent of PDD, the only ante-mortem diagnosis was identification of lymphoplasmacytic infiltrates in the tissues

of affected birds, most commonly with a crop biopsy. Histopathologic lesions can be present in the brain, spinal cord, peripheral nerves, nerves of the GI tract, heart, adrenal gland, lungs, and kidneys. Transmission is fecal/oral, and positive results of PCR testing of choanal, cloacal, or fecal swabs confirms the presence of ABV. Serologic assays such as ELISA can also confirm exposure. Although the presence of ABV in the droppings indicates shedding, many birds are positive for ABV with no clinical signs of PDD. If or when these birds may develop disease is unknown.

Because shedding of the virus is intermittent, one negative result of fecal or cloacal PCR testing does not exclude disease. Testing at least three times at weekly intervals, with all three tests being negative, is best before declaring a bird negative for ABV. Differential diagnoses are heavy metal toxicosis, foreign body intestinal obstruction, internal papillomatosis, internal neoplasia, and GI infections (including bacterial and fungal proventricular infections).

Clinicopathologic findings vary, but increased plasma CK activity and mild lymphocytosis, monocytosis, or heterophilia may be seen. Proventricular biopsies in affected birds are prone to dehiscence and are not done routinely. Crop biopsy is a less invasive diagnostic tool and may be useful if the collected sample contains sufficient innervation to be diagnostic; however, a negative crop biopsy does not exclude the presence of PDD.

Treatment for PDD includes providing easily digestible foods and may be aided by administration of an NSAID (eg, meloxicam, celecoxib). Isolation of positive birds is important in disease prevention. Testing by PCR (a minimum of three tests) and separating positive birds from negative birds is a recommended control measure, although the number of false-negative tests (due to intermittent shedding) makes this a long and potentially difficult task. ABV is not a long-lived virus in the environment; therefore, good hygiene and ultraviolet light can help to limit spread of disease in a home or aviary setting.

Poxvirus Infections

Poxviruses are large DNA viruses that induce intracytoplasmic, lipophilic inclusion bodies (Bollinger bodies) in the epithelial cells of the integument, respiratory tract, and oral cavity. All birds are considered susceptible to poxvirus infection, but many companion and aviary

birds are rarely exposed to a susceptible strain. Because of import restrictions, poxvirus in blue-fronted Amazon parrots is no longer commonly seen. In pet bird practice, veterinarians will generally encounter only canary, lovebird, and pigeon poxviruses and fowlpox (see p 2824), which have specific host ranges. Poxviruses are environmentally stable, increasing the likelihood that a viable organism will come into contact with a susceptible host. Poxviruses cannot penetrate intact skin, and a break in the skin or mucous membrane must be present for infection to occur.

Poxvirus infection may cause cutaneous, diphtheritic, or systemic infections based on the strain of virus, route of exposure, affected species, and age and health of the bird. The cutaneous form appears as nodular proliferations or wartlike lesions on the unfeathered skin around the eyes, beak, nares, and legs. The diphtheritic form is characterized by lesions on the mucosa, tongue, pharynx, and larynx. The septicemic form is characterized by a ruffled appearance, depression, cyanosis, anorexia, and wartlike tumors of the skin. The cutaneous form is most commonly seen in psittacines and raptors.

Clinical signs depend on the form of disease, location of the lesions (eye, oral, ear), and overall health of the bird and may include lethargy, respiratory distress, partial blindness, difficulty eating, weight loss, emaciation, and skin lesions. Diagnosis of poxvirus infection is typically confirmed through history, physical examination findings, and histologic findings of Bollinger bodies in affected tissues.

Treatment is usually nonspecific and may include supportive care, fluids, parenteral vitamin A, ophthalmic ointments for eye infections, assisted feedings, and antibiotics to prevent or treat secondary infections. Lesions on the skin may need daily cleaning. Transmission is via insect vectors (mosquito bites) or other entry through breaks in the skin. Therefore, mosquito control and indoor housing are vital to prevent outbreaks. Vaccines for canarypox, fowlpox, and pigeonpox are available but are specific for their host species.

Viscerotropic Velogenic Newcastle Disease

(Exotic Newcastle disease)

Viscerotropic velogenic Newcastle disease (VVND, see p 2856), caused by a paramyxovirus group 1, affects most avian species and is a significant threat to the poultry

industry. Transmission is by respiratory aerosols, fecal contamination of food or water, direct contact with infected birds, and fomites.

Birds may be asymptomatic or die acutely. Clinical signs include depression, anorexia, weight loss, sneezing, nasal discharge, dyspnea, conjunctivitis, bright yellow-green diarrhea, ataxia, head bobbing, and opisthotonos. In prolonged cases, unilateral or bilateral wing and leg paralysis, chorea, torticollis, and dilated pupils also may be seen. Primary differential diagnoses include other paramyxoviruses (non-Newcastle), psittacine proventricular dilatation syndrome, and heavy metal toxicosis. Lesions include hepatomegaly, splenomegaly, petechial or ecchymotic hemorrhages on serosal surfaces of all viscera and air sacs, airsacculitis, and excess straw-colored peritoneal fluid. Diagnosis is traditionally via viral isolation, but agar gel immunodiffusion tests that can be performed on whole blood or serum are available.

Only symptomatic treatment is possible and thus not advised. If suspected, VVND must be reported to appropriate federal and state authorities. Vaccination is prohibited in birds entering the USA, because it does not eliminate the carrier state and hampers viral detection during quarantine.

Other Paramyxovirus Infections:

There are several less pathogenic strains of paramyxovirus. Paramyxovirus groups 2 and 3 are endemic in aviculture. Paramyxovirus group 2 causes mild illness in passerines and a more serious disease in psittacines. Clinical signs in psittacines include tracheitis, pneumonia, and enteritis. Paramyxovirus group 3 is reported most frequently in *Neophema* spp, lovebirds, and Gouldian finches and typically causes mild disease. Clinical signs may be absent, and disease results in acute death. In disease of longer duration, respiratory signs, pancreatitis, and torticollis may occur.

Diagnosis is the same as for paramyxovirus group 1. Treatment for paramyxovirus groups 2 and 3 infections is supportive care. The vaccine for paramyxovirus group 1 should not be used in psittacines, because it can cause fatal reactions.

West Nile Virus

West Nile virus (WNV) infection is an arthropodborne virus in the genus *Flavivirus* (family Flaviviridae). WNV was first reported in birds in the USA in August 1999. Many species of birds can be infected, and it

has been reported in >320 species of birds. The American crow (*Corvus brachyrhynchos*) and other corvids have suffered particularly high morbidity and mortality. Other affected species include canaries, psittacines, and raptors. Although psittacines appear to be somewhat resistant, the disease has been reported in parakeets, cockatoos, conures, rosellas, caiques, lorikeets, and a King parrot. Affected parrots have been adults housed outdoors with documentation of mosquito populations present. Mosquitoes (*Culex* spp) are the principal vectors of disease.

Clinical signs include depression, anorexia, weight loss, head tremors, ataxia, blindness, seizures, and death. Juvenile birds are the most commonly affected. Ophthalmologic findings in raptors are anterior uveitis, exudative chorioretinal lesions, and chorioretinal scarring.

Antemortum diagnosis can be difficult. Initial diagnosis may be based on clinical signs, species, and age; however, many diseases may cause similar clinical signs. Serologic tests (serum neutralization) may indicate antibody response to infection. Paired samples submitted 2 wk apart may reveal a rise in antibody levels and give a more definitive diagnosis. Adult birds may have high circulating antibody levels in endemic areas. Diagnosis is often determined at necropsy. The brain and kidney are the preferred tissues to submit for histopathologic examination.

There is no specific treatment for WNV in birds. Some birds may improve with supportive care (fluids, feeding, antibiotics/antifungals as needed) and time. A vaccination protocol using a recombinant vaccine has been successful in some birds. The recommendation is vaccination of captive birds 2–4 wk before mosquito season, with a booster 3 wk after the initial dose.

During the mosquito season, birds should be housed indoors or in completely covered outdoor facilities. Mosquito netting and mosquito traps should be used, and any standing or stagnant water sources eliminated.

Avian Influenza

Avian influenza is caused by an orthomyxovirus. Because of the zoonotic potential of some strains and the recent discovery of new mutations, this virus may become a more significant pathogen. Both the zoonotic potential and the economic effects on the poultry industry are causes for concern. (See also AVIAN INFLUENZA, p 2902.)

GERIATRIC DISEASES

Until recently, geriatric medicine has been a neglected area of avian medicine. Infectious diseases, inadequate diets, and poor husbandry meant that most pet birds did not live long enough to develop geriatric conditions. As the knowledge base of avian medicine, nutrition, and proper husbandry has grown, so has the life span of pet birds increased. Most pet birds have the potential to live 20–80 yr, depending on their size (with smaller birds having a shorter life span and larger birds a longer life span). With pet birds living longer, the incidence of geriatric-onset diseases, including cataracts, neoplasia, arthritis, and cardiovascular disease, has increased.

Cataracts

Cataracts occur in many species of psittacine birds as they age, notably macaws, Amazon parrots, and cockatiels. These species may be prone to cataracts or may be overrepresented in the older pet bird population. If the onset of cataracts is gradual, adaptation to decreased vision usually occurs; if not, clinical signs can be depression, inactivity, and reluctance to come out of or move around in the cage.

The eyes of older birds should be examined annually to detect early changes in lens opacity. Because of the small size of the exposed cornea and pupil in psittacines, and the numerous acquired diseases that can occur, screening by an ophthalmologist is recommended. Cataracts often develop secondary to infection or trauma or may be age related. Uveitis may also be present. Additional ophthalmic conditions that may be encountered in geriatric birds are keratoconjunctivitis sicca, corneal ulcerations, third eyelid abnormalities, hypopyon, anterior uveitis, conjunctival granulomas, infection of the conjunctiva (eg, *Chlamydia*, *Mycoplasma*, poxvirus), Harderian gland adenoma, and lymphoma.

In large psittacine birds, surgical removal of cataracts is successful in many cases. The bird's general health and the degree to which the cataracts affect its quality of life should be evaluated before surgery. Commonly used mydriatics are not useful in birds because of the skeletal (as opposed to smooth) muscle found in the iris. In any bird with decreased vision, minimal alteration of the home environment is critical. Early cataracts, especially if uveitis is present, may be painful. NSAIDs, either ocular drops (flurbiprofen) or systemic (meloxicam, celecoxib), or both, can be used to reduce inflammation and pain.

Arthritis

Septic and traumatic arthritis may occur at any age. Septic arthritis is most common in the digits. Osteoarthritis is also common in geriatric birds and can lead to other issues such as pododermatitis if not caught early and treated. The weight of the bird, its general physical condition, previous injuries, and any concurrent medical conditions can all contribute to the onset and severity of arthritis. Concurrent pododermatitis is often present and may be both a cause and result of decreased activity. Malnutrition, which decreases the integrity of the plantar epithelium, and concurrent obesity are often present in affected birds. The cage environment, especially the variety, diameter, and texture of perches, can be important in providing comfort and stability for arthritic birds while preventing or minimizing pododermatitis. If possible, the nails should be left with sharp points to add strength and stability to the grip. Wings should not be clipped, to help with balance.

Clinical signs vary, depending on the location of the arthritis and the severity of disease. Birds may exhibit lameness or be less active. A flighted bird may not want to fly or may not fly as well. The bird may not be perching normally or may fall off perches. Other signs of arthritis are swollen or warm joints, decreased range of motion, feather picking or mutilation, or excessive vocalization.

Diagnosis is based on clinical signs, physical examination findings, and imaging (radiographs or CT scan). Radiographic lesions include narrowing of the joint space, sclerosis of the subchondral bone, misalignment of the joint, and osteophyte formation. CT scans help determine the severity of the bony changes. Commonly affected joints are the tarsus, stifle, and phalangeal joints. The joints of the thoracic limb appear to be less commonly affected.

A multimodal treatment plan is recommended, incorporating both medical and nonmedical modalities. Medical treatment includes the use of NSAIDs, chondroprotectants, and possibly opioids. The most common NSAID used in avian medicine is meloxicam (0.5–1 mg/kg, PO, once to twice daily), a COX-2 inhibitor. Potential adverse effects of NSAIDs are renal ischemia, so they should be used with caution longterm and at the lowest therapeutic dose possible. Anecdotal, glucosamine (20 mg/kg, PO, bid, or 35 mg/kg, PO, once daily or every other day) or polysulfated glycosaminoglycan (5 mg/kg, IM, once weekly for 4 wk then monthly) has been used successfully. The

latter should be used carefully, because some birds have had fatal coagulopathies from the injections.

Opioids may be necessary for acute exacerbations of a chronic arthritic condition or for conditions not responding initially to NSAIDs. Tramadol (15–30 mg/kg, PO, bid–qid) or butorphanol (0.5–3 mg/kg, IM, every 4 hr (depending on species of bird), may be used until the NSAIDs take effect.

Additional management includes husbandry changes, a weight loss and exercise plan, a healthier diet (rich in omega-3 fatty acids), and physical therapy. Encouraging flighted birds (without clipped wings) to fly in a safe environment is the best form of exercise. If a safe environment is not possible, encouraging climbing, walking, or even stepping up multiple times can be exercise for parrots. Foraging for food, by putting multiple foraging boxes on opposite sides of the cage or enclosure, promotes exercise. If the bird is overweight, then weight loss is essential, because studies have shown that obesity is a risk factor for osteoarthritis in many species. This may involve converting the bird slowly to a pelleted diet with added essential fatty acids. Fatty acids may have an anti-inflammatory effect and be renal protective. Flax seed oil (0.1–0.2 mL/kg/day, PO) is recommended as the best source of fatty acid supplementation for birds. Other husbandry changes, such as changes in perch texture or diameter or padding perches, can be helpful in birds with weak or painful legs or feet.

Articular gout is also common in older birds (see p 1926). Differentiation between arthritis and articular gout is critical because of the vast differences in progression, quality of life, and prognosis.

Pododermatitis

Pododermatitis, or bumblefoot, is a relatively common condition of older pet birds. It is a general term for any inflammatory or degenerative condition of the avian foot and can range from mild redness to bony changes. Bumblefoot develops most commonly when birds are either housed with inappropriate perching or secondarily to an injury in one leg, which causes the bird to shift its weight to the other (good) leg and creates increased pressure and potential ulceration on the plantar surface of the foot. Birds most at risk are birds with leg fractures; arthritis of a hip, stifle, or tarsal joint; and obese birds or birds on a poor diet (eg, vitamin A deficiency). These are the same conditions that can predispose a bird to

arthritis. Bumblefoot is often a sequela of osteoarthritis. Pododermatitis is a progressive disease. A localized hyperemic lesion develops, followed by ulceration and, if untreated, abscess formation and osteomyelitis. Initially, the skin on the metatarsal and digital pads becomes flattened and smooth. The skin may become proliferative and then ulcerate, allowing bacterial access, which leads to inflammation and infection. As the infection progresses, tendon sheaths become affected, and osteomyelitis and septic arthritis develop.

Birds may present with lameness, depression, and anorexia due to the inflammation, pain, and infection. Diagnosis is based on clinical signs, physical examination findings, radiographs, and culture results. Affected birds should be examined thoroughly for predisposing injuries or illness.

Treatment includes correcting inappropriate husbandry (adding padded perches or perches covered with artificial grass) and conversion to a healthier, preferably formulated diet. Weight loss and exercise should be encouraged in obese birds (flying, climbing, or walking). In early cases, this may be all that is necessary.

As the disease progresses, a bandage may be necessary to relieve the pressure on the lesion. The lesions should be kept clean. Strict sanitation of the perches and feet is important to prevent bacterial infections. If a scab is present, it should be softened and removed or surgically debrided. Antibiotic use should be based on results of culture and sensitivity testing. *Staphylococcus* spp is most commonly identified; other reported bacteria include *Escherichia coli* and *Proteus* spp. Effective antibiotics are amoxicillin/clavulanate (125 mg/kg, PO, tid), enrofloxacin (10–15 mg/kg, PO, bid), and marbofloxacin (5 mg/kg/day) for 10–14 days. Pain management is important and includes a combination of NSAIDs and/or opioids, depending on the severity of disease and after any surgical debridement. One regimen is meloxicam (0.5–1 mg/kg, once to twice daily) along with tramadol (15–30 mg/kg, PO, bid–tid), and, in severe cases or after surgery, butorphanol (0.5–3 mg/kg, IM, every 4 hr, depending on species). Local anesthetics may be helpful after surgery.

Renal Disease

Renal disease may be seen at any age, but older birds are more likely to develop renal insufficiency. Causes are multiple and

include glomerulonephropathies, renal tubular gout, and chronic bacterial nephritis.

Clinical signs include weight loss, depression, polyuria, polydipsia, and articular gout. Diagnosis is made based on a persistent hyperuricemia before and after fluid therapy. Imaging (radiographs or CT scan) may demonstrate small or large kidneys with or without mineralization. Occasionally, urethroliths may be seen. Renal biopsy is necessary for definitive diagnosis.

Treatment includes supportive care (fluid therapy) and antibiotics as needed based on diagnostics. Colchicine (0.04 mg/kg, PO, bid) and allopurinol (10–30 mg/kg, PO, bid) have successfully treated certain disease processes. After stabilization, conversion to an appropriate diet should be initiated. Essential fatty acids (omega 3) at 0.1–0.22 mL/kg/day, PO, have been used anecdotally to manage renal disease in birds.

Cardiac Disease

As birds live longer and diagnostic techniques improve, cardiac disease is being diagnosed more frequently. It can be difficult to detect and may mimic other problems, such as respiratory disease. Cardiac disease has been associated with atherosclerosis in pet birds, and potential risk factors are a sedentary lifestyle, a high-fat diet, and hypercholesterolemia.

Clinical signs are weakness, depression or lethargy, increased respiratory rate and effort, or tachycardia. With right-side heart disease, hepatomegaly and ascites are common. Disease also may be subclinical, then present acutely, with the bird arresting when diagnostic tests or treatments are attempted. In birds, right-side cardiac disease is more prevalent than left-side.

Consultation with a cardiologist on any avian patient with suspected cardiac disease is advised. Diagnosis of the cardiovascular abnormality and forming a therapeutic plan requires knowledge of avian anatomy and physiology and a cardiologist's diagnostic skills and pharmacologic recommendations. Radiographs and cardiac ultrasound can aid in the diagnosis.

The stress of handling can increase intracardiac blood flow velocity 300% in avian patients; therefore, inhalant anesthesia or sedation is preferred over manual restraint for performance of echocardiograms in all but the most docile birds. The equipment necessary for echocardiology in birds includes an ultrasound unit with Doppler

function, 100 frames/sec minimum speed, and microcurved or phased array probes with a minimum 7.5 MHz frequency. Anatomic constraints in birds also limit the echocardiograph windows available. Parameters for chamber sizes, blood flow velocities, functional contractility, and valvular insufficiency have been determined for several species, and studies are ongoing in this area.

Reported therapies include enalapril (0.25–0.5 mg/kg/day, PO), furosemide (0.15–2 mg/kg, PO, SC, or IM, once to twice daily), pimobendan (6 mg/kg, PO, bid), and digoxin (0.01–0.02 mg/kg, PO, bid). Although most avian therapeutic regimens are still extrapolated from those used in mammals, numerous reports indicate that cardiac drug therapy can improve cardiac function, thereby increasing the quality and length of life.

Pulmonary Hypertension: The cardiovascular system of birds differs anatomically and physiologically from that of mammals. The right atrioventricular valve is a single, muscular valve with no chordae tendinae. The physiologic responses that maintain low pulmonary vascular resistance (both vascular distensibility and vasculature recruitment) are absent in birds, resulting in the inability of the pulmonary vasculature to accommodate increased cardiac output by either altering vascular diameter or changing the percentage of vascular channels being used. This may be, at least in part, responsible for the high incidence of pulmonary hypertension syndrome in poultry (*see p 2871*) as well as right-side heart disease in psittacines. Studies on the impact of pulmonary hypertension in broiler hens have demonstrated that the response to pulmonary arterial hypertension in chickens involves an increase in two vasoactive substances: a vasodilator and a vasoconstrictor. The vasoconstrictor predominates over the vasodilator in broiler hens susceptible to pulmonary hypertension. For geriatric psittacine patients with pulmonary hypertension, vasodilator therapy should be explored. Macaw asthma may theoretically cause pulmonary hypertension, both from chronic capillary hypoxia and subsequent polycythemia.

Atherosclerosis: Atherosclerosis is a proliferative lesion of the tunica media and tunica intima of elastic and muscular arteries. Atherosclerotic plaques cause

abnormal vascular flow and loss of endothelial integrity. These changes in vessel walls can initiate thrombosis. In birds, lesions are primarily in the aorta and brachiocephalic arteries. Atherosclerosis is common in psittacine birds. It is generally a geriatric condition, except in African grey parrots, in which this disease has been observed in very young birds. Amazon parrots, macaws, and African grey parrots seem to be particularly susceptible.

Predisposing factors appear to include age (most affected birds are 10–15 yr old), sedentary lifestyle, and a high-fat diet. Clinical signs are rarely reported in birds, and the condition is often associated with sudden death. Clinical signs that may be seen are exercise intolerance, dyspnea, episodic weakness, and neurologic signs (eg, seizures, tremors, paresis). At necropsy, grossly thickened arterial walls are seen.

Diagnosis can be difficult. Radiographically, the right aortic arch may be enlarged, with increased density. Lipemia is often present, and marked increases in cholesterol and triglyceride concentrations may be seen. Unfortunately, definitive antemortem tests are lacking.

Medical treatment is anecdotal. A variety of treatments have been advocated to lower cholesterol levels, but none appears to be consistent in its efficacy. Isoxsuprine (10 mg/kg/day, PO) has been used anecdotally with some success. Essential fatty acids (flax seed oil at 0.1–0.2 mL/kg/day, PO) have been advocated and used to reduce cholesterol and inflammation.

Liver Disease

Liver disease can affect birds of any age but is more common in geriatric birds. Hepatic lipidosis is most common, possibly resulting from longterm feeding of an inappropriate (high-fat) diet. Chronic liver disease can result in fibrosis of the liver and decreased liver function and failure.

Clinical signs of liver disease are anorexia, lethargy, overgrown beak and nails with bruising, biliverdinuria, discolored feathers, and, in later stages, ascites. Birds often are overweight or have a history of being obese. Clinical pathology may reveal high liver enzyme levels (AST) and bile acids, a nonregenerative anemia, and high triglyceride and cholesterol concentrations. Imaging (radiographs or CT scan and/or ultrasound) may reveal hepatomegaly or microhepatica. Liver biopsy may be necessary to confirm the diagnosis and determine etiology and prognosis.

Treatment involves supportive care (fluid therapy), antibiotics as needed, and medications to support hepatic function such as silymarin (milk thistle) (100–150 mg/kg, PO, bid) and ursodeoxycholic acid (10–15 mg/kg/day, PO).

NEOPLASTIC DISEASES

Neoplasia occurs with some frequency in pet birds of all ages and includes cancer of the skin, sinuses, oral cavity, GI tract, lungs, air sacs, liver, spleen, kidneys, reproductive tract, bone, vascular and connective tissue, and brain. The incidence of cancer is likely to rise as pet birds age. Often, external tumors can be seen on physical examination and diagnosed by fine-needle aspirate and cytology or biopsy. Internal neoplasia often requires imaging (radiographs, ultrasound, or CT scan), endoscopic examination, or exploratory surgery to determine the type and extent of the neoplasia. Treatment protocols are becoming more successful but are still extrapolated from other species and often have been performed in only one or two birds. More information (clinical studies and research) is needed on diagnostic tests, treatments (including adverse effects), and prognosis of neoplasia in companion birds.

Pseudoneoplastic Skin Conditions

Xanthomas are not neoplasms but locally invasive subcutaneous, yellow, fatty masses in the skin. Xanthomas are rarely found in internal organs. The distal wing, keel, and the sternopubic area are common locations, although xanthomas may be found anywhere. Cockatiels and budgerigars are overrepresented, although xanthomas are seen in most psittacine species. The lesions may be pruritic and may be associated with lipomas or sites of chronic irritation. The cause is unknown; however, dietary improvement, including sufficient vitamin A, has been curative in less advanced cases. Xanthomas tend to be vascular. Therapy includes surgical resection, although in large masses closure may be difficult, and strict attention to hemostasis must be observed. Amputation is not recommended for xanthomas on the wing tip.

Lipomas occur most frequently in budgerigars, rose-breasted cockatoos, Amazon parrots, and cockatiels. These benign, soft, yellowish, encapsulated subcutaneous masses are most often located on the keel or in the sternopubic area. If traumatized, they may become

inflamed or necrotic. Lipomas can grow rapidly and result in ulceration of the overlying skin. Treatment includes conversion to a low-fat diet, weight loss in obese birds, and surgical excision. Recurrence is common with incomplete removal.

Cutaneous, Subcutaneous, and Other Neoplasms

Fibrosarcomas may be lobular, subcutaneous masses without skin involvement or may be seen as erythemic skin lesions. They may also develop in the oral cavity, bone, or abdominal cavity. Fibrosarcomas tend to be locally invasive and recurrent. Surgical excision followed by radiation and chemotherapy has shown some success.

Liposarcomas are malignant tumors of the lipocytes and have rarely been reported in pet birds. They have been described in cockatiels, budgerigars, a conure, an African grey parrot, and a quaker parakeet. They are similar in appearance to lipomas (yellowish, gray mass) but are firmer, more infiltrative, and vascular. Cytologic examination may not differentiate between a lipoma and liposarcoma, so surgical biopsy is recommended. Therapy includes surgical excision, although recurrence is common with incomplete removal.

Squamous cell carcinoma (SCC) is a malignant tumor comprised of moderately undifferentiated poorly differentiated squamous cells. SCCs are most common on the skin and beak, in the oral cavity, esophagus, or crop, and on the distal wing and phalanges. These tumors tend to be locally invasive. Cutaneous SCCs often appear as proliferative masses or woundlike ulcers. Tumors often develop at sites of chronic irritation. It has been experimentally demonstrated that inflammation can promote neoplastic proliferation. SCCs of the uropygial gland can occur and result in enlargement of the gland and ulceration. SCCs of the beak result in overgrowth and deformation of the beak. Tumors involving the sinuses or oral cavity typically have poorly defined borders and are associated with necrosis and hemorrhage.

Clinical signs of SCCs of the sinus or oral cavity are dyspnea, dysphagia, anorexia, exophthalmos, and nasal discharge. Clinical signs of birds with SCCs of the crop or esophagus include anorexia, regurgitation, and depression. Cutaneous SCCs tend to be locally aggressive and recur, but there are few reports of metastasis. Tumors are often associated with chronic (secondary) bacterial and fungal infections. **Diagnosis** is based on imaging (radiographs, CT scan)

and fine-needle aspirate and cytology or biopsy of the lesion.

Recommended treatment is surgical excision with or without radiation therapy. Cobalt-60 radiation therapy and intraleisional carboplatin and cisplatin have had limited success in treatment of SCCs. Radiation therapy with a strontium-90 probe has had some success in treatment of SCCs of the uropygial gland after surgical excision or debulking.

Musculoskeletal neoplasms reported in psittacines include osteosarcoma, chondroma, chondrosarcoma, hemangioma, and leiomyosarcoma. Wide surgical resection is the suggested treatment.

Internal carcinomas include **ovarian neoplasia** (various cell origins), **renal carcinoma**, **hepatic adenocarcinoma**, and **hepatobiliary adenocarcinoma** (related to papillomas in Amazon parrots).

Clinical signs of coelomic tumors include anorexia, weight loss, depression, and/or dyspnea (from organ enlargement and compression of air sacs). Gastric carcinomas, generally diagnosed at necropsy, are often found at the proventricular-ventricular junction. **Death** from gastric neoplasia may be caused by hemorrhage, gastric perforation and sepsis, endotoxic shock, or inanition and subsequent wasting. **Diagnostic tests** include radiographs with or without barium contrast, CT scan, or ultrasound with fine-needle aspirate and cytology or biopsy.

Both carboplatin and cisplatin have been used successfully in various forms of internal carcinoma. Toxicity studies with cisplatin in cockatoos indicate that psittacine tolerance for this drug may be greater than that of mammals. Several cases of ovarian neoplasia have been treated with GnRH agonists (leuprolide or deslorelin implant) with some success.

Pituitary adenomas are most prevalent in budgerigars and cockatiels but have been observed in other psittacine species. Tumors may cause acute neurologic conditions (eg, seizures, opisthotonos, ataxia, blindness, and difficulty flying). Affected birds may also show signs related to the pituitary hormone(s) affected (eg, adrenocorticotrophic hormone [ACTH] associated with polydipsia and polyuria). **Diagnostic tests** are of limited use. Pituitary tumors are typically diagnosed based on species and clinical signs and are confirmed at necropsy.

Thymoma and thyroid adenocarcinomas have been reported in several psittacine species. Primary **pancreatic neoplasias** of variable cell origins have been reported.

Lymphoma/lymphosarcoma is the most common lymphoid neoplasia in psittacine and passerine birds. Multicentric lymphosarcoma is most common, whereas lymphocytic leukemias occur rarely. Lymphoma can involve the spleen, liver, kidneys, GI tract, skin, bone, oviduct, lungs, sinuses, thymus, testes, brain, mesentery, trachea, and pancreas. The liver is most commonly affected, followed by the spleen and kidneys. Numerous reports of exophthalmos in psittacines, particularly young African grey parrots, have been diagnosed as retrobulbar lymphoma. Cutaneous lymphoma often occurs on the head or neck. Lesions are grayish yellow, diffuse or multifocal, and may resemble xanthoma or inflammation. Clinical signs vary based on location of the tumor but may include depression, anorexia, weight loss, coelomic distention, paresis, lameness, blindness, regurgitation, or dyspnea. Canaries often present for having stopped singing.

Diagnosis is based on physical examination findings, imaging (radiographs with or without contrast, ultrasound, or CT scan) and fine-needle aspirate or biopsy of affected organs, masses, or bone marrow. A CBC often reveals leukocytosis or lymphocytosis rather than a leukopenia. Anemia (PCV <35%) is commonly reported. No evidence of retroviral activity has been associated with psittacine lymphoma.

Treatment has included surgical excision with or without chemotherapy. Chemotherapy regimens have included one or more of the following: corticosteroids, orthovoltage x-ray, chlorambucil, doxorubicin, L-asparaginase, cyclophosphamide, α -interferon, and/or vincristine sulfate. Diphenhydramine and dexamethasone have been used to reduce the incidence of allergic reaction or anaphylaxis. Although chemotherapy and radiation therapy have been successful, treatment success overall has been variable.

Primary respiratory neoplasia is uncommon in psittacines, except for a mixed pulmonary tumor reported in cockatiels. Metastatic pulmonary neoplasia may occur.

Chemotherapy and Radiation Therapy Agents

Most reports of chemotherapy in birds have demonstrated both higher tolerance for chemotherapeutic agents than expected and less tumor response than desired. Anecdotal reports indicate that neoplasia in birds is more resistant to radiation than that in mammals. Very few case reports and even fewer

research reports are available for chemotherapy or radiation therapy protocols in birds. Because very little is known about chemotherapy and radiation in birds, a current literature search and consultation with a veterinary oncologist are recommended before treatment of a pet bird diagnosed with cancer. In addition to the antineoplastic drugs that have been used in birds discussed below, see ANTINEOPLASTIC AGENTS, p 2722.

Vincristine was used in the chemotherapeutic regimen of an African grey parrot with malignant lymphoreticular neoplasia, a Moluccan cockatoo with lymphoma, and a Pekin duck with lymphoma and leukemia.

Cisplatin/carboplatin was evaluated in eight sulfur-crested cockatoos. A dose of 1 mg/kg infused over 1 hr was tolerated well, and plasma levels were in a therapeutic range. Adverse effects were weight loss, regurgitation, and bone marrow suppression. Intratumoral cisplatin and radiation therapy were used to treat fibrosarcoma in a macaw. Intralesional cisplatin was used unsuccessfully in treatment of SCC in a Buffon's macaw. Carboplatin was used successfully to treat a bile duct carcinoma in a yellow-naped Amazon parrot and pancreatic duct adenocarcinoma in a green-winged macaw.

L-Asparaginase was used to treat lymphoma in a Moluccan cockatoo. Adverse effects associated with treatment were weight loss, lethargy, anorexia, and regurgitation. Doxorubicin was used successfully in a blue-fronted Amazon parrot with osteosarcoma. Doxorubicin in combination therapy was unsuccessful in treating lymphoma in a Moluccan cockatoo. Chlorambucil was used successfully in treatment of cutaneous pseudolymphoma in a blue and gold macaw. Cyclophosphamide has been used to treat lymphoma in a Moluccan cockatoo.

Radiation therapy has been used in birds with variable results (see p 1651).

NUTRITIONAL DISEASES

Proper nutrition for companion birds historically has been and continues to be a concern for avian veterinarians, aviculturists, and owners. Although avian nutrition has greatly improved in the past decades, nutritional disease is still common in pet birds. The availability of formulated diets and hand-feeding formulas have been pivotal in improving avian nutritional health, but many birds are still fed inadequate diets. The two most common reasons for malnutrition in companion birds are feeding

diets that allow the birds to choose what they want to eat (either mixtures of seeds/nut and pellets, or table foods the owner considers healthy) and feeding pure seed or seed-based diets. Feeding a mixture of pellets and seeds is also common, resulting in selective eating and consequently inadequate nutrient consumption.

Many of the illnesses seen in pet birds have their basis in malnutrition. This includes hepatic disease, renal insufficiency, respiratory impairment, musculoskeletal disease, and reproductive problems. For additional information on nutrition in pet birds, see p 2288.

Obesity: Obesity is common in companion birds. High-fat diets (seeds, nuts, and many table foods), overabundance of food, and a sedentary lifestyle are all contributing factors. Obesity is typically defined as a bird being 20% over ideal weight, with a body condition or keel score of 4 out of 5 (see p 1887). Galahs, macaws, Amazon parrots, and quaker parrots are prone to obesity. Clinical signs may not be evident but include lameness (pododermatitis and/or arthritis) and respiratory issues from excessive abdominal fat.

Obese birds should be converted to a pelleted diet with portion control. Exercise should be encouraged by providing a larger cage with multiple food bowls around the cage to encourage movement. Rope or spiral rope perches will encourage climbing and balance. A flight cage outdoors should be provided for flighted birds, and walking or climbing stairs encouraged for non-flight birds. Obese birds are more prone to arthritis, fatty liver disease (hepatic lipidosis), atherosclerosis, and cardiac disease.

Fatty liver disease (hepatic lipidosis), gross lesions, in a cockatiel. A pale liver is located beneath the heart, nestled in a pad of abdominal body fat. Courtesy of Dr. Louise Bauck.

Vitamin A Deficiency: Vitamin A plays an important role in avian health and is crucial for a healthy immune system. Hypovitaminosis A causes squamous metaplasia of epithelium within the oropharynx, choana, sinuses, GI tract, urogenital tract, reproductive tract, and uropygial gland as well as hyperkeratosis of the feet. All-seed diets and even mixed diets of $\frac{1}{2}$ seeds and $\frac{1}{2}$ pellets are deficient in vitamin A.

Clinical signs are nasal discharge, sneezing, periorbital swelling, conjunctivitis, dyspnea, polyuria, polydipsia, poor feather quality, feather picking, and anorexia. Birds may have absent or blunted papilla of the choanal slit. White plaques (hyperkeratosis) may develop in and around the mouth, eyes, and sinuses. In chronic epithelial conditions (eg, pododermatitis, sinusitis, and conjunctivitis) that have been refractory or recurrent, often vitamin A deficiency is the primary cause. Birds with reproductive disease on poor diets should be considered deficient.

Treatment involves treating secondary infections, supplementing with vitamin A, and converting the bird to a good quality pelleted diet. Parenteral vitamin A can be given (100,000 U/kg, IM). Vitamin A precursors, such as spirulina, sprinkled daily over the food are a safe way to supplement diets deficient in vitamin A. The diets of all pet birds should be evaluated for vitamin A content.

Iodine Deficiency: Goiter, or thyroid hyperplasia, occurs in budgerigars on all-seed diets deficient in iodine. This condition is no longer common because of the availability of pelleted and fortified diets. Classic signs are respiratory stridor, wheezing, or clicking due to the pressure of the thyroid on the syrinx. Lugol's iodine (1 drop/250 mL of drinking water) can be used until conversion to a pellet or fortified seed diet is accomplished and clinical signs have subsided.

Calcium, Phosphorus, and Vitamin D₃ Imbalance:

Seed-based diets are well known for their calcium:phosphorus imbalance and amino acid deficiencies. Sunflower seeds, which tend to be selected preferentially by many psittacines, are low in calcium, deficient in essential amino acids, and high in fat. Safflower seeds are actually higher in fat content than sunflower seeds, contrary to popular belief, and also contain inadequate amino acids and calcium.

Metabolic Bone Disease (Nutritional Secondary Hyperparathyroidism):

Nutritional secondary hyperparathyroidism can occur in young and older pet birds. Because the calcium to phosphorus ratio in most seeds is poor (high phosphorus and low calcium), birds on a seed diet become seriously depleted. The effects of a calcium-deficient diet are often compounded by inadequate exposure to unfiltered sunlight in birds housed indoors, resulting in vitamin D₃ deficiency as well. In young birds, especially African grey parrots, hypocalcemia may present as osteodystrophy, with curvature and deformation of the long bones and vertebrae. African grey parrots are also prone to an acute hypocalcemia syndrome that is associated with both hypocalcemia and hypovitaminosis D₃.

Clinical signs include weakness, ataxia, tremors, depression, seizures, and pathologic fractures. In reproducing birds, eggs are often thin-shelled, egg production and hatchability are decreased, and embryonic death occurs. Calcium deficiency can lead to cessation of egg laying, egg binding, or cloacal prolapse. Diagnosis is based on decreased total and ionized plasma calcium levels and radiographic evidence of decreased bone density or pathologic fractures. Serum 25-hydroxycholecalciferol levels can also be measured and are usually low.

Treatment is supportive care, calcium and vitamin D supplementation, conversion to an appropriate diet, and exposure to ultraviolet light, preferably natural sunlight. If pathologic fractures are present, splinting or bandaging may be necessary, along with cage rest, NSAIDs, or analgesics. Initial treatment should consist of calcium gluconate (100 mg/kg, IM).

Pet birds should have exposure to natural sunlight when possible. Owners should provide an outdoor cage that provides opportunities for climbing and/or flight and access to direct sunlight. Birds should be monitored closely when outdoors, even in a cage, because many predators can injure a pet bird through cage bars.

Vitamin D Toxicosis: Although excessive oral calcium intake is not thought to cause clinical problems in most cases, excessive oral vitamin D₃ can cause harmful calcium accumulation in tissues such as the kidneys. Supplements should be used carefully, especially in susceptible species (eg, macaws).

Iron Storage Disease: Iron storage disease refers to disease that occurs with excessive iron accumulation in the liver.

Hemachromatosis is reserved for cases associated with actual pathology. As iron levels within the liver increase, hepatic lysosomes are damaged and release ionic iron, resulting in oxidative damage to membranes and proteins. Iron storage disease is common in mynahs and toucans, and in certain zoo birds such as birds of paradise; it has been occasionally reported in pet psittacine species, particularly lorries. Iron storage disease is associated with excessive intake of dietary iron. However, not all birds are affected when fed similar diets, and stress or genetic factors may also play a role. Certain foods rich in vitamin C, such as citrus fruits, increase dietary iron uptake. Current dietary iron recommendations for toucans and mynahs are <50–100 ppm.

Clinical signs are anorexia, weight loss, depression, distended abdomen with ascites, dyspnea, and biliverdinuria. The liver, spleen, and heart are the most commonly affected organs. Circulatory failure, ascites, and hypoalbuminemia are often seen clinically. Diagnosis is by liver biopsy.

Treatment includes periodic phlebotomy, iron chelation, and dietary modification. Recommending low-iron diets routinely for pet mynahs and toucans is prudent (commercial formulas are available). Foods high in vitamin C should be avoided. Supplementation with chelators such as tannins, fiber, and phytates has been suggested.

Additional Nutritional Concerns: In addition to the well-documented nutritional deficiencies in diets designed for psittacines, described above, the following dietary concerns should also be noted: 1) the potential sensitivity of individual birds to dyes and preservatives added to some seed and pelleted foods; 2) the high incidence of hepatic lipidosis, atherosclerosis, and right-side heart failure in sedentary captive birds consuming primarily seed diets; 3) the occurrence of hepatic fibrosis and cirrhosis secondary to aflatoxicosis from improperly stored seed and pet-grade peanuts; 4) the difference between food provided by well-meaning owners for their birds to eat (table foods, formulated pelleted diet, vegetables, etc) and what the birds actually consume (seed); and 6) the low palatability of most vitamin and mineral supplements added to water, which are not only ineffectual but can lead to decreased water consumption and dehydration.

Foods that owners should be advised to avoid feeding their birds at any time are

chocolate, caffeinated beverages, alcohol, junk food (salt, sweets), milk products, onions, avocados, and apple seeds.

Wild birds spend many hours a day foraging for food. Captive and pet birds usually consume all of their caloric needs at one food bowl, with very little time or energy expended. To promote a healthier lifestyle for companion birds, foraging opportunities should be provided that increase activity, promote a healthier diet, and stimulate birds intellectually. Owners need to provide a cage large enough for the bird to climb and play in, with rope or other perches that stimulate activity and balance. Multiple small food bowls should be placed throughout the cage to encourage movement. Foraging toys with food bits promote activity as well. An outdoor flight cage that allows natural sunlight and increased activity is ideal.

REPRODUCTIVE DISEASES

Birds are oviparous, meaning they lay and incubate eggs. Chicks may be precocial (hatched with downy feathers and able to eat on their own soon after hatching) or altricial (featherless and completely dependent on being fed by parent birds until weaned). Passerine and psittacine birds are altricial. Sexual maturity occurs from 6 mo of age in smaller birds to 3–5 yr in larger parrots. Most hens have only a left ovary and oviduct and are heterogametic (the female determines the sex of the chick). The male has two testes located internally cranial to the cranial pole of the kidney.

Most wild birds have a specific breeding season. Captive and pet birds breed at any time based on environment (photoperiod), nutritional status, and absence or presence of a mate (bird) or perceived mate (human) and/or nest box. Females store calcium in their bones (hyperostosis), which is later used in egg shell production. Ovulation occurs in response to increasing levels of estrogen and luteinizing hormone. The oviduct is composed of four segments: the infundibulum, where fertilization occurs; the magnum, where albumen is deposited; the isthmus, where the inner and outer shell membrane is added; and the uterus (shell gland), where calcification of the shell occurs. The entire period of egg formation takes ~24 hr. Most pet birds lay 2 to 4 eggs in a clutch, although indeterminate layers such as cockatiels and budgerigars can produce much larger clutches.

Most pet birds are not sexually dimorphic, so determining the sex requires endoscopic examination or DNA sexing.

Common reproductive problems in pet birds include behavioral issues, failure to reproduce, excessive egg production, dystocia (egg binding), impacted oviduct, egg yolk peritonitis, cloacal prolapse, and neoplasia.

Behavioral Problems: Behavioral problems that can be related to reproductive issues include feather picking, mutilation, and excessive screaming. These behaviors can also occur for other reasons, so a full evaluation must be done to determine the cause. Behavioral problems are most common in hand-raised parrots overly bonded to their owners. Psittacines are intelligent, social animals. In the wild, most live in flocks, have a set breeding season (based on temperature, photoperiod, humidity), and raise chicks with their mate. In captivity, most pet birds are kept all year at stable temperatures and are provided adequate food, which is often high in fat. This can promote breeding behavior year round.

Many hand-raised parrots are overly bonded to their owner at sexual maturity, resulting in sexual frustration that may lead to over-grooming behaviors and excessive contact calls (screaming) when the owner leaves the room or house. Some of these over-stimulated (excessively handled and petted) birds begin laying eggs or masturbating early, leading to egg binding or cloacal prolapse (*see* p 1922) along with feather destructive behavior or screaming.

Significant behavior modifications may need to be implemented (*see* p 1927) along with conversion to a pelleted diet. In some cases, a GnRH agonist may be necessary to decrease production of reproductive hormones. This should ideally only be done along with implementing necessary behavioral modifications.

Excessive or Chronic Egg Laying:

Excessive egg laying is when a bird has repeat clutches, lays more eggs than normal, or produces more eggs than is normal. It is common in small birds, eg, budgerigars, lovebirds, and especially cockatiels. Affected birds typically are on a high-fat and high-calorie diet. Other birds typically are housed either in the same cage or close by, or birds are overly bonded to the owner. They often have an extended photoperiod (>12 hr). In some color mutations, there may be a genetic predisposition.

Clinical signs may not be evident, with only a history of excessive egg laying, or the bird may present nonperching, weak, depressed, and tail bobbing (indicating

dyspnea), with decreased defecation or voluminous droppings. Birds often have a wide-based stance, are broody, and may have pathologic fractures from hypocalcemia. Excessive egg laying, if untreated, often leads to more serious reproductive issues such as dystocia, impacted oviduct, egg yolk peritonitis, or cloacal prolapse.

Diagnosis is based on the history, physical examination findings, high plasma calcium levels, and radiographic findings of hyperostosis and/or evidence of an egg. Reproductively active birds often have high cholesterol, triglyceride, and total protein concentrations.

Treatment involves decreasing day length to 8 hr of daylight, conversion to a pelleted diet, removal of nest boxes and any toys the bird may be overly bonded to, removal of any mate, and discussion with the owner of appropriate handling of their bird. Calcium supplementation and a GnRH agonist may be needed to reduce the production of reproductive hormones. Usually, leuprolide acetate (800 mcg/kg, IM, every 3 wk for three injections, then prn) is administered. If the above changes and medications are unsuccessful, then a salpingohysterectomy may be necessary. This will prevent egg laying but not always ovulation, because it is impossible in birds to remove all ovarian tissue. Prognosis is good with early cases that respond to management, dietary changes, and GnRH agonists.

Egg Binding: Dystocia (egg binding) is a common occurrence in captive hens, most notably in cockatiels, budgerigars, and lovebirds. Usually, these birds are chronic egg layers, and calcium deficiency (resulting in misshapen or soft-shelled eggs) is a factor. Other causes include vitamin A deficiency, oviductal disease or neoplasia, abdominal wall herniation, being a first-time layer, and genetic factors. An inappropriate environment and lack of a nest box can be contributing factors for some birds. Egg binding may also be seen in large psittacines, although excessive egg laying is not as commonly associated with the condition in these birds. Obesity, general nutritional inadequacy, behavioral factors, and husbandry conditions may be involved. Egg-bound birds often present as emergencies. These birds should receive supportive care (ie, rehydration, parenteral calcium, increased humidity, and warmth) before attempting extraction of the egg.

Clinical signs include a bird on the bottom of the cage, depression, closed eyes, bobbing tail, and dyspnea. The abdomen

may be distended. An egg is not always palpable. Diagnostic tests may need to wait until the bird is stable; they include a CBC, plasma biochemical profile (including ionized and total calcium), and radiographs. These tests may need to be done stepwise in a critical patient.

Medical treatment includes fluid therapy, parenteral calcium supplementation, analgesics, and/or NSAIDs, and continued maintenance in a warm humid incubator. Oxytocin and the avian equivalent arginine vasotocin both cause uterine contractions and induce oviposition, as can prostaglandins F or E. If the egg is adherent to the uterine wall or unable to be passed (often due to swelling, adhesions, or collection of feces and urates), administration of these drugs could theoretically lead to uterine rupture, but this has rarely been reported.

If medical management fails, then sedation, inhalant anesthesia, and manual extraction may be required. With the bird under anesthesia, the cloaca is lubricated with sterile jelly. Barring adherence of the egg to the uterus, steady digital pressure applied between the end of the sternum and the egg will cause the slow descent of the egg. At this point, the uterus will often evert and reveal the white pinhole where the uterine opening is located. This opening will gradually dilate. Very seldom will any additional pressure or manipulation be required. After the egg is delivered, the uterus typically will normally involute. If oviposition does not occur with digital pressure or because of a soft-shelled egg, oovocentesis is indicated. After aspiration, firmer shells are collapsed and carefully removed or allowed to pass. Postoperative care includes antibiotics, NSAIDs, and a GnRH agonist to reduce further egg laying. After egg extraction, the hen may continue to be depressed, with labored breathing, and often will not appear clinically normal for up to 24 hr. A second egg may be produced by the following day, so repeated palpation is indicated.

Surgical intervention (salpingohysterectomy) is warranted if the egg is severely adhered to the oviduct, multiple eggs are present, or the egg is ectopic. Prognosis for egg binding is fair to good if medical treatment or manual extraction of the egg is effective. Husbandry, nutritional, and behavioral issues as discussed under excessive egg laying (*see above*) need to be addressed.

Impacted Oviduct: An impacted oviduct is often a sequela of dystocia or salpingitis.

The oviduct becomes impacted with excess mucin, albumen, and soft-shelled or malformed eggs. These materials often become adhered to the oviduct wall and become inspissated. Clinical signs are depression, anorexia, distended abdomen, and possibly dyspnea.

Diagnosis is based on a history of chronic egg laying or dystocia. Imaging (radiographs, CT scan, or ultrasound) may reveal an enlarged oviduct. Hyperostosis may be present. The bird may have a leukocytosis and high total protein, cholesterol, and triglyceride concentrations. Treatment is supportive (fluids, analgesics, NSAIDs, and antibiotics). Surgery is recommended but is high risk.

Cystic Ovarian Disease: Birds with cystic ovarian disease often present with a history of previous egg production, but egg laying may not have occurred for several years. Cystic ovarian disease is most commonly seen in budgerigars and canaries.

Clinical signs may include depression, inactivity, abdominal distention, ascites, and often dyspnea. Abdominal palpation often reveals distention with ascitic fluid.

Diagnosis is similar to other reproductive diseases. The fluid is usually a transudate, although it should be examined for evidence of secondary infection or egg-yolk peritonitis. Careful aspiration of fluid from the ventral midline may relieve respiratory distress. Imaging (radiographs or ultrasound) when the bird is stable will often demonstrate hyperostosis of the femurs and other long bones. On the lateral view, the ventriculus will be displaced cranially, and a space-occupying mass will be noted in the renal and gonadal area. Ultrasonography can often detect cystic follicles, in addition to normal follicular development.

Treatment is supportive care, abdominocentesis if ascites is present, antibiotics, and GnRH agonists to reduce reproductive hormone production, stimulate atresia of the follicles, and decrease cyst size and production. Surgery may not be needed if there is no concurrent infection or neoplasia.

Egg Yolk Coelomitis: Egg yolk coelomitis is another common sequela of chronic reproductive disease. It can occur after salpingohysterectomy because of the inability to completely remove the ovary and the potential for ovulation to occur into the coelomic cavity. Other causes are ectopic ovulation, salpingitis, neoplasia, cystic hyperplasia, or ruptured oviduct. Egg

yolk, along with bacteria (eg, *Escherichia coli*, *Staphylococcus*) in the coelomic cavity results in infection. Egg yolk coelomitis causes a severe inflammatory reaction and can lead to an egg-related pancreatitis or a yolk emboli (which can resemble a stroke). This occurs most commonly in cockatiels.

Clinical signs are similar to other reproductive disorders, but typically abdominal distention and ascites are present. Birds often present severely compromised and require supportive care before diagnostic testing. A leukocytosis and monocytosis may be present. Imaging (radiographs or ultrasound) may reveal an enlarged oviduct or a fluid-filled abdomen. Endoscopic examination may be diagnostic but should be done only by an experienced clinician in a bird with ascites. Abdominocentesis may need to be performed to relieve dyspnea. Other treatments include fluids, antibiotics, analgesics, anti-inflammatories, a warm incubator, and oxygen as needed. Many birds will improve with supportive care and antibiotics, but some may require salpingohysterectomy. Prognosis is fair with medical management and becomes guarded to grave with surgical intervention.

Cloacal Prolapse: Cloacal prolapse can occur in any bird that strains frequently. It is seen in egg-bound hens and in adult cockatoos, typically males. The exact cause is not known, but the following characteristics have been associated with most cases: 1) hand-raised birds, 2) delayed weaning or continued begging for food, 3) close attachment to at least one person, 4) signs of either a child/parent or a mate/mate relationship with the owner, who may not be aware of these signs, and 5) a tendency to hold the feces in the vent for prolonged periods (eg, overnight), rather than defecating in the cage or when the bird has been taught to defecate on command. Cockatoos independent of people do not have this medical problem.

If detected and treated early, surgery combined with behavioral modification may correct the problem and prevent secondary infections and other complications. Treatment includes cleaning exposed tissue, carefully debriding any necrotic or infected tissue, using hyperosmotic fluids to reduce swelling, and gently replacing the tissue. Stay or transcutaneous sutures may be required for several days and are more effective if combined with GnRH agonists and changes in management (eg, reduced handling of pet cockatoos by owners). Owners may be unwilling to alter their

behavior, because often their attraction to the bird is because the bird is willing to allow stroking and cuddling. If the bird still perceives its owner as either a parent or mate, it will continue to strain and the problem will likely recur. Behaviors that should be avoided include stroking the bird, especially on the back (ie, petting); feeding the bird warm foods or food by hand or mouth; and cuddling the bird close to the body. If an owner is serious about trying to change their bird's behavioral patterns, consultation with a board-certified veterinary behaviorist who is experienced with psittacines is advisable.

In severe cases, where the vent is flaccid, vent reduction and/or cloacopexy may need to be performed but should only be done with behavior modification. Females may require salpingohysterectomy, because the vent reduction and cloacopexy may not allow passage of an egg.

Reproductive Failure: Most owners do not breed their pet birds, but reproductive failure is an issue for aviculturists who do. When evaluating a pair of birds for reproductive failure, a complete history is important. Is this a bonded pair (do they sit close to each other and allopreen, etc)? How long have they been together? Have they had a successful clutch in the past? What is their diet? Are the cage size, nest box, and perches appropriate for the species of bird? Most pet birds prefer an enclosed nest box and a stable perch for breeding. Is the owner certain of the sex? One of the most common reasons birds do not reproduce is same-sex pairs. Confirming the sex by DNA testing or

endoscopic examination (to evaluate health and status of reproductive organs) is important. Common findings during endoscopy include same-sex pairings, immature birds, and reproductive disease. Physical examination, hematologic testing, and biochemical profiles are recommended to determine overall health. Treatment will depend on the examination and diagnostic findings and may include alterations in the environment or medical therapy if indicated.

Medical and Surgical Management:

In many cases of reproductive disease, birds with moderate to severe disease require intensive nursing and supportive care. Often, physical examination and diagnostic tests must be postponed until the bird is stabilized in a warm (85°–90°F) oxygen incubator with supportive care. Procedures may need to be done in a stepwise fashion over time to minimize stress. Treatments may include warm parenteral fluid therapy, nutritional support, analgesics, anti-inflammatories, and antimicrobials (based on results of a Gram stain or culture and sensitivity testing). Some birds may require surgery. Reproductive surgery in birds is complicated by the difficulty in removing the ovary. Because of the position of the ovary cranial to the kidney, near the left adrenal gland and major vasculature, removing the entire ovary is not possible. The standard approach to the avian reproductive tract is a left coeliotomy. Endoscopic orchidectomy and salpingohysterectomy have been described but require specialized training.

TABLE 19 DRUGS USED IN AVIAN REPRODUCTIVE DISEASE

Drug	Type/Class	Dosage
Calcium gluconate (10%)	Calcium supplement	50–100 mg/kg, SC, IM
Calcium glubionate	Calcium supplement	25 mg/kg, PO, bid
Leuprolide acetate	GnRH agonist	700–800 mcg/kg, IM, every 2–3 wk
Deslorelin acetate	GnRH agonist	4.7-mg and 9.5-mg implants SC, dorsal back between scapulas every 3–6 mo
Oxytocin	Hormone	5–10 U/kg, IM; may repeat once
Dinoprostone	Prostaglandin E ₂	0.02–0.1 mg/kg, topically to uterovaginal sphincter
Dinoprost tromethamine	Prostaglandin F ₂	0.02–1 mg/kg, IM, intracloacal once

TOXICOSES

Heavy Metal Toxicosis: Lead toxicosis is commonly reported in companion birds as well as in free-ranging avian species, especially waterfowl. In pet birds, toxicosis often occurs from ingestion of metal in the home, such as blinds, costume jewelry, mirror backings, bird toys, hardware cloth, and curtain weights. Ingested lead degrades in the ventriculus and then is slowly released into the GI tract and blood. The lead is stored in soft tissues and bone and is slowly excreted over time. Lead toxicosis affects numerous biochemical processes in birds.

Clinical signs vary depending on the amount of lead ingested and may include anorexia, weight loss, regurgitation, diarrhea, depression, ataxia, weakness, seizures, blindness, polyuria, and polydipsia. *Amazona* spp, *Aratinga* spp, *Eclectus* parrots, and some other species may develop hemoglobinuria.

Diagnosis is based on clinical signs, biochemical analysis, hematologic findings, blood lead levels, and diagnostic imaging. Hematologic testing may reveal a microcytic, hypochromic anemia. Increased concentrations of AST, total protein, uric acid, and CK may be present. Radiographs may reveal metallic densities within the GI tract. However, the absence of metal in the GI tract does not exclude toxicosis. A blood level >50 mcg/dL (0.5 ppm) is considered diagnostic of lead toxicosis. Blood lead levels >20 mcg/dL (0.2 ppm) with clinical signs is considered consistent with lead toxicosis. Lead levels of 3–6 ppm or higher are considered significant in tissue (kidney, liver, brain, or bone).

Treatment includes supportive care (fluids, nutrition, etc) and chelating therapy with calcium edetate disodium (Ca EDTA) (30–35 mg/kg, SC or IM, bid) for 3–5 days until asymptomatic (with fluid therapy), followed by oral treatment with dimercaptosuccinic acid (DMSA) (25–35 mg/kg, PO, bid) or, less commonly, D-penicillamine (30–50 mg/kg, PO, bid). Midazolam or diazepam may be necessary for control of seizures. Bulk diets (with psyllium, peanut butter) may assist in removal of lead from the GI tract. In severe cases, flushing of the GI tract under general anesthesia may be necessary. Sources of lead in the environment must be removed.

Lesions associated with lead toxicosis seen on postmortem examination include demyelination of peripheral nerves, vascular necrosis, renal nephrosis, hemosiderosis in multiple organs, and focal areas of vascular damage in the cerebellum.

Zinc toxicosis is frequently reported in pet birds. Sources of zinc include any

galvanized toys, chains, mesh, bells, keys, and pennies (post 1982). Galvanized wire contains mainly zinc, but some may also contain lead.

Clinical signs of zinc toxicosis include anorexia, GI disease, weakness, regurgitation, polydipsia, and polyuria. Diagnosis is based on history and clinical signs and an increased blood zinc level. Radiographs may reveal metallic densities within the GI tract. Blood samples for zinc analysis should be collected in glass or all-plastic syringes and tubes. Rubber stoppers on serum tubes and the grommets on some plastic may artifactually increase the zinc levels in the collected sample. Blood zinc levels >2 ppm are diagnostic for zinc toxicosis.

Treatment of zinc toxicosis is similar to lead toxicosis with supportive care, Ca EDTA, DMSA, and D-penicillamine. The source of zinc should be determined if possible and removed from the environment. Zinc is not stored in the bone like lead, so it chelates faster than lead.

Polytetrafluoroethylene Toxicosis:

Polytetrafluoroethylene (PTFE) gas poisoning occurs commonly in pet birds housed in or near kitchens. The gas is released from nonstick cookware such as Teflon® when the pans are overheated, at temperatures reaching 280°C (536°F). Other sources of PTFE include irons, ironing board covers, some self-cleaning ovens, heating elements from some reverse cycle heat pumps, and some heat lamps. See also POLYTETRAFLUOROETHYLENE (POISONINGS IN POULTRY), p 2862, and SMOKE INHALATION, p 3022.

Often, the only clinical sign is acute death. Other signs depend on the level of exposure and size of the bird. Small birds often die suddenly with minimal exposure. Larger birds may present with dyspnea, wheezing, ataxia, weakness, in respiratory distress, or seizing. With a large enough exposure, large birds can die acutely. Diagnosis is based on a history of exposure and sudden death, or a history and clinical signs consistent with exposure.

Treatment is supportive with a warm, oxygenated incubator, fluids, NSAIDs, broad-spectrum antibiotics, and diuretics. Prognosis is guarded. Necropsy often reveals severe hemorrhage and congestion of the lungs.

Tobacco: Passive inhalation of tobacco smoke (second-hand smoke inhalation) or contact with tobacco on hands, fingers, hair, or clothes of smokers can lead to chronic respiratory disease and dermatologic problems on the face and feet of pet birds.

Clinical signs may include coughing, sneezing, nasal and ocular discharge, dyspnea, conjunctivitis, or feather destructive behavior and mutilation. Ingestion of tobacco products has led to hyperexcitability, seizures, and death. Diagnosis is based on history, clinical signs, and response to treatment.

Treatment will depend on severity of clinical signs. For birds that are dyspneic or showing neurologic signs, supportive care and oxygen may be needed. If the bird has ingested tobacco, activated charcoal may be warranted. Treatment involves removing the bird from the exposure and placing it in a smoke-free environment. Owners who smoke should wash their hands before handling their birds.

Other aerosols, including some carpet fresheners, plastics either melted or burned in a microwave oven, perfumes, deodorizers, votive candles, and new heating duct systems may also be irritating or toxic to caged birds.

TRAUMATIC INJURY

Trauma is a common presentation for avian patients. Cat or dog bite wounds or large birds attacking smaller birds all occur frequently. Pet birds allowed to roam or fly freely in the house can become injured flying into walls, windows, or ceiling fans, or falling off shoulders, play gyms, or the top of their cage. Birds can also be injured in their cage. A foot or band may get caught in a toy or in the bars. Other common traumatic injuries include puncture wounds, lacerations, fractures, limb amputations, and crushing injuries.

Stabilization is paramount; birds presenting with trauma are often cold and stressed and have suffered blood loss. The bird should be placed in a warm, oxygenated incubator immediately after presentation and observed from a distance. Is there respiratory distress (tail bobbing) or open-mouth breathing? Is there active bleeding? Is the bird able to perch? Is it using both legs? Is there a wing droop?

After the initial assessment, the clinician must decide whether to maintain the bird in the incubator or oxygen, perform a brief physical examination and begin immediate supportive treatments, or perform a more thorough physical examination with or without diagnostic tests. Before picking up the bird, a detailed plan must be determined, and then all items set up ahead of time for anticipated treatments and diagnostics.

Examination and treatments may need to be done in steps, placing the bird back in the oxygenated incubator to recover if it

becomes stressed or weak at any point during handling or treatments. Emergency treatments include warm fluids (SC, IV, or intraosseous), analgesics, anti-inflammatories, and antibiotics. Maintenance fluids are estimated at 50 mL/kg divided bid-tid. In dehydrated birds, 50% of the total daily maintenance can be administered SC (25 mL/kg) and repeated every 6–8 hr until hydration is reestablished. Often, birds are stressed and in pain and may benefit from sedation for diagnostic testing and treatments. In stressed birds, midazolam (0.5–1 mg/kg, IM, or 1–2 mg/kg, intranasally), with or without butorphanol (0.5–1 mg/kg, IM or intranasally) can be used.

Often with trauma cases, diagnostic tests or extensive treatments or surgery should be postponed until the bird is stable, which may take 12–48 hr. All birds with trauma should be treated with the goal of the bird's survival first and treatment of traumatized tissue second. For example, a bird that has been struggling for hours with its leg band caught, with possibly a fractured tibiotarsal bone, is in more danger of dying from stress related to the prolonged struggling than from the fracture.

Diagnostic tests should be based on physical examination findings and may include radiographs to determine whether fractures or luxations are present.

With predator bite wounds, antibiotic therapy consisting of treatment for both anaerobic and aerobic bacteria is crucial to increase the chances of a successful case outcome.

MISCELLANEOUS DISEASES

Diabetes Mellitus: Diabetes mellitus (DM) is an uncommon disease of pet birds and can be challenging to diagnose. Normal glucose levels in birds are significantly higher than those in mammals (200–400 mg/dL). Birds often have a significant hyperglycemia with stress, which can occur when handled or restrained. Glucosuria can occur at 600 mg/dL in birds, so birds with a stress hyperglycemia can also have glucosuria without a diagnosis of DM. Therefore, a persistent hyperglycemia and glucosuria need to be documented for a diagnosis of DM in birds.

Controlling blood glucose levels is a balance between the activity of glucagon and insulin within the pancreas. In mammals, pancreatic disease often leads to DM and is due to a lack of or resistance to insulin, which causes the blood glucose to rise. The cause of hyperglycemia and DM in birds is less clear. Blood glucose levels in some birds (granivorous birds) seem much more respon-

sive to glucagon levels than to insulin levels, whereas other bird species may be more responsive to insulin. It is still debatable and may depend on the species as to whether DM in birds is caused by abnormalities with insulin, glucagon, or both.

Clinical signs of DM in pet birds include polyuria, polydipsia, increased glucose levels in the blood and urine, and weight loss. DM is often seen in conjunction with obesity or pancreatic or reproductive problems and may be transient in such cases. A persistent hyperglycemia and glucosuria need to be documented for a diagnosis of DM. Diagnosis is based on persistent increases in blood glucose (>700–800 mg/dL) and glucosuria, along with clinical signs of disease.

Treatment includes converting the bird to a healthier (pelleted) diet and limiting treats. Response of birds to mammalian insulin is variable, and insulin treatment is generally less effective in birds than in mammals. Regular insulin at 0.1–0.2 U/kg has been used successfully to stabilize birds. Longer-acting insulins (NPH or ultra-Lente) at 0.067–3.3 U/kg, once to twice daily, have been used for long-term control. Bird owners are often reluctant to give injections to their birds, so often oral antidiabetic medications are used. Glipizide (0.5 mg/kg, PO, bid, or 1.25 mg/kg/day, PO) and metformin (100–500 mg/L of drinking water) have been used anecdotally. Water intake, urine output, weight, and glucosuria should be monitored to determine whether the treatment protocol is effective. In some cases, dietary conversion and weight loss can result in resolution of the clinical signs, reducing or eliminating the need for oral medications or insulin.

Gout: Gout is the abnormal deposition of uric acid in the body. Uric acid is the major end product of protein breakdown in birds. It is produced and secreted primarily in the kidneys and liver and eliminated by tubular secretion. Elimination is independent of glomerular filtration rate. Hydration has only a minimal effect on plasma uric acid levels; therefore, hyperuricemia can be an indicator of renal disease in birds. Gout typically occurs secondarily from increased plasma uric acid levels. Articular gout occurs in the joints (most often the metatarsal and phalangeal joints) of birds, and visceral gout occurs on the serosa of various organs and is commonly found on the pericardium, liver, and spleen.

Clinical signs of articular gout are pain, lameness, swelling in the joints, depression, anorexia, and dehydration. Visceral gout is

rarely diagnosed antemortem and is typically found at necropsy. Acute death is often the only clinical sign. The serosal surface of various organs and the renal tubules are the locations of uric acid deposition. Diagnosis of articular gout is by identifying gout tophi—whitish yellow, subcutaneous, and intra-articular deposits that demonstrate uric acid crystals on staining. Uric acid levels commonly are increased.

Treatment includes fluid therapy to reduce uric acid levels and analgesics for pain. Articular gout tends to be severely painful. If effective pain control cannot be accomplished, euthanasia should be considered. Surgical removal of these tophi is not practical in most cases, because they are extremely vascular and the risk of fatal hemorrhage is high. Additionally, unless the underlying condition can be identified and corrected or controlled, new tophi will appear very rapidly. Allopurinol (10–30 mg/kg/day, PO) and colchicine (0.04 mg/kg, PO, once to twice daily) may be useful in control of articular gout. The genetic, nutritional, or environmental factors that predispose a bird to gout are not fully understood. However, current treatment of birds with increased uric acid levels include conversion to an appropriate diet (this may be a pelleted diet in some species) or a diet change to whole grains, seeds, fruits, and vegetables for some smaller birds such as cockatiels and budgerigars (for whom a pelleted diet may be a factor in renal disease). Essential fatty acids (omega 3) at 0.1–0.22 mL/kg/day, PO, have been used anecdotally to manage renal disease in birds.

This macaw has a single, large ingrown feather or feather cyst. Canaries are commonly affected with multiple feather cysts. Courtesy of Dr. Louise Bauck.

Feather Cysts: Feather cysts are ingrown feathers that result in a granulomatous mass. Recurrence is common unless the extensive dissection of the feather follicle is accomplished. In birds with multiple affected feathers, such as the genetically predisposed Norwich canary, this is not practical.

Feather Destructive Behavior: The phrase “feather plucking” is commonly used to describe behavior that ranges from mildly excessive preening to self-mutilation. Management of this condition is frequently challenging. Feather plucking seldom has a single etiology, and it is prudent to thoroughly explore all possible contributing factors, including underlying medical problems. Good communication concerning feather plucking in birds at the onset will help owners realize that this is a complicated behavior that is difficult to stop. The goal should be to improve the health of the bird and to reduce (or eliminate) the plucking behavior if possible.

Possible medical causes for feather plucking include: 1) Endoparasites (especially giardiasis in cockatiels) and, rarely, tapeworms or roundworms. 2) Ectoparasites (rarely). 3) Hepatic disease, with associated pruritus. 4) Coelomic cavity granuloma or mass. 5) Neoplasia, which typically causes localized plucking of the area associated with an underlying mass. 6) Folliculitis or dermatitis that is primary, or secondary to excessive plucking and/or mutilation. Bacteria, viruses, fungi, or yeasts may be involved. 7) Allergies. Although difficult to confirm, a change in environment or diet when allergens are suspected may lead to a decrease in plucking and a tentative diagnosis by elimination. 8) Endocrine abnormalities, the most likely being hypothyroidism. However, hypothyroidism is overdiagnosed in part because of the lack of established normal values for avian thyroid levels, the low range for baseline T₄ noted in birds, and difficulty in obtaining a reliable thyroid-stimulating hormone (TSH) response test. Nevertheless, some obese birds that demonstrate a lack of weight loss after a rigid diet, accompanied by poor quality feathers and infrequent molts, may be thyroid deficient. The plucking exhibited by these birds is often an attempt to rid themselves of old, damaged feathers. 9) Heavy metal toxicosis, notably zinc. Barbering and feather plucking from zinc ingestion have been hypothesized. Many of these cases lack radiographic evidence of heavy metal and require a blood zinc analysis for diagnosis.

Malnutrition is likely a more common contributing factor to feather plucking than the medical conditions listed above. Basic seed and table food diets often create multiple nutritional deficiencies. These deficiencies cause abnormal skin and feather development resulting in plucking behavior, as well as myriad other medical problems that may occur. The dyes and preservatives added to seeds and most pelleted diets may be a factor for some birds. The relatively low humidity in most households also has a drying effect on the skin. Being deprived of natural sunlight, fresh air, humidity, and the normal light/dark cycle has negative physiologic and psychologic effects on birds.

A diagnostic evaluation for a bird with feather destructive behavior may include a CBC, biochemical profile, viral testing, skin biopsy, radiographs, and/or endoscopic examination. Behavioral feather picking should be determined only after a complete evaluation that excludes as many medical causes as possible.

Treatment is based on the findings of the diagnostic evaluation. A hormonal bird may need an injection of leupolide acetate, a GnRH agonist, to reduce reproductive behavior, along with environmental changes (*see p 1920*).

Although treatment of medical and environmental factors may reduce the severity of feather plucking, a strong behavioral component is often involved. Treatment of some of the above-mentioned problems may lead to initial improvement, followed by a relapse. Psychologic stressors can lead to feather plucking as a displacement behavior. Unfortunately, once the stress has been relieved, the habit may still remain. Feather plucking does not occur in the wild, where birds are occupied with finding food, maintaining their social status in the flock, seeking a mate, avoiding predators, and breeding and raising young. Therefore, often the best-kept birds, which have all their apparent needs met, will pluck feathers for behavioral reasons. Psychologic conditions that may cause feather plucking in birds vary. Overstimulation may cause plucking in a nervous bird. Another bird that plucks from boredom may feel both stimulated and slightly threatened by increased activity in the home and stop plucking to pay attention to the environment and guard itself against potential predators. Birds that reach sexual maturity may begin to pluck as an outlet for their increased energy and agitation. Owners of these birds often report that their birds show more cage territoriality, more

aggression toward family members, and potentially, sexual behavior toward a perceived human mate or inanimate objects.

All feather destructive behavioral issues require a multimodal treatment approach that involves proper nutrition, enrichment, providing foraging opportunities and, in some cases, psychotropic medications (see TABLE 20). Neither of these categories of drugs tends to produce long-term positive results, and adverse effects may be seen. As is true of most medications administered to pet birds, these drugs are not approved by the FDA.

Psychotropic drugs should not be used alone but only in conjunction with dietary modifications, enrichment, and foraging opportunities. In addition, changes may need to be made in the owner/bird interactions. Dietary modifications include both conversion to a healthier formulated diet and providing foraging opportunities for the bird. Owners can place food in

multiple food dishes throughout the cage or hide food inside foraging toys to stimulate normal foraging behavior. Enrichment can be provided in the form of natural branches, toys, wood to chew on, multiple play gyms throughout the house, natural sunlight, and ideally a flight cage to encourage activity. Exercise should be encouraged, either through flight or walking and climbing activities. Rope and boing perches stimulate activity and balance. Teaching birds tricks such as waving, dancing, and recall can provide intellectual stimulation and positive interaction between the owner and bird.

In addition to traditional medical therapies, acupuncture has been reported to be helpful in some cases. Dietary supplementation with omega fatty acids has been reported to be helpful. Whether this is due to the antiprostaglandin effect or a true fatty acid deficiency is not certain.

TABLE 20

PSYCHOTROPIC MEDICATIONS USED FOR FEATHER PLUCKING IN PET BIRDS

Medication ^a	Dosage	Comments
PSYCHOTROPIC MEDICATIONS		
Amitriptyline	1–2 mg/kg, PO, once to twice daily	Maximal effects may require treatment for several weeks.
Clomipramine	1 mg/kg/day, PO	Effects similar to those of amitriptyline but may be effective in some cases in which amitriptyline is not.
Diazepam	2.5–4 mg/kg, PO, as needed	Limited usefulness; most birds require a dose that causes sedation to inhibit plucking.
Haloperidol	0.15 mg/kg, PO, once to twice daily for larger birds; 0.2 mg/kg, PO, bid for smaller species	Serious adverse effects, including anorexia, hepatic dysfunction, and CNS signs have been reported; most often used in cockatoos.
Fluoxetine	2 mg/kg/day, PO, once to twice daily	Effectiveness reported to vary; maximal effects may require treatment for several weeks.
HORMONES		
Medroxyprogesterone acetate	—	Decreases sexual behavior; not recommended because of serious adverse effects, including weight gain, polyuria, polydipsia, lethargy, hepatopathy, diabetes mellitus, and death.
GnRH agonist, eg, leuprolide acetate	300–800 mcg/kg, IM	Decreases sexual behavior by negative feedback, reducing production of sex hormones.

^a All are extra-label usages.

An ideal medical treatment is not likely to be found for featherplucking in captive birds. Environmental manipulation, ensuring quality nutrition, and psychologic adaptations suited to the species and temperament of the bird offer the best hope to reduce this syndrome. Consultation with a board-certified behaviorist familiar with psittacines may be indicated.

Hypersensitivity Pneumonitis:

A respiratory condition similar to chronic obstructive pulmonary disease (COPD) has been reported in macaws (primarily Blue and Gold macaws). These birds often have a history of being housed with birds that produce large amounts of powder down, such as cockatiels and cockatoos in poorly ventilated environments. The birds may also have secondary bacterial or fungal infections.

Clinical signs include increased respirations, exercise intolerance, dyspnea,

respiratory distress, and cyanosis of the facial skin.

Diagnosis is based on a history of being housed with feather down-producing birds in poor ventilation with respiratory disease and often polycythemia (>60%–70%). Pulmonary biopsy is diagnostic. Histopathologic lesions are confined to the lower respiratory tract. The most prominent lesion is atrial smooth muscle hypertrophy and some atrial loss due to fusion and epithelial bridging.

Treatment is supportive care and removal of the bird from the offending environment. Improved ventilation and separation from birds that produce powder down is critical. NSAIDs such as meloxicam (0.5–1 mg/kg, PO, once to twice daily) may help reduce inflammation. Albuterol (0.05 mg/kg, PO, bid) has been used anecdotally. Birds should be housed to reduce stress and minimize exertion. Often, birds with confirmed pulmonary hypersensitivity will not have a normal life expectancy.

POTBELLED PIGS

Potbellied pigs (PBPs) have a short to medium wrinkled snout, small erect ears, large jowls in proportion to the head, short neck, pronounced potbelly, swayed back, and straight tail with a switch at the end. The CON and LEA lines of PBPs at 1 yr of age should not be >18 in. at the withers (ideal height ≤14 in.) or weigh >95 lb (ideal weight ≤50 lb). The life span of PBPs is probably 8–20 yr with ~10–15 yr typical. Very small or obese PBPs may have a shortened life span. For hematologic and serum biochemical reference ranges, see TABLES 6 and 7, pp 3176 and 3178.

The term “teacup” pigs has no strict definition, and it is difficult to make an educated guess of mature size without seeing the parents and grandparents, which is rarely possible. Mature size is also heavily influenced by adequate nutrition. In general, when pigs are “selected for smaller size,” in addition to nutritional stunting, many other possible problems of miniature pigs may be magnified. These include hypoglycemia, idiopathic seizures, musculoskeletal deformities, heart disease, cleft palate, atresia ani, and reproductive problems such as dystocia and agalactia.

MANAGEMENT

Environment: PBPs are sensitive to extremes of heat and cold and should be provided a clean, dry, draft-free environment. Adults are usually comfortable in a temperature range of 65–75°F (18.3–23.9°C). Because pigs do not sweat, temperatures ≥85°F (29.4°C) are stressful to adults. Extended exposure to high temperatures combined with high humidity may be fatal to PBPs not acclimated to such an environment. Cooling methods for adult PBPs include moving air across the body, wetting the skin for evaporative cooling (more efficient as humidity decreases), providing shade, and resting on cool surfaces.

Newborn pigs are very susceptible to drafts and chilling and require an environmental temperature of ~90°F (32°C). Chilled pigs will pile on each other and shiver, and their hair will stand on end. A poor environment may cause neonates to become moribund and hypoglycemic (*see* MANAGEMENT OF THE NEONATE IN LARGE ANIMALS, p 2088) within 24–36 hr. Heat lamps or pads can be used to provide supplemental warmth, but their use

should be monitored closely because of the electrocution risk from chewed cords; pigs that become too hot will spread out and pant.

Housing: PBPs may be housed outdoors or indoors (or both) but must be appropriately acclimated to the specific environmental situation.

PBPs housed outdoors should have a large pen (≥ 50 sq ft/pig) with a structure within to provide sleeping, feeding, and watering areas. Pigs will use dirt for elimination, and daily removal of feces and addition of fresh dirt to cover and absorb urine is required. Hay or straw may be added to partially satisfy the need to root. However, "rooted-up" pen ground should be filled in with fresh dirt from time to time. Fencing should be well secured in the ground to prevent it from being rooted up, but it should also be portable so that the entire pen can be moved periodically, giving access to fresh, clean dirt. The old pen dirt should then be smoothed out and left unused for several months before being used again. If pens are maintained on solid surfaces (eg, concrete pads), feces and urine should be removed daily, and fresh hay or straw provided as needed. Water dispensers must be secured to keep pigs from spilling the water by rooting or damaging the device by chewing.

PBPs housed indoors should have a particular area (eg, a laundry room), with an elimination area in one corner and a sleeping and eating area in another corner. A litter box with the side cut down to accommodate easy entry and exit may be used for elimination. Nontoxic material should be used for litter because pigs are curious and tend to chew on everything. A blanket may be provided to allow the pig to burrow under and partially satisfy the need to root while indoors; a box of dirt is another alternative.

Exercise: PBPs should be exercised whether kept outside or indoors. They may be trained to walk on a leash or released into exercise areas. Daily exercise is important not only for physical health but also to relieve boredom that may otherwise manifest as destructive chewing or rooting or as aggression. Even if the PBP does not exercise much when given the opportunity, the various stimuli from an outside environment appear to be beneficial to overall temperament. Many household and garden plants are toxic to PBPs, which are adventurous eaters (*see* p 3103).

Temperament: As healthy, neutered PBPs mature, they may become more aggressive

and challenge other PBPs or people for status. Such challenges need to be addressed, or the pet may learn to use aggression to get what it wants. A combination of aversive techniques (eg, hand clapping, gruff vocalizations, stomping) and rewarding the PBP for positive behavior may help manage the problem. Failure to deter this unwanted behavior is a common reason why PBPs are placed in rescue operations or abandoned.

Vaccinations: Neutered PBPs should be vaccinated against erysipelas and tetanus. Tetanus toxoid is especially important in PBPs housed outside in contact with other species (eg, petting zoos). Leptospirosis vaccine (6-way) may also be considered, but there is a substantial risk of high fever after use. Vaccines are not specifically approved for PBPs, so those commercially available for domestic swine are substituted. Two initial vaccinations 3–4 wk apart are followed by boosters every 6 mo for erysipelas and every year for tetanus, or both boosted yearly at the time of annual physical examination. Breeding PBPs should be minimally vaccinated against erysipelas, leptospirosis (6-way), and parvovirus; they should be vaccinated twice, 3–4 wk apart, before breeding and before rebreeding or every 6–12 mo. Other vaccines should be used as exposure risk indicates. Routine vaccination against various pathogens not only minimizes sickness but helps prevent zoonotic disease and may satisfy requirements for pet licensure. Safety and efficacy are concerns when using commercial domestic swine vaccines in PBPs. Consideration should always be given to the amount of antigen per body weight that is injected, especially in small pigs. Excessive antigen administration may cause adverse reactions. No rabies vaccine is approved for use in PBPs because of the extremely low incidence of rabies in swine in the USA.

Parasite Control: External and internal parasites are possible health problems in PBPs, and the zoonotic potential of sarcoptic mange and roundworms should be considered when counseling owners. Fecal samples via fecal flotation may be evaluated in PBPs as early as 6 and 10 wk old for whipworms and roundworms, respectively. Dewormers, such as oral fenbendazole at 3 mg/kg/day for 3 days; ivermectin at 300 mcg/kg, SC; or doramectin at 300 mcg/kg, IM, should be used as indicated. Injectable ivermectin and doramectin are highly effective against sarcoptic mange, the most common external parasite in PBPs.

Dental Care: The eight needle teeth (four deciduous lateral incisors and four deciduous canines) of newborn PBPs should be trimmed to prevent injury to littermates and laceration of the sow's underline. Four permanent canine teeth erupt at ~5–7 mo of age and are first trimmed at or after 1 yr of age. Elongated permanent canine teeth may cause discomfort, malocclusion, and persistent chewing motion and salivation. In PBPs, the canine teeth grow continually and should be cut about once a year using obstetrical wire, mechanical saws, or other instruments. Sedation or anesthesia is required. Teeth should be cut as close as possible to the gum line without cutting the oral mucosa or lips; there should be no exposed root canal after cutting the canine teeth of any type of swine. Tetanus antitoxin (500–1,500 U, depending on PBP size) and antibacterials are usually administered. In PBPs properly vaccinated with tetanus toxoid, a tetanus antitoxin injection is unnecessary. Tartar buildup can be removed manually by instrument scraping at the same time the canine teeth are cut. Dental cleaners for small animals may be used with care, positioning the head of the PBP downward during use to prevent water aspiration.

Geriatric PBPs may have abscessed and/or exposed tooth roots; sedation (tiletamine-zolazepam 2.2 mg/kg, IM, in ham) and examination of the oral cavity with or without endoscopy is indicated if anorexia and/or bruxism are reported. Radiographs may be necessary to diagnose tooth root abscessation. Swelling followed by a draining tract at the angle of the mandible, especially in geriatric PBPs, indicates canine tooth abscessation. Removal is challenging even for skilled surgeons and may result in mandibular fractures. However, PBPs seem to recover well after tooth extraction followed by antibiotics and tetanus prophylaxis.

REPRODUCTION

Females: First estrus occurs as early as 3 mo of age in gilt piglets. The lack of estrus or a distended abdomen in a young gilt may be due to pregnancy if she has been exposed to littermate boars. If the female does not cycle, the abortifacient prostaglandin $F_{2\alpha}$, given as two injections (8 mg and 5 mg in a 25-kg pig) 12 hr apart, can be administered when corpora lutea have become susceptible to luteolysis after day 13 after estrus. Estrus should occur 3–7 days later.

Dystocia is of special concern in PBPs. Because the birth canal is too small to inspect for unborn pigs via palpation, radiography or ultrasonography may be indicated to reveal undelivered piglets. Oxytocin (5–10 U) may be used to aid delivery if the vaginal canal is patent. The decision to perform a cesarean section, if indicated, should be made promptly, before the sow becomes toxic and has friable uterine tissue and vessels. Cesarean section may be performed by several approaches, but the right flank approach has two advantages: the piglets nurse away from the incision, and gravity pulls the incision shut, minimizing the chance of dehiscence. Regardless of surgical approach, surviving piglets will probably require hand-raising.

Ovariohysterectomy in PBPs at 4–6 mo of age is ideal. Older female PBPs generally display irritable behavior for 2–3 days of estrus out of every 21 days of the estrous cycle. Performing an ovariohysterectomy during estrus in older PBPs is a formidable task because of the tremendous vasculature in the broad ligaments of the horns of the uterus; surgery should be delayed until ~7–10 days after estrus. A distal midline approach, as if performing a cystotomy, is routinely used for ovariohysterectomy. The uterine horns fold back and are located beside the body of the uterus with the ovaries. No ovarian ligament tearing is necessary as in dogs and cats. Penetration of the cervix by sutures should be avoided when ligating the uterine stump to prevent intermittent postsurgical hemorrhage from the vulva. A right flank approach may be used in extremely obese PBPs, in which wound dehiscence could be a complication. Isoflurane or sevoflurane anesthesia provides excellent muscle relaxation. (Malignant hyperthermia [see p 1027] has been reported only once in a PBP under isoflurane gas anesthesia, so it is thought to be rare in PBPs.) Hypothermia during and after surgery is an important concern. A baseline rectal temperature should be recorded at anesthesia induction, and normal body temperature should be maintained until recovery is complete. Injectable anesthetics such as xylazine plus tiletamine-zolazepam can delay normal thermoregulation for 5–6 hr after anesthesia. Because some PBPs may become apneic when placed in prolonged dorsal recumbency, intubation is preferred to masking; however, PBPs may be difficult to intubate, and prolonged efforts at intubation may cause laryngeal edema and postsurgical complications.

Early spaying also reduces the risk of ovarian cysts, uterine tumors, and cystic endometrial hyperplasia. An obviously distended abdomen is seen with large ovarian or uterine masses (≥ 20 –30 lb). Vulvar hemorrhage may be a sign of uterine tumor and can be life-threatening. Although most ovarian or uterine masses can be surgically removed, some are so extensive and invasive that euthanasia is required.

Males: PBP boars retained for breeding should be kept in secure pens; they should not be kept as pets because of the unpredictable behavior of boars around other animals or people. Neutering is usually performed at 8–12 wk of age, using injectable or gas anesthesia. One protocol for injectable anesthesia is xylazine at 2.2 mg/kg, IM, followed by tiletamine-zolazepam at 6.6 mg/kg, IM, both injections in the ham. Determining whether both testicles are descended before surgery is important because cryptorchidism is seen in PBPs. An inguinal hernia is another possible complicating factor. The midline skin incision is made cranial to the scrotum, and structures such as the vas deferens and blood vessels are ligated and excised similar to the procedure in dogs. Both inguinal ring areas should be closed to prevent herniation. Removal of tunic, cremaster muscle, and extraneous subcutaneous tissue, followed by closure to obliterate empty space, help prevent seroma formation. At the time of castration, the preputial diverticulum or “scent gland” may be removed by eversion and excision to minimize the pooling and discharge of foul-smelling preputial fluid. Umbilical hernia may complicate removal. Early castration may interfere with the development of the preputial diverticulum, making its removal unnecessary, especially in PBPs kept outside. Tetanus antitoxin (if no current tetanus toxoid vaccination) and antibacterial injection are given after surgery of the reproductive tract.

FEEDING AND NUTRITION

Fresh water should be available at all times to prevent dehydration and salt toxicity (water deprivation). Balanced diets are essential to provide proper daily nutrients and prevent obesity. Starter, grower, and maintenance rations for PBPs are commercially available as crumbles or pellets. The recommended amount per body weight should be fed divided into at least two meals/day. Rations for commercial domestic swine,

available in meal, crumble, or pellets, may also be used with professional veterinary guidance. Green leafy vegetables, alfalfa, and green grasses (but not weeds, because some are toxic) can be added to the ration to satisfy appetite. Fruits such as apples and grapes may be given in limited amounts. High-energy treats should be avoided because PBPs tend to become overweight.

Even when calorie intake is restricted, weight loss is difficult because the minimal amount of exercise possible in obese PBPs burns few calories. Lameness is another common factor limiting exercise capacity. Maintaining normal hoof length via trimming is important for mobility. Swimming is an alternative form of exercise for obese, lame PBPs, but acclimation and supervision is necessary.

Young weaned PBPs thrive best if adequate colostrum was consumed within the first 24 hr of life. PBPs deprived of colostrum easily succumb to diarrheal and septicemic disease. For early nutrition, commercial milk replacers are available, but 2%–3% pasteurized milk or powdered milk also can be used successfully. Approximately 1 oz every 4–6 hr should be fed from a bottle with a nipple until the pig is trained to drink the milk from a shallow bowl or pan; usually, this can be done in <24 hr. The volume fed should be increased as the pig grows but decreased if diarrhea occurs. Overeating diarrhea may be controlled with kaolin/pectin preparations given every 4 hr. Infectious diarrhea that may be from gram-negative bacteria (eg, *Escherichia coli*) should respond to parenteral or oral gentamicin or oral spectinomycin. The diet can be converted to solid feed by mixing a small amount with milk to make a gruel and gradually increasing the ratio of feed to milk (conversion to all feed in ~14 days). Increasing amounts of fresh water should be provided as the diet is converted.

Urolithiasis from triple phosphate crystalluria may occur in PBPs but can be prevented through addition of urinary acidifiers to the ration. At least one commercial PBP feed contains ammonium chloride, and feed additives containing ammonium chloride or citric acid are available. Owners may feed fruits or vitamin C in an attempt to acidify the urine. A constant source of clean, fresh water is also important to prevent the accumulation of triple phosphate crystals. Adding fruit juice to water may increase water consumption and help acidify the urine. Inadequate water consumption by sedentary PBPs in cool weather has been associated with urolithiasis.

DISEASES

Furnishing adequate housing, nutrition, and care will minimize disease in PBPs, as in other species. Many diseases of PBPs are similar to those of domestic commercial swine, although some are more common in PBPs.

Gastrointestinal System

Gastritis and gastric foreign bodies are common in PBPs because they are omnivorous and prone to ingest many types of objects. Keeping PBPs indoors where they are unable to root and restricting calorie intake to prevent obesity probably contribute to this continual search for food. Dividing the daily ration into two or more portions and furnishing low-calorie foods (eg, lettuce, cabbage, celery, carrots, or green grasses) may help satisfy appetite. If an ingested foreign body is small or pliable enough, it may pass through the GI tract and cause mild gastritis that is self-limiting or only requires antibiotic therapy. Larger objects may remain in the stomach or partially pass into the duodenum or a more distal part of the small intestine. Clinical signs such as vomiting and colic can be acute but may be more subtle and increase in intensity over several days or weeks. Radiographs may reveal obvious foreign material or delayed gastric emptying. CBCs may indicate infection but are usually not informative; serum enzyme and electrolyte panels may only reflect dehydration. Surgical correction is indicated but may not be successful if extensive necrosis of GI tissue is present. Fluid replacement and nutritional supplementation plus antibacterial therapy and tetanus prophylaxis are indicated in convalescing PBPs.

Lower GI obstruction due to bowel stricture occurs in geriatric PBPs. Anorexia, scant fecal production, and a bloated abdomen with massively distended intestines seen radiographically are typical. Sedation and endoscopic examination of the oral cavity, esophagus, and stomach are indicated to exclude other problems. Exploratory laparotomy and anastomosis with or without bowel resection is usually remedial.

Colibacillosis or *Escherichia coli* diarrhea is generally an important disease in young PBPs. Mortality may be high in piglets that have not ingested adequate colostrum in their first 24 hr of life. Older PBPs apparently develop resistance to colibacillosis. Diagnosis is through signalment, history, and fecal culture.

Sanitation to minimize infective doses of pathogenic coliforms in the environment of young, nursing PBPs is important for prevention. Commercial swine vaccines to prevent colibacillosis are available but must be given to sows before farrowing to stimulate immunity and secretion of IgA into the milk. Treatment is based on in vitro antibacterial sensitivity testing, but antibiotics such as oral or injectable gentamicin or injectable ceftiofur are usually effective.

Enterocolitis from *Salmonella* Typhimurium infection can affect PBPs of any age, but it usually occurs after weaning. Sources of salmonellae include waste food from overturned garbage cans, exposure to carrier swine (such as the dam), or fecal material from other animal species. Mild to severe diarrhea with mucus and blood can result. Diagnosis is through signalment, history, and fecal culture or PCR. *Salmonella* spp are characteristically resistant to many antibiotics, so in vitro antibacterial sensitivity testing is important. Parenteral gentamicin at 2.2 mg/kg/day for 3 days may be effective in the interim. Untreated PBPs may die. Some recovered PBPs may develop rectal stricture after enterocolitis, resulting in megacolon and a distended abdomen. Subsequent straining to defecate can cause rectal prolapse. Surgical correction of the rectal prolapse will not correct the underlying problem. Owners should be advised that many *Salmonella* spp, including *S* Typhimurium, are zoonotic. Healthy PBPs may be tested via fecal culture or PCR to determine their salmonella status. Multiple tests are more accurate predictors than single tests. Vaccines available for commercial swine have not been used much in PBPs.

Bacteremia or septicemia after *S* Choleraesuis infection may also affect PBPs, usually after weaning. Sources of infection are similar to those of *S* Typhimurium. Mild to inapparent diarrhea followed by fever, lethargy, anorexia, cyanosis of extremities, recumbency, and death may ensue. Diagnosis, treatment, prevention, and zoonotic potential are similar to those of *S* Typhimurium; zoonosis is mainly a threat in immunocompromised people.

Constipation may be seen in PBPs; however, each normal bowel movement of a PBP is typically composed of one or more cylindrical formations made up of smaller, multiple fecal balls that may give the impression that the PBP is constipated. True constipation may occur due to low water intake in sedentary PBPs or to an actual disease. Careful evaluation is

warranted before treatment is administered. Enemas may be contraindicated if there is pathology such as colitis. In simple constipation, fecal softeners or mild laxatives such as sodium sulfate or magnesium sulfate may be used. These should be given with food, if possible, because forced P $\bullet$ administration can result in aspiration pneumonia and death, especially with mineral oil. Encouraging increased water intake by flavoring with fruit juice or liquid gelatin may be helpful. Regular exercise is also beneficial to promote normal feces.

Rectal prolapse occurs due to straining from bowel irritation from diarrheal disease, rectal stricture after S typhimurium enterocolitis or previous rectal prolapse repair, cystitis or urolithiasis, persistent coughing, dystocia, or possibly genetic predisposition. Small, uncomplicated, recent rectal prolapses may be repaired via anesthesia and purse-string closure of the rectum that allows for minimal passage of feces. Larger, complicated prolapses require surgical excision. Recurrence is less likely after surgery but is possible regardless of method of repair.

Lymphosarcoma, lymphoma, and carcinoma of the intestines occur in aged PBPs. Signs are vomiting, anorexia, melena, anemia, and chronic weight loss followed by death (or euthanasia). Confirmation is by postmortem histopathology.

Integumentary System

Dry, flaky skin with minimal to severe pruritus is seen in virtually all PBPs. Wiping down the skin with wet towels each week will remove the flakes. Moisturizing lotions (eg, aloe vera) also temporarily alleviate this problem. Fatty acid supplementation can be used as a more longterm remedy, but caution must be exercised not to promote obesity.

Sarcoptic mange is the most important ectoparasitic disease of PBPs. Intense pruritus and dermatitis are the basis for a presumptive diagnosis. In many cases, the owners have pruritic skin lesions on the arms or abdomen. Examination of skin scrapings (deep enough to contain some blood) from several sites usually confirms the diagnosis in advanced cases but may be negative in less advanced cases if very few mites are present. In young PBPs, the source of infestation is usually the dam; in older PBPs, the source is usually other infested pigs. Young PBPs isolated from other pigs and kept as pets may harbor mange mites as a subclinical problem until

mite populations increase sufficiently to make the condition obvious. Treatment with ivermectin (300 mcg/kg, SC, repeated in 2 wk) or doramectin (300 mcg/kg, IM, repeated in 3 wk) is indicated. Recently acquired young PBPs should be given a routine preventive injection of either parasiticide when first presented for examination.

Melanoma is an important skin tumor in swine. Tumor removal and evaluation of metastatic potential through histopathology is important for prognosis. Spontaneous regression of melanomas, with subsequent depigmentation of the hair, skin, and iris, is occasionally seen in PBPs; affected swine usually have normal life spans.

Sunburn may develop in PBPs exposed to sudden, high-intensity sunlight. Skin lesions may or may not be obvious, but affected PBPs appear painful and seem to have hindlimb weakness or paresis. A sunburned PBP may be “down in the back legs” and show intense pain with vocalization. A thorough history is important for the diagnosis. Exposure to further sunlight should be prevented. Symptomatic treatment is remedial.

Bleeding back syndrome (dippity pig syndrome) is of unknown etiology. Signs are almost identical to those of sunburn (pigs dip their backs, vocalize, and show signs of extreme pain) but with no history of sun exposure. Circular, serum-oozing lesions of various sizes are seen on lumbar skin surfaces. Affected PBPs recover in several days with restricted activity with or without symptomatic treatment. The condition may recur in some animals.

Erysipelas, caused by *Erysipelothrix rhusiopathiae*, is a generalized bacterial infection that affects swine. For details on clinical signs, diagnosis, and treatment, see p 626.

Musculoskeletal System

Lameness due to lower back, hindlimb, or forelimb weakness is common in PBPs. Because of their conformation, PBPs are susceptible to muscle pulls, ligament damage, and fractures of the back and limbs. Because PBPs usually struggle against manual restraint (predisposing to injury), sedation or anesthesia is often used for procedures such as prolonged examination, radiography, foot trimming, blood collection, and dental work. Tiletamine-zolazepam at 2.2 mg/kg body weight, IM (in the ham), provides excellent analgesia and chemical restraint for these minor procedures; recovery, although

smooth, is prolonged and requires careful monitoring. Gas anesthesia is also used and has the advantage of rapid recovery time. Fasting for 24 hr and withholding water for 4–6 hr before sedation or anesthesia is recommended.

PBPs with injuries to the back or limbs are usually treated with anti-inflammatory drugs, such as buffered aspirin with antacid, flunixin meglumine, or glucocorticoids (eg, dexamethasone). Polysulfated glycosaminoglycan and/or glucosamine/chondroitin sulfate products may be tried in nonresponsive cases.

Fractures of the distal humerus and elbow area and femur are common. These occur from jumps off furniture (distal humerus), dog bites (elbow area), restraint (elbow area and femur), equine kicks (femur), and other trauma. Repair via pins, screws, plates, and external devices successfully restores some range of motion if fractures are immobilized properly and any sepsis is controlled.

Infectious arthritis may affect the very young to older PBPs. Lameness with or without joint swelling in one or more limbs is the usual clinical finding. *Erysipelothrix rhusiopathiae*, *Streptococcus* spp, *Mycoplasma hyosynoviae*, *M. hyorhinis*, *Staphylococcus* spp, and *Haemophilus parasuis* are possible causes. Treatment early in the disease course with an effective antimicrobial (eg, lincomycin at 11 mg/kg, bid for 3 days) may be effective. Treatment after chronic changes have occurred, antimicrobial ineffectiveness against the etiologic agent, or misdiagnosis are reasons for treatment failure and persistence of lameness. In chronic cases, pain management with anti-inflammatory drugs should be considered. Polyarthritis from neonatal infection of the navel may be due to various environmental bacteria, including *Pseudomonas* spp. If degenerative arthritis and joint fusion from chronic inflammation are present after polyarthritis, euthanasia may be warranted. Osteochondrosis may also be considered in shoulder, elbow, hip, and stifle lameness, but this condition is not common in slow-growing, light-muscled animals such as PBPs.

Overgrown and/or cracked hooves are a common cause of lameness. Regular exercise on abrasive surfaces (eg, concrete) will wear hoof ends and help keep them the appropriate length. In PBPs with overgrown, elongated hooves, normal yearly length can be maintained by routine yearly trimming under sedation or anesthesia. Hoof cracks can be caused by overgrown hooves. PBPs with cracked hooves may

additionally require antiseptic cleaning with tamed iodine and systemic antimicrobial therapy (ceftiofur at 4.4 mg/kg/day for 3–10 days, or ampicillin at 11 mg/kg, PO, bid for 7–10 days).

Zygomycosis from *Mucor* spp infection has occurred in the distal hindlimb of a PBP. The large growth that encompassed the entire foot was composed of infected/abscessed tissue that involved bone. Amputation was remedial.

Tetanus may occur after wound contamination from dog bites, skin abrasions, oral cavity abrasions, or surgical procedures. Tetanus toxoid should be part of the routine vaccination schedule of PBPs at high risk of exposure. If there is no current tetanus toxoid vaccination, tetanus antitoxin (500–1,500 U, depending on body weight) should be administered IM in the neck after recovery from any surgery or dental procedure (eg, trimming of canine teeth). Treatment for tetanus is by massive doses of tetanus antitoxin and penicillin early in the disease, along with tranquilizers, isolation to minimize external stimuli, and supportive therapy.

Nervous System

Systemic bacterial infection can be caused by (in approximate decreasing order of importance) *Streptococcus suis* type 2, other *Streptococcus* spp, *Salmonella* Choleraesuis, *Haemophilus parasuis*, *Escherichia coli*, other gram-negative bacteria, and *Listeria monocytogenes*. CNS signs may include fever, depression, incoordination, staggering, postural abnormality, head tilt, circling, nystagmus, seizures, and death. PBPs are most commonly affected from birth through 4–6 mo of age. Treatment with the appropriate antibacterial therapy (eg, extra-label florfenicol, which penetrates the blood-brain barrier) in the early stages of infection is most effective; however, death may be the first clinical sign. Because *S suis* type 2 is a zoonotic disease agent, care should be exercised to prevent human infection when performing necropsies on pigs dying from suspected CNS disease.

Overheated PBPs may be depressed, inactive, and recumbent and show open-mouth breathing or panting with an initial fever followed by a subnormal and decreasing temperature. The prognosis is grave, but some overheated PBPs may respond to resting on a cool surface and cooling only the head with water for 10–15 min followed by packing ice bags around the head. If the temperature is still not

controlled, cold-water enemas can be used while additional areas of the skin surface are packed in ice. Symptomatic treatment is continued as indicated.

Salt toxicity occurs after water deprivation for ≥ 36 hr followed by sudden rehydration or, less commonly, after prolonged consumption of high-salt foods. Affected PBPs may have seizures, walk aimlessly, or show other CNS signs such as blindness or postural abnormalities. Diagnosis in the affected live animal is confirmed by high levels of serum sodium, usually 160–183 mEq/dL (normal range 142–153 mEq/dL). Gradual rehydration and symptomatic treatment to counteract cerebral edema is indicated, but severely affected PBPs may only be stabilized to a vegetative and blind status. The histopathologic finding of eosinophilic infiltration into brain tissue is also diagnostic.

Seizure from unknown cause occurs in PBPs. Animals <1 yr old seem most susceptible. Frequency may range from 1–2 seizures per month to several per day. Infrequent seizures may require no preventive medication. Diazepam is used to control more frequent episodes. Phenobarbital in addition to diazepam may be required to control the most severe cases. Seizures may cease as the affected PBP ages.

Respiratory System

Atrophic rhinitis is an infectious disease of swine that initially causes sneezing, nasal discharge, tearing, and growth retardation. Younger PBPs are more commonly affected. For details on clinical signs, diagnosis, and treatment, see p 1465.

Pneumonia can be a very serious disease in PBPs because of their relatively small lung capacity. The most common cause of pneumonia is from initial *Mycoplasma hyopneumoniae* infection (see p 1467), which immunocompromises the lungs, followed by *Pasteurella multocida* infection. Young pigs contract these infectious agents from their dams or from mixing with infected pigs after weaning. Antibiotic treatment may be more effective if directed against *P. multocida*, because this bacterium becomes the most important pathogen once coughing is present for several days. Vaccines available for *M. hyopneumoniae* in domestic commercial swine have been used in young PBPs to prevent mycoplasma pneumonia and subsequent *Pasteurella* pneumonia. Vaccination in older PBPs is probably unnecessary unless risk of exposure warrants continued use.

Actinobacillus pleuropneumoniae (see p 1469) causes a life-threatening pneumonia that may occur after infection from the sow or exposure to carrier animals. Signs range from coughing, fever, and lethargy to sudden death, depending on the serotype of *A. pleuropneumoniae*. Prompt antibiotic treatment with penicillin or ceftiofur is indicated. Recovered PBPs usually have permanent tissue loss in affected lung areas and may have recurrent respiratory problems. Vaccines available for domestic commercial swine may be used in PBPs if there is an exposure risk.

Swine influenza (see p 1470) is an important viral pneumonia in PBPs that are taken to fairs, exhibitions, and petting zoos and exposed to other pig populations. It is usually self-limiting after 7–10 days but can be fatal. H1N1, H3N2, H1N2, and H2N3 are the most common strains in domestic swine. Multivalent vaccines available for domestic swine could be used in PBPs if indicated. Swine influenza is a zoonotic disease.

Urinary System

Cystitis and urolithiasis are common in PBPs. Signs include frequent urination or straining to urinate. Urinalysis, urine culture, CBC, serum chemistry, radiography, and ultrasonography are important diagnostic aids. A sterile urine sample for culture can be obtained via cystocentesis. Cystitis without triple phosphate crystalluria should respond to extended antibacterial therapy based on in vitro sensitivity testing. Acidification of the urine may minimize recurrence of infection. Nephritis can occur after cystitis as an ascending infection. Leptospirosis may be a primary cause of nephritis. Increased BUN and creatinine values may aid in the diagnosis of nephritis and kidney failure. A 6-way vaccine for leptospirosis is routinely given to breeding PBPs (see p 1930) but may also be considered for routine use in rescue operations where many PBPs are housed in close contact. Vaccination may possibly reduce renal shedding of leptospires should PBPs become chronically infected and, therefore, minimize transmission of this zoonotic disease.

In a PBP that is straining and unable to urinate, the bladder size should be reduced immediately by cystocentesis after sedation and radiography (plain or contrast) or ultrasonography to evaluate the location of urethral and bladder stones. If the blockage is in the urethra, cystotomy is recommended (both sexes) to identify and remove

calculi in all possible locations. Calculi in the urethra of males may be removed by cutting through the sheath to expose the distal penis, catheterizing the urethra, and backflushing into the bladder. Calculi that cannot be removed by this method must be surgically removed by incising the urethra at the location of the blockage. However, scar tissue at the healed incision may also cause urethral obstruction. Suturing of the urethra is followed by cystotomy and bladder flushing to minimize recurrence and then by inspection for more calculi. The bladder is then closed, and a Foley catheter is inserted into the bladder, tunneled through the abdominal muscles, and sutured to the skin. Several days later, the Foley catheter is occluded, and the urethra is inspected to determine patency and urine flow; if not patent, the Foley catheter is opened again, and the process is repeated several days later. When the urethra becomes patent, the Foley catheter is removed. Although the urethra in females is short, blockage can still occur. Because urethral catheterization is difficult without endoscopy, a Foley catheter is inserted into the vagina and inflated, and a purse-string suture is placed at the vulva. Retrograde flushing through the urethral opening in the vaginal floor is attempted. A cystotomy is then performed to remove all possible calculi, followed by routine closure of the bladder. Foley catheter placement into the bladder may not be necessary. Further treatment includes antibiotic therapy and acidification of the urine. Despite these efforts, some affected PBPs do not recover and require euthanasia. Perineal urethrostomies are usually only temporarily successful because the surgical site becomes occluded by amorphous material or urethral polyps, and patency cannot be reestablished. However, surgical methods have been

described to correct failed perineal urethrostomies in PBPs. Rupture of the bladder is a grave complication because normal bladder tone may not return even after stones have been removed and the bladder has been surgically repaired. Laser lithotripsy has been used to fracture urethral calculi not removable by flushing.

Routine urinalysis as part of an annual examination may enable early diagnosis and prevention of serious urinary tract disease in PBPs.

Psychogenic water consumption should be considered in PBPs (especially young PBPs) with polydipsia and polyuria. PBPs may develop a habit of drinking water and urinating frequently because of possible boredom or unknown causes. Cystitis and crystalluria should be eliminated as differential diagnoses. Measuring urine specific gravity before and after a 12-hr water fast will demonstrate whether the affected PBP is able to concentrate urine. Ability to concentrate urine indicates normal kidney function and helps exclude diabetes insipidus. Estimating the daily water intake and urine output will further aid the diagnosis of psychogenic water intake or establish that water consumption and urination are, in fact, normal. Relieving boredom may be helpful to change this behavior. Affected young PBPs typically outgrow this condition. If water is restricted and offered only with meals, care must be taken to prevent salt toxicity.

Chronic kidney failure is a common cause of death in geriatric PBPs. Lethargy, anorexia, dehydration, azotemia, ammonia breath odor, and low temperature are possible presenting signs. Symptomatic treatment such as rehydration and antibiotics (procaine penicillin 22,000 IU/kg/day, IM, for 3 days) may be at least temporarily helpful in less severe cases.

RABBITS

The European or Old World rabbit (*Oryctolagus cuniculus*) is the only genus of domestic rabbits. Wild rabbits and hares include cottontail rabbits (*Sylvilagus*) and the "true" hares or jackrabbits (*Lepus*). Rabbits have been bred for fur, meat, wool, exhibition, and for use as laboratory animals. The closest relative to the rabbit is the pika (*Ochotona princeps*), which lives

in cold climates such as the Rocky Mountains. Rabbits are not rodents.

MANAGEMENT

Management of rabbits for meat, fur, or wool production is quite different from maintenance of a pet or house rabbit. The American Rabbit Breeders Association

(www.arba.net) provides guidance for both production and pet rabbit care. The House Rabbit Society (www.rabbit.org) is another resource regarding pet rabbit care.

Restraint: Proper handling and restraint is important. Rabbits have powerful hindlimbs, which can kick out and lead to broken backs. Rabbits should never be held by the ears; they should be scruffed at the neck, and the body firmly supported at the rump. If they are not held properly and securely, fractures or luxations of lumbar vertebrae can easily follow struggling. If a rabbit appears to be very stressed or excited, a sedative may be indicated to avoid injuries caused by handling. Midazolam at 0.5–1 mg/kg, IM, is often enough to adequately sedate the rabbit for a thorough physical examination.

Physical Examination and Sample Collection:

Most techniques for physical examination suitable for dogs and cats may be applied to rabbits. A thorough oral examination, including palpation of the face and bottom of the jaw, should be performed to evaluate dental health. An otoscope or a pediatric nasal speculum can assist visualization of the molars. Conscious rabbits will usually resist a full dental examination, and sedation or anesthesia is required. Sex can be determined by depressing the external genitalia to reveal a slit-like vulva in females or the penis in males. The testicles descend at 10–12 wk. Normal body temperature is 103.3°–104°F (39.6°–40°C). Body temperature <100.4°F or >105°F is cause for concern.

Blood can be collected from the cephalic vein, lateral saphenous vein, and the jugular vein. The lateral saphenous vein is easy to access when the rabbit is held and resting on someone's forearm, with the restrainer holding the leg above the stifle joint. The lateral saphenous vein runs across the lateral aspect of the tibia at the middle of the length of the bone. In larger rabbits (>3 kg), the ear veins can also be used. The auricular or marginal ear vein provides a site for venous administration or catheterization. Drugs should not be injected through the ear veins, because this can lead to phlebitis and subsequent ear sloughing. Only physiologic crystalloid fluids should be administered via the ear vein. The central artery can be accessed for direct blood pressure monitoring during anesthesia; no drugs should be injected into the central artery. The auricular vasculature is sensitive to temperature; having the rabbit warm (or

at least having the ear warm) and applying a topical anesthetic cream greatly facilitate these procedures.

Clinical Pathology: Clinical pathology in rabbits varies from that in other domestic animals. The normal neutrophil:lymphocyte ratio is 1:1. The rabbit neutrophil is called a "pseudoeosinophil" or heterophil because of its red-staining cytoplasmic granules. Both the heterophil and the granules are smaller than the eosinophil and eosinophil red granules. Rabbits do not usually respond with a leukocytosis to an active infection. In case of stress, the ratio of the heterophils and lymphocytes changes toward a relative heterophilia without increasing the total WBC count. Many sick rabbits have hemoglobin and PCV values much lower than normal; this makes the PCV one of the best indicators of healthy or sick animals. Calcium metabolism in rabbits results in higher normal blood calcium levels (up to 16 mg/dL) and a wider range than in other animals, which can lead to an erroneous diagnosis of hypercalcemia. Rabbit urine ranges from yellow to brown or reddish. A dipstick can quickly differentiate normal rabbit urinary pigments from hematuria. Traces of glucose and protein are normal in rabbit urine.

Therapeutics: Very few products are licensed for use in rabbits, leading to extra-label use of drug therapies approved for use in other species. Particular caution must be exercised in use of antibiotics that suppress normal GI microflora and result in enteric dysbiosis and/or enterotoxemia. This has been called "antibiotic toxicity." Antibiotics contraindicated in rabbits include clindamycin, lincomycin, erythromycin, ampicillin, amoxicillin/clavulanic acid, and cephalosporins. The flea treatment fipronil is contraindicated in rabbits because of severe toxic reactions in some individuals. Supportive care for rabbits often includes aggressive IV fluid support. The maintenance fluid rate for rabbits (120 mL/kg/day) is much higher than that for dogs and cats. Hospitalized rabbits often require doubling of maintenance rates, or 10 mL/kg/hr. In addition to fluid support, pain control is also commonly needed. NSAIDs and opioids are often used in synergy. The dosage of meloxicam in rabbits is 1 mg/kg/day, which is also significantly higher than that in dogs and cats. Opioids such as oxymorphone or hydromorphone can readily be used and have not been shown

to cause GI stasis. In most cases, additional force feeding is not required, and the rabbit should be offered food after fluid and pain management has been initiated. Syringe-assisted feeding can be offered to see whether the rabbit is interested in food intake. In rare cases in which the rabbit refuses to eat, eg, cases of severe hepatic lipidosis, active feeding is necessary; treatment may require aggressive nutritional support via syringe feeding, nasogastric tube (3–5 French), or pharyngostomy tube (soft esophagostomy tube designed for cats). The least invasive method is often the most successful approach. Various commercial products for assisted feeding of rabbits are available. Products are available for immediate critical care (eg, Emeraid®) as well as for longterm assisted feeding and to meet the needs of the recovering rabbit (eg, Recovery®, Recovery Plus®, Critical Care®).

Reproduction: Rabbit breeds of medium size are sexually mature at 4–4.5 mo, giant breeds at 6–9 mo, and small breeds (eg, the Polish Dwarf and Dutch) at 3.5–4 mo of age. The rabbit is an induced ovulator and, contrary to popular belief, has a cycle of mating receptivity; rabbits are receptive to mating ~14 of every 16 days. The degree of mating receptivity is indicated by the color of the vaginal orifice and by the amount of moisture on the labia. A doe is most receptive when the vagina is red and moist. Does that are not receptive have a whitish pink vaginal color with little or no moisture. Many breeders test mate the doe 10–16 days after breeding as a way to detect pregnancy, but this is unreliable. Palpation of the doe's abdomen for "grape-sized" embryos in the uterus is a much better technique to detect pregnancy. The best time to palpate is 12 days after breeding. Pseudopregnancy is common in rabbits and can follow any induced ovulation, the introduction of a male rabbit in the environment, or other stimuli.

A ratio of 1 buck to 10 does is common practice, but many commercial growers find that 1 buck to 20–25 does is more economical. Bucks can be used daily without decreasing fertility; more frequent use requires periods of rest. The doe should always be taken to the buck's cage for breeding. The breeding program should continue year round. Does that experience long periods of rest between litters tend to become obese and difficult to breed. Does constantly in gestation and lactation may become underweight, and their receptivity to the buck and fertility decrease dramati-

cally. If breeding is delayed several weeks and the doe is given full feed, weight is quickly regained.

The gestation period is ~31–33 days. Does with a small litter (usually ≤4) seem to have a longer gestation period than does that produce larger litters. If a doe has not kindled by day 32 of gestation, oxytocin (1–2 IU) should be given to induce parturition; otherwise, a dead litter is almost always delivered sometime after day 34. Occasionally, pregnant does abort or resorb the fetuses because of nutritional deficiencies or disease.

Nest boxes should be added to the cages 28–29 days after breeding. If boxes are added too soon, the does foul the nests with urine and feces. A day or two before kindling, the doe pulls fur from her body and builds a nest in the nest box. The young are born naked, blind, and deaf. They begin to show hair on day 2–3 after birth, and their eyes and ears are open by day 10. Neonatal rabbits are unable to thermoregulate until about day 7. Rebreeding can occur any time after parturition, because the doe can conceive 24 hr after kindling. Some commercial growers use accelerated breeding schedules and rebreed 7–21 days after parturition, whereas most people raising rabbits for show or home use rebreed 35–42 days after parturition.

Most medium-sized female rabbits have 8–10 nipples, and many kindle 12–15 young. If a doe is unable to nurse all the kits effectively, kits may be fostered by removing them from the nest box during the first 3 days and giving them to a doe of approximately the same age with a smaller litter. If the fostered kits are mixed with the doe's own kits and covered with hair of the doe, they are generally accepted. Moving the larger kits to the new litter instead of the smaller kits increases the chance of success. Does nurse only once or twice daily. Kits nurse <3 min. Kits are weaned at ~4–5 wk of age.

Rearing Orphaned Kits: Kits can be hand-reared, but mortality is high. They should be kept warm, dry, and quiet. Kitten milk or goat milk replacer or a formula of ½ cup evaporated milk, ½ cup water, 1 egg yolk, and 1 tbsp corn syrup can be used. Feedings vary from ½ tsp to 2 tsp, depending on the age of the kits. Kits should be fed only every 12 hr to avoid overfeeding and to mimic the natural feeding behavior of the doe. Cottontail kits start eating greens around day 15–18, whereas domestic rabbit kits are weaned when ~6 wk old.

Surgery: Preoperative fasting is not required or recommended. Rabbits cannot

vomit. Additionally, rabbit stomachs are never empty, even after prolonged fasting. However, a short fast (1–2 hr) should be done to assure that the oral cavity is free of food. Premedication with butorphanol or diazepam/midazolam will reduce stress from preoperative handling. Premedication with atropine will be useful for only a short time, because many rabbits have an atropinase that clears the drug from the system rapidly. Instead, glycopyrrolate may be used to reduce bradycardia and upper airway and salivary secretions (0.01–0.1 mg/kg, IM or SC, or 0.01 mg/kg, IV). Isoflurane is recommended for general anesthesia, but premedication with a combination of an NSAID and an opiate (such as meloxicam at 1 mg/kg, PO, and butorphanol at 0.4 mg/kg, IV) can reduce the minimum alveolar concentration (MAC) of isoflurane from 2.5% to 2.3%. Lidocaine administered as a constant-rate infusion has also been shown to reduce the MAC of isoflurane (lidocaine can be given at a loading dose of 2 mg/kg, IV, followed by 100 mcg/kg/min).

The long and narrow pharynx and large tongue make rabbits difficult to intubate. Laryngospasm can be minimized by application of lidocaine on the epiglottis. There are several reported techniques to intubate rabbits; all require selection of the appropriate tube size and length to avoid tracheal injury. A pediatric laryngeal mask, uncuffed Cole, or cuffed Murphy eye type endotracheal tube (ET) can be used, but selecting the appropriate size (2–4 mm) is critical. The risk of tracheal injury increases with repeated intubation attempts, but ET cuff pressure, prolonged duration of intubation, and movement of the ET during mechanical ventilation and animal positioning for anesthesia seem to be more critical because of the vascular anatomy of the rabbit trachea. Rabbits are best intubated with visualization, using an endoscope or similar technology. Direct visualization of the epiglottis and ET placement can also be accomplished by using a laryngoscope with a Miller 0 blade, a rabbit oral specula, and cheek dilators. The glottis should be visualized using the endoscope, and the tube carefully advanced toward the glottis. The natural position of the epiglottis is behind the soft palate. The ET can be used to disengage the glottis from the soft palate, and then introduced into the glottis and down the trachea. Care must be taken to not damage the arytenoid cartilages when inserting the tube into the trachea, because these cartilages reduce the diameter of the glottis significantly and can be easily damaged by a

larger-size tube. If no visual aid is available, the rabbit can be intubated blindly, but this procedure requires much skill and has the potential for iatrogenic trauma if not performed properly. In the classic blind technique, the rabbit is placed in a sternal position with the head held and the nose pointing at the ceiling. The ET is guided behind the incisors and to the larynx. The operator listens for the sounds of inspiration and expiration and times the advancement of the ET with maximal inspiration. A second technique involves placing the rabbit in lateral recumbency with the head dorsiflexed. The ET is advanced along the hard palate to the back of the throat until condensation can be seen within the lumen of the ET. The condensation is used to judge the cycles of inspiration and expiration, and the ET is advanced at maximal inspiration. Proper ET placement should be confirmed regardless of placement method. An alternative to intubation is a supraglottic airway device (V-gel®). A species-specific pharyngeal device is placed in the oral cavity and advanced caudally until it sets in place automatically. The device sits on top of the glottis and seals the surrounding structures, creating an airtight connection between the trachea and the tube.

Adequate general anesthesia can be achieved for a short procedure with injectable ketamine (25–50 mg/kg) in combination with a tranquilizer such as xylazine (5–10 mg/kg, IM). The combination of ketamine (10–20 mg/kg, IM) and dexmedetomidine (0.125–0.25 mg/kg, IM) provides adequate anesthesia; ~½ of the original dose can be repeated if anesthesia needs to be prolonged. Atipamezole can be given IM in equal volume to dexmedetomidine volume for reversal.

It is critical for rabbits to start eating postoperatively, and analgesic treatment for 1–2 days will help prevent inappetence. A rabbit in pain may chatter or grind its teeth while sitting in a hunched position. Analgesic treatment may include opioid drugs such as buprenorphine (0.01–0.05 mg/kg, SC, IM, or IV, bid-tid) or butorphanol (0.05–0.4 mg/kg, SC or IM, bid-tid), or NSAIDs such as carprofen (1.5 mg/kg, PO or SC, bid), flunixin (0.5–2 mg/kg/day, PO, deep IM, or IV, for no more than 3 days), or meloxicam (1 mg/kg/day, PO or SC). Tramadol used at 11 mg/kg, PO, causes no adverse effects and has been reported empirically to be effective in rabbits. However, a study showed that this dose does not achieve plasma levels that would be considered adequate in people. Prolonged opiate exposure has not been associated with GI stasis.

Postoperative supportive care is critical to a successful surgical outcome. Hay and water should be offered as soon as possible after surgery. Alfalfa hay can be used to improve appetite. Banana is favored as a treat by many rabbits. Hand feeding or syringe-assisted feeding is necessary if the rabbit does not eat on its own soon after the surgery. If the rabbit does not eat within 2–3 hr after surgery, the analgesic protocol should be reevaluated. The rabbit should be assisted fed until it refuses further food intake in each session.

Castration can reduce aggressive behavior and is suggested for house rabbits and group-housed rabbits. It has no advantage for meat-type rabbits. The testicles are lateral and anterior to the penis, as in marsupials and not as in most other placental mammals. Castration is performed using a closed technique or by an open technique with closure of the large superficial inguinal ring to prevent herniation.

Female pet rabbits should be spayed because of the high risk of uterine cancer. Rabbits have two uterine horns connected to the vagina by two separate cervixes. The oviduct loops around and is much longer than in cats or dogs. Ovariohysterectomy is more complicated in older or multiparous rabbits because of the large amount of fat in the mesometrium. Postoperative adhesions are a common complication, which may be reduced by calcium-blocker treatment (verapamil, 200 mcg/kg, SC, tid for 3 days). To avoid adhesions, all blood clots should be removed before closing the abdomen, and the GI tract should not be handled at all. The use of spay hooks is not recommended in rabbits, because the intestinal loops are easily damaged; tissue forceps (eg, Adson-Brown) are a better choice.

Although the vast majority of trichobezoars can be managed medically with aggressive fluid therapy (10–12 mL/kg/hr) and appropriate pain medication (eg, oxymorphone), a small percentage of GI cases need to be surgically corrected. Surgery should usually be considered if the condition has not improved after 24 hr of aggressive medical therapy. When gastrotomies are performed, the stomach is elevated by stay sutures through a cranial celiotomy incision. An incision is made through the greater curvature of the stomach. It is important to remove stomach contents from the pyloric sphincter and to examine the stomach lining for abnormalities. A fine, absorbable monofilament suture should be used for closure of the stomach wall and

incorporate, but not penetrate, the gastric mucosa. Pre- and postsurgical care should include fluids and antibiotic therapy.

Rabbits can chew out skin sutures; therefore, skin closure should be performed with a 4-0 absorbable synthetic suture with a cuticular-cuticular pattern. Tissue glue may be added to finish this closure. Rabbits tolerate staples.

Euthanasia: Rabbits may jump or scream when the traditional overdose of barbiturate is given in the marginal ear vein. Sedation with midazolam (5 mg/kg, IM or IV) or propofol (10 mg/kg, IV) is recommended before administration of the barbiturate. As a further precaution, euthanasia solution may be diluted 1:1 with saline to prevent a negative reaction and to reduce viscosity of the solution to facilitate a faster and smoother injection.

Other Management Techniques: Toenails on the hindlimbs may severely scratch unprotected arms of handlers. Nails should be trimmed every 1–2 mo. Declawing is not recommended, but some rabbits tolerate application of adhesive nail caps.

Some breeders tattoo or place ear tags on their rabbits for identification purposes. For show purposes, the right ear is reserved for registration marks applied by registrars of the American Rabbit Breeders Association. A tag placed in the anterior cartilaginous part of the ear, nearer to the head, is less likely to be pulled out.

HOUSING

Pet Rabbits: A rabbit hutch placed in the back yard, basement, or garage has been and continues to be traditional housing for rabbits. The hutch should be conveniently accessed for proper care of the rabbit, because diseases of neglect are common in rabbits abandoned in a hutch at the back of the yard. Care must be taken to prevent the hutch from being exposed to severe heat, because rabbits are prone to heat stroke. The flooring of the hutch should be covered with some type of soft padding to provide a comfortable resting spot. Sore hocks can lead to more problems if the rabbits are housed on wire or wooden flooring for long periods. Keeping the area around the hutch clean is important to avoid a large population of flies, which often lead to fly strike (myiasis) that is often fatal. There should be adequate ventilation and protection from dogs or other predators such as raccoons.

House Rabbits: In the natural setting, rabbits use a latrine system. This behavior can easily be exploited by providing a litter box. Rabbits usually readily accept a litterbox with little training. Rabbits have continuously growing teeth and need to chew on things to appropriately wear down the teeth. If no appropriate food material that requires significant chewing efforts (eg, hay) is offered, rabbits are likely to gnaw on various objects in the environment, such as furniture, curtains, carpeting, or electrical wiring, which is dangerous for the rabbit and creates a fire hazard. Rabbits should be confined to safe quarters when unsupervised.

Cages and Ancillary Equipment:

Rabbits can gnaw, and caging should be constructed of durable materials. Cages should be easily sanitized and allow easy cleaning. All-wire cages with a minimum of 12-gauge wire (16-gauge recommended for cage floor to support the weight of the rabbit) are preferred. Aquariums are not appropriate housing for rabbits (or other small mammals) because of inadequate air circulation. The size of the cage depends on the size of the rabbit. Giant breeds (>12 lb) require a minimum of 30 × 36 in. to 36 × 48 in. Medium breeds (7–12 lb) require 24 × 30 in. to 30 × 36 in. Smaller breeds can be accommodated by 18 × 24 in. The cage should be tall enough to allow the rabbit to stand on its hindlimbs. The cage should be equipped with a feed hopper and a watering system. Feed hoppers are best constructed of sheet metal with holes or a screen in the bottom for removal of “fines” (small, broken feed particles). Rabbits drink more than other animals of similar size, and they should be offered ad lib potable water. Rabbits will consume significantly more water when water is offered from a dish versus a sipper bottle. Rabbits often chew on the watering valve and may eventually destroy it unless it is made of stainless steel or has a stainless centerpiece. If a water dish cannot be offered, water bottles with sipper tubes are a good alternative. However, food dishes are easily contaminated and should be washed and disinfected daily. A barren cage is inadequate; the cage environment should be enriched (eg, cage furniture, toys) to provide stimulation. Optimally, rabbits should be given run time outside of the cage daily.

Nest boxes should be constructed so that they can be easily placed in the cage and later removed for cleaning and disinfecting

between litters. Disinfecting the nest box after cleaning and again just before placing it in the cage helps reduce incidence of disease. The box should be large enough to prevent crowding but small enough to keep the kits warm. A standard size nest box for medium-sized rabbits is 16 × 10 × 8 in. Wooden, metal, or plastic nest boxes with nesting material (eg, straw, hardwood shavings, CareFresh® bedding) serve well in either warm or cold weather. Rough edges such as splintering wood should be avoided, because they contribute to mastitis when does hop in and out of the nest box.

Pens: Pens should have a nonslip floor and may be bedded with straw or shredded paper covered with straw or hay to increase absorbency. Shavings or sawdust are not the best, because the scent is too powerful. Pen sides should be at least 4 ft high or high enough to allow the rabbit to stand erect on the hindlimbs.

Group Housing: When setting up group housing, compatibility is a major factor. Personalities should be evaluated for docility and aggressiveness. Strain influences personality. Rabbits that have grown up together are best, although adults may be so aggressive toward each other that serious fights occur. Neutering will improve compatibility. A period of adjacent proximity is prudent before group housing rabbits. Another factor to consider is stocking density. Floor space recommendations vary from 3.5 to 10 sq ft/rabbit to allow territory establishment. Others recommend 3.5 hop lengths per rabbit as a general rule. Regardless, group-housed rabbits should be provided escape and hiding places and should be frequently monitored.

Production Housing: Housing requirements for rabbits depend on climate. Minimal housing (an A-frame roof without sides) can be used in moderate climates, whereas a climate-controlled rabbitry may be necessary in hot or cold climates. Rabbitries should be located on nearly level ground and use well-drained soil or tile-drained pits for manure. Shade should be provided over as much of the rabbitry as possible. Rabbits are prone to heat stress. Although rabbits tolerate subzero temperatures when provided proper shelter, the optimal rabbit environment is 61°–72°F. Increased humidity levels should also be avoided, because they will increase the likelihood of heat stress and potentially dermatopathies. Good ventilation at all times is imperative.

Sanitation: Cleaning frequency depends of the type of facility or caging system. Rabbits typically choose a preferred latrine site, such as a corner of the cage. This normal behavior can be exploited during litterbox training. A strategically placed litterbox is readily accepted by most pet rabbits. Sanitation is especially important in rabbit production. Poor sanitation leads to disease and deaths; therefore, cleaning and sanitizing must be constant. Nest boxes must be disinfected between uses. Cages, feeders, and watering equipment should be sanitized periodically with an effective and inexpensive sanitizing solution such as diluted household chlorine bleach (1 oz/1 quart water) or other less corrosive disinfectants. Complete cleaning should be performed before housing new stock.

An active rabbitry constantly experiences a loose hair problem. Does pull hair from their bodies to make nests, and some of this hair becomes airborne. It sticks to almost any surface, including cages, ceilings, and lights, and must be removed periodically. The most effective ways to remove hair from cages are washing or using a propane torch or flame. Washing, brushing, sweeping, and vacuuming also are effective in other parts of the rabbitry. Pens or wire-floored cages should be brushed or hosed every 2 wk. An acid wash may be required to descale rabbit urine from solid floor pans.

Frequent manure removal is essential. Excess manure leads to unacceptable levels of ammonia in the air, which predisposes to respiratory disease. The manure can be composted in an efficient pit system.

NUTRITION

Rabbits are small herbivores with specialized feeding needs and digestive systems. They are selective eaters and choose nutrient-rich leaves and new plant shoots over mature plant material that is higher in fiber. Rabbits are therefore considered concentrate selectors, because they naturally pick and choose foods higher in energy density, which predisposes them to obesity in captivity. Anatomically, rabbits are nonruminant herbivores with an enlarged hindgut. The large cecum supports a population of microorganisms that uses nutrients not digested in the small intestine. Most of the bacterial population in the cecum is made up of the gram-positive *Bacteroides* sp. This makes the rabbit very sensitive to oral antibiotics; administration of oral antibiotics can disturb the *Bacteroides* population and lead to fatal GI upsets.

Separation of digesta on the basis of particle size occurs in the hindgut. Peristaltic action rapidly moves large particles (>0.5 mm), primarily lignocellulose, through the colon and excretes them as hard fecal pellets. This is the "indigestible fiber" component of the diet. The clinical importance of a diet high in long particle length is to maintain the motility of the cecum and colon. This is why these fibers are sometimes referred to as "scratch factor," because they mechanically stimulate GI motility. Antiperistaltic action moves smaller particles (<0.3 mm) and soluble material into the cecum, where they undergo fermentation. This component of the diet is known as "digestible" or "fermentable" fiber. At intervals, the cecal contents are expelled as "soft feces" or cecotrophs and consumed by the rabbit directly from the anus. Cecotroph ingestion is highest when rabbits are fed a diet high in nondigestible fiber. This reingested material provides microbial protein, vitamins (including all the B vitamins needed), and small quantities of volatile fatty acids, which are essential in rabbit nutrition. However, because amino acids obtained in this manner make only a minor contribution to the rabbits' protein needs (particularly young, growing rabbits), the diet must supply the additional amino acids, although the requirements for essential amino acids in rabbits have not yet been defined.

Rabbits digest fiber poorly because of the selective separation and rapid excretion of large particles in the hindgut. A generous amount of dietary fiber (~15% crude fiber) is needed to promote intestinal motility and minimize intestinal disease. High-fiber intake can be provided by use of alfalfa timothy hay (~30%–35% fiber). Fiber may also absorb bacterial toxins and eliminate them via the hard feces. Diets low in fiber promote an increased incidence of intestinal problems, eg, enterotoxemia. Carbohydrates will actually inhibit motilin release. Motilin is a polypeptide hormone secreted by cells of the duodenum and jejunum, which stimulates the GI smooth muscle. Excess starch can also be substrate for the proliferation of pathogenic bacteria such as *Clostridium spiroforme*, which produce a potent toxin. Cecum fermentation produces volatile fatty acids, which are responsible for 40% of the rabbits' calorie requirement. Volatile fatty acids also aid in the control of pathogenic organisms by helping to maintain the normal pH (6–7) in the cecum.

A dietary supply of vitamins A, D, and E is necessary. Bacteria in the gut synthesize B vitamins and vitamin K in adequate

quantities; thus, dietary supplements are unnecessary. Disease and stress may increase the daily vitamin requirements. Feed preparation and storage must be done in a manner that will reduce losses from oxidation, which destroys vitamins A and E more readily than other vitamins. Diets containing $\geq 30\%$ of alfalfa meal generally provide sufficient vitamin A. Levels of vitamin A in the diet must be $>5,000$ IU/kg and $<75,000$ IU/kg. Levels out of this range may cause abortion, resorbed litters, and fetal hydrocephalus. Vitamin E deficiency has been associated with infertility, muscular dystrophy, and fetal and neonatal death. Pet rabbit diets sold in pet stores or even in bulk at feed stores may not have adequate turnover, which may result in nutritional deficiency. Hay packaged for small mammals may have been sitting on the shelf for an extended period.

All the components of the basic diet (ie, protein, fiber, fat, and energy) should be managed in consideration of the life stage (growth, gestation, lactation, maintenance), breed, condition, and lifestyle of the rabbit. Ratios should meet the nutrient requirements of the National Research Council (see TABLE 21). Pelleted rabbit feeds provide good nutrition at reasonable cost. Fresh, clean water should always be available. Prolonged intake of typical commercial diets containing alfalfa meal by laboratory or pet rabbits kept for extended periods under maintenance conditions may lead to kidney damage and calcium carbonate deposits in the urinary tract. Ad lib timothy hay is usually recommended for the maintenance diet of adult rabbits. Reducing the calcium level to 0.4%–0.5% of the diet for nonlactating rabbits helps reduce these problems. This can be accomplished by feeding

pelleted diets with a timothy hay base. Adult pet rabbits not intended for breeding should be fed a high-fiber pelleted diet, restricted to $\frac{1}{4}$ cup/5 lb body wt/day to prevent obesity and maintain GI health.

Production Rabbit Nutrition: Rabbits are efficient converters of poorly digestible materials to meat. Therefore, it is easy to overfeed or underfeed does and growing, adolescent rabbits (fryers). The amount to feed depends on the age of the fryers or on the stage of pregnancy or lactation of the does. A general rule in feeding fryers is to feed all that can be consumed in 20 hr, with the feed hopper empty ~ 4 hr/day. Does are usually fed ad lib once they kindle. The general practice is to bring does from restricted to full feed slowly during the first week of lactation. Does bred to kindle five times during the year generally have their feed restricted between litters; those bred intensively should be on full feed continually once they begin the first lactation.

BACTERIAL AND MYCOTIC DISEASES

Pasteurellosis

Pasteurellosis is common in domestic rabbits. It is highly contagious and transmitted primarily by direct contact, although aerosol transmission may also occur. The etiologic agent is *Pasteurella multocida*, a gram-negative, nonmotile coccobacillus. In conventional colonies, 30%–90% of apparently healthy rabbits may be asymptomatic carriers. This is important to consider when nasal cultures are collected, because not every positive result indicates a pathologic condition. To get a

TABLE 21 NUTRIENT REQUIREMENTS OF RABBITS

	Protein (%) Total	Protein (%) Digestible	Fat (%)	Fiber (%)	Digestible Carbohydrates (NFE, %) ^a	Total Digestible Nutrients (%)
Maintenance	12	9	1.5–2	14–20	40–45	50–60
Growth and finishing	16	12	2–4	14–16	45–50	60–70
Gestation	15	11	2–3	14–16	45–50	55–65
Lactation (with litter of 7–8)	17	13	2.5–3.5	12–14	45–50	65–75

^a NFE = nitrogen-free extract

true representative culture of the nasal bacterial fauna, the rabbit needs to be heavily sedated or anesthetized and a deep nasal culture obtained by introducing the culture tip relatively far into the nasal opening. Several barrier colonies of laboratory rabbits have been established as *Pasteurella*-free.

Clinical Findings: Pasteurellosis presents with a variety of clinical symptoms, including rhinitis, pneumonia, abscesses, reproductive tract infections, torticollis, and septicemia. Rabbits may develop *Pasteurella* septicemia and die acutely without any clinical signs. Septicemia necropsy findings may reveal only congestion and petechial hemorrhages in multiple organs.

Rhinitis (snuffles or nasal catarrh) is an acute, subacute, or chronic inflammation of the mucous membranes of the air passages and lungs, induced primarily by *Pasteurella*, but *Pseudomonas*, *Bordetella bronchiseptica*, *Staphylococcus*, and *Streptococcus* have also been isolated. The initial sign is a thin, serous exudate from the nose and eyes that later becomes purulent. The fur on the inside of the front legs just above the paws may be matted and caked with dried exudate, or this area may be clean with thinned fur as a result of pawing at the nose. Infected rabbits usually sneeze and cough. In general, snuffles occurs when the resistance of the rabbit is low. Recovered rabbits are likely carriers. Pneumonia can ensue.

Pneumonia is common in domestic rabbits. Frequently, it is a secondary and complicating factor in the enteritis complex. The cause is typically *Pasteurella multocida*, but other bacteria such as *Klebsiella pneumoniae*, *Bordetella bronchiseptica*, *Staphylococcus aureus*, and pneumococci may be involved. Upper respiratory disease (snuffles, see above) is often a precursor of pneumonia. Inadequate ventilation, sanitation, and nesting material are predisposing factors. The number of cases of pneumonia is directly proportional to the level of ammonia in the cage, hutch, or rabbitry. Ventilation is of utmost importance to provide good air quality. Affected rabbits are anorectic, listless, dyspneic, and might have a fever. Treatment should include systemic antibiotics, optimally based on a culture and sensitivity, because of possible resistance to common pathogens. The rabbits are usually dehydrated, and supportive care with hydration and syringe feeding is often necessary as well. Topically administered ophthalmologic antibiotic products instilled

into the nostril can also be beneficial. Necropsy reveals bronchopneumonia, pleuritis, pyothorax, or pericardial petechiae.

Otitis media or interna ("wry neck" or head tilt) results from infections with various agents. *Pasteurella multocida* was reported to be isolated from 97% of cases of otitis media, including clinical and subclinical cases. *Bordetella bronchiseptica* and staphylococci were also found in 5%–10% of cases. An accumulation of pus or fluid in the middle or inner ear causes the rabbit to twist its head, eg, "wry neck" or torticollis. However, not all rabbits with middle ear infections show torticollis. Longterm antibiotic treatment is required for drug penetration into the affected area. Antibiotic therapy may only prevent worsening of clinical signs, and the prognosis is guarded with medical therapy alone. Total ear canal ablation and bulla osteotomy are often indicated when medical management of otitis media and interna fails. Proper imaging of the ear lesions is indicated before surgery. Often, a CT scan of the head will help to identify the lesion and potentially help to differentiate otitis media/interna from intracranial disease in cases of torticollis (eg, *Encephalitozoon cuniculi* infection).

Conjunctivitis and dacryocystitis (weepy eye) is a common problem in rabbits. Predisposing factors include mechanical irritation, eyelid diseases, and dental disease. Conjunctivitis in rabbits may be associated with other disease processes, especially dacryocystitis. The most incriminated cause of conjunctivitis is *P. multocida*; however, this may be only a secondary infection. Primary infections are less common than opportunistic infections. Transmission is by direct contact or fomites. Affected rabbits rub their eyes with their front feet. Bacterial conjunctivitis can be treated with topical chloramphenicol, ciprofloxacin, or gentamicin combined with systemic broad-spectrum antibiotic therapy if topical treatment alone is ineffective. Dacryocystitis and acquired nasal duct obstruction may arise from chronic rhinitis that travels up the nasolacrimal duct to the eye or occasionally from dental disease such as tooth root inflammation or abscessation. Treatment includes gentle flushing with saline of the duct through the nasolacrimal punctum, but care is warranted to not damage the nasolacrimal duct during flushing. Dacryocystorhinography or injection of contrast material into the lacrimal punctum will provide good radiographic detail of the duct throughout

its course and show the site of obstruction. In long-standing cases of dacryocystitis and conjunctivitis, the punctum and segments of the nasolacrimal duct may progressively narrow and be replaced with scar tissue until they are irreversibly obstructed. This results in permanent epiphora, and owners should be advised accordingly. To relieve discomfort and inflammation associated with these conditions, the use of topical nonsteroidal anti-inflammatory ophthalmic preparations such as flurbiprofen can be considered. Systemic NSAIDs such as meloxicam should also be used.

Conjunctivitis also accompanies rabbitpox (see p 1951) and myxomatosis (see p 1950).

Subcutaneous and visceral **abscesses** caused by *Pasteurella* may be clinically silent for long periods and spontaneously rupture. When bucks penned together fight, their wounds frequently develop abscesses. Abscesses in rabbits are treated differently than abscesses in cats; rupture or drainage via Penrose is not the recommended course. Thick-walled abscesses should be surgically excised en bloc if possible. Open wounds should be debrided or curetted, marsupialized, and left to heal by second intention. Facial abscesses are often related to dental disease (see p 1954). Drainage of the abscess accompanied by systemic antibiotic therapy based on culture and sensitivity tests has been successful, although recurrence can be common.

Pasteurella can cause **genital infections**, but several other organisms also may be involved. The spirochete *Treponema paratluiscuniculi* is the causative agent of rabbit syphilis. Genital infections are manifest by an acute or subacute inflammation of the reproductive tract and most frequently are found in adults, more often in does than bucks. In the case of *Treponoma*, a severe conjunctivitis or dermatosis between the toes can also be a key clinical sign. If both horns of the uterus are affected, the does often become sterile; if only one horn is involved, a normal litter may develop in the other. The only sign of pyometra may be a thick, yellowish gray vaginal discharge. If bloody discharge from the vulva is observed and a large uterine horn can be palpated, uterine adenocarcinoma should be included in the differential diagnosis. Bucks may discharge pus from the urethra or have an enlarged testicle. Chronic infection of the prostate and seminal vesicles is likely, and because venereal transmission may ensue, it is best to cull the animal in a production rabbitry colony. Surgical removal of the infected

reproductive organs in conjunction with antibiotic therapy is indicated for pet rabbits. The contaminated hutch and its equipment should be thoroughly disinfected.

Diagnosis: Diagnosis of pasteurellosis is based on clinical signs and isolation of *P. multocida*. Carriers can be identified by an indirect fluorescent antibody test on nasal swabs. A technique that uses small, saline-moistened, pediatric nasopharyngeal swabs has proved superior to the standard, larger nasal swab. The swab is directed medially through the external nares past the turbinates and onto the dorsal surface of the soft palate; sedation is recommended. The swab is then retracted and can be used in the fluorescent antibody test or plated onto a culture medium. An ELISA test to detect antibodies against *P. multocida* may also help detect carriers. PCR can discriminate between different isolates, but it is not commercially available. It is important to remember that *Pasteurella* can be sampled from a large percentage of clinically normal rabbits, and culture results must be interpreted carefully and in combination with the clinical signs and the antibiogram from sensitivity testing. Not every strain of *Pasteurella* is pathogenic.

Treatment and Control: Treatment is difficult and will most likely not eradicate the organism. Antibiotics seem to provide only temporary remission, and the next stress (eg, kindling) may cause relapse. Prolonged treatment for 6–8 wk is often needed. Many of the newer antibiotics are already ineffective because of an increase in resistant strains. Before treatment, a culture and sensitivity should be done to determine the best antibiotic to use. Very often, systemic antibiotic therapy can be augmented by local antibiotic therapy. Gentamicin ophthalmologic drugs instilled into the nostrils can be a significant aid to treat upper respiratory tract problems with systemic antibiotics. Fluoroquinolones are usually good drugs if no resistance has built up. Oral medication is usually well tolerated and without adverse effects. In case of unsatisfactory results, doxycycline can be added, because both drugs appear to have a synergistic effect. Sometimes, amikacin or azithromycin must be used based on culture results. Although medication in the drinking water is not recommended because of the tainting of the flavor and potential underdosing, this is sometimes the

only possible route to treat animals on a larger scale. Enrofloxacin (200 mg/L of drinking water for 30 days) can be effective for upper respiratory *P. multocida* infections. Procaine penicillin (60,000 IU/kg/day, SC, for 10–14 days) is also recommended for individual rabbits, but caution is warranted, because deaths from enterotoxemia can follow if the drug is accidentally given orally.

An effective intranasal vaccine is in development but not commercially available; therefore, the best method of control in large rabbitries is strict culling. Two methods to free a production colony of *Pasteurella* have been reported. The first involves culture and culling of positive animals; once the colony is *Pasteurella*-free, it must be maintained in isolation. In the second method, pregnant does past kindling are treated with enrofloxacin. While does remain *Pasteurella*-culture positive, the kits remain *Pasteurella*-culture negative. Carriers can be identified by an indirect fluorescent antibody test on nasal swabs.

Listeriosis

Listeriosis, a sporadic septicemic disease characterized by sudden deaths or abortions, is most common in does in advanced pregnancy. Poor husbandry and stress may be important in initiating the disease. Clinical signs are variable and nonspecific and include anorexia, depression, and weight loss. In contrast to the disease in cattle and sheep, listeriosis seldom affects the CNS in rabbits. The causal agent, *Listeria monocytogenes*, spreads via the blood to the liver, spleen, and gravid uterus. At necropsy, the liver consistently contains multiple, pinpoint, gray-white foci. Because diagnosis is rarely made premortem, treatment is seldom attempted. *L. monocytogenes* can infect many animals, including people. It is difficult to isolate with normal methods, and special techniques are often required.

Intestinal Diseases

Intestinal disease is a major cause of death in young rabbits. Although most diarrheal diseases were once lumped together (as the enteritis complex) or simply called mucoid enteritis, specific diseases are being delineated. Diet, antibiotic treatment, and other factors create disturbances of the GI microflora and may predispose rabbits to dysbiosis and intestinal disease. For discussion of GI stasis due to hairballs, see p 1956.

Enterotoxemia: Enterotoxemia is a severe diarrheal disease, primarily of rabbits 4–8 wk old when naturally infected; it also can affect rabbits at all life stages if an inappropriate antibiotic is given orally. Signs are lethargy, rough coat, greenish brown fecal material covering the perineal area, and death within 48 hr. Often, a rabbit looks healthy in the evening and is dead the next morning. Necropsy reveals the typical lesions of enterotoxemia, ie, a fluid-distended intestine with hemorrhagic petechiae on the serosal surface. The primary causative agent is *Clostridium spiroforme*, which produces an iota toxin. Little is known about transmission of the organism; it is assumed to be a commensal normally present in low numbers. The type of diet seems to be a factor in development of the disease; enterotoxemia is seen less often when high-fiber diets are fed. Because most β -lactams, lincomycin, clindamycin, and erythromycin induce *Clostridium*-related (eg, *Clostridium difficile*) enterotoxemia because of their selective effect on normal, gram-positive bacteria, their oral use is contraindicated in rabbits. Enterotoxemia is a consideration for these antibiotic therapies. These diarrheas are remarkably similar to those that occur naturally (described above as enterotoxemia). Treatment of colony rabbits is seldom attempted because of the rapidity of death. However, when population size permits, cholestyranine has been used with promising results, both as a preventive and a treatment. Reducing stress of the young rabbits (weaning, etc) and ad lib feeding of hay or straw are helpful in prevention. Adding 250 ppm of copper sulfate to the diet of young rabbits also helps prevent enterotoxemia. Individual animal treatment for enterotoxemia should include aggressive fluid therapy and intensive supportive care. Monitoring of hydration status, body temperature, and heart rates is extremely important. There is little evidence that antibiotics are helpful. Prognosis for advanced cases is often poor. Diagnosis depends on history, signs, lesions, and demonstration of *C. spiroforme*. Centrifugation of intestinal contents at 20,000 g for 15 min followed by culture of the supernatant-pellet interface will reveal the organism. For a definitive diagnosis, the presence of iota toxin in the supernatant of centrifuged cecal contents can be demonstrated by in vivo or in vitro assays.

Tyzzer Disease: Tyzzer disease (see p 199), caused by *Clostridium piliforme*, is characterized by profuse watery diarrhea, anorexia, dehydration, lethargy, staining of the hindquarters, and death within 1–3 days in weanling rabbits 6–12 wk old. Acute outbreaks have been associated with >90% mortality. Some rabbits may develop chronic infections that present clinically as a wasting disease. Infection occurs by ingestion and is associated with poor sanitation and stress. The lesions consist of necrotic enteritis along with multifocal necrosis in the liver and heart. Diagnosis is made histologically; special stains (eg, Giemsa or Warthin-Starry silver) show the characteristic intracellular bacterium. Culturing is impractical, because the bacterium does not grow on artificial media. Serologic tests are available from animal diagnostic laboratories. Tyzzer disease affects a wide spectrum of other species but has not been reported in people, although titers have been documented in pregnant women. Although antibiotics used in treatment of other animals have not been effective in rabbits, oxytetracycline has been of some value in limiting an outbreak. No vaccine is available. Aggressive disinfection and decontamination of the housing facility to reduce the presence of hardy spores is indicated with either 1% peracetic acid or 3% hypochlorite.

Colibacillosis: *Escherichia coli* as a cause of rabbit diarrhea has been confused by the circumstance that *E. coli* often proliferate when rabbits develop diarrhea for any reason. Enteropathogenic strains of *E. coli* (serotype O103) commonly express the *eae* gene, which codes for intimin, an outer membrane protein associated with the attaching and effacing lesions. Serotypes O15:H, O109:H2, O103:H2, O128, and O132 are also important. Healthy rabbits do not have *E. coli* of any strain associated with their GI tract.

Two types of colibacillosis are seen in rabbits, depending on age. Rabbits 1–2 wk old develop a severe yellowish diarrhea that results in high mortality. It is common for entire litters to succumb to this disease. In weaned rabbits 4–6 wk old, a diarrheal disease very similar to that described for enterotoxemia is seen. The intestines are fluid filled, with petechial hemorrhages on the serosal surface, similar to the pathology described for both Tyzzer disease and enterotoxemia (see above). Death occurs in 5–14 days, or rabbits are left stunted and unthrifty. Diagnosis is made by isolating *E. coli* on

blood agar and then having the isolate biotyped or serotyped. Electron micrographs of *E. coli* attached to the mucosa are also helpful. In severe cases, treatment is not successful; in mild cases, antibiotics may be effective. Severely affected rabbits should be culled, and facilities thoroughly sanitized. High-fiber diets appear to help prevent the disease in weaned rabbits.

Proliferative Enteropathy: Proliferative enteropathy caused by *Lawsonia intracellularis* has been reported to cause diarrhea in weanling rabbits. Clinical symptoms include diarrhea, depression, and dehydration, which resolve over 1–2 wk. Disease does not cause death unless associated with a dual infection with another enteropathogenic agent. Diagnosis is based on necropsy findings of a thickened and corrugated ileum and histologic identification of the rod-shaped or curved or spiral silver-staining organism in crypt enterocytes. The organism requires cell-containing media (enterocytes) for culture. Immunohistochemistry and PCR may be useful to identify *L. intracellularis*. Isolation of sick animals and symptomatic treatment is advised. Chloramphenicol or florfenicol is the treatment of choice, but some rabbits appear sensitive to these antibiotics when given orally, so careful GI monitoring is required.

Mucoid Enteropathy: Mucoid enteropathy is a distinct diarrheal disease of rabbits, characterized by minimal inflammation, hypersecretion, and accumulation of mucus in the small and large intestines. The cause is unknown, and it may occur concurrent with other enteric diseases. Predisposing factors include dietary changes, dietary fiber <6% or >22%, antibiotic treatments, environmental stress, and challenges with other bacteria. Clinical signs are gelatinous or mucus-covered feces, anorexia, lethargy, subnormal temperature, dehydration, rough coat, and often a bloated abdomen due to excess water in the stomach. A firm, impacted cecum may be palpable. The perineal area is often covered with mucus and feces. Diagnosis is based on clinical signs and necropsy findings of gelatinous mucus in the colon. Rabbits may live for ~1 wk. Treatment is difficult and often unrewarding in severe cases, but intense fluid therapy, antibiotics, and analgesics should be tried. Prevention is the same as for any rabbit enteropathy by focusing on an adequate, fiber-rich diet.

Mastitis

(Blue breasts)

Mastitis is common in commercial rabbitries and is occasionally seen in smaller units but rarely in pet rabbits. Poor sanitation enhances spread throughout the rabbitry. Mastitis affects lactating does and may progress to a septicemia that rapidly kills the doe. Generally, it is caused by staphylococci, but streptococci and other bacteria have been isolated. Initially, the mammary glands become hot, reddened, and swollen. Later, they may become cyanotic, hence the common name, "blue bag." The doe will not eat but may crave water. Fever $\geq 105^{\circ}\text{F}$ (40.5°C) is often noted. If antibiotic treatment is started early (the first day the doe goes off feed), the rabbit may be saved and damage limited to one or two mammary glands. If more than two glands are lost, keeping the doe may not be economical. Because penicillin often causes diarrhea in rabbits, does should be treated only after the pelleted ration has been replaced with hay or some other high-fiber diet (see p 1947). Kits should not be fostered to another doe, because they will spread the infection to the foster mother. Handrearing of infected young may be attempted but is difficult. The incidence of mastitis can be reduced if nest boxes are maintained without rough edges to the entrance, which can traumatize the teats when the doe jumps in and out of the nest box. It is essential for the nest box to be sanitized before and after use. Vaccines have not proved to be beneficial to prevent mastitis.

Treponematosis

(Vent disease, Syphilis, Spirochetosis)

Treponematosis, a specific venereal disease of domestic rabbits, is caused by the spirochete *Treponema paratuisuniculi*. It is seen in both sexes and is transmitted by breeding and from the doe to offspring. Although closely related to the organism that causes human syphilis (*T pallidum*), *T paratuisuniculi* is not transmissible to other domestic animals or people. The incubation period is 3–6 wk. Small vesicles or ulcers are formed, which ultimately become covered with a heavy scab. These lesions usually are confined to the genital region, but the lips and eyelids may be involved. Infected rabbits should not be bred. Diagnosis is based on the lesions and observation of the spirochete's corkscrew motility under darkfield microscopy. Serologic tests used to diagnose *T pallidum*, such as the VDRL slide test and the rapid-plasma regain card test, are

widely available and can be used to diagnose *T paratuisuniculi*. Hutch burn is a differential diagnosis.

Benzathine penicillin G, 42,000 IU/kg, SC, at weekly intervals for 3 wk, is necessary to eradicate treponematosis from a herd. Procaine penicillin (60,000 IU/kg/day, SC, for 7 days) is also recommended for individual rabbits. All rabbits must be treated even if no lesions are present. Lesions usually heal within 10–14 days, and recovered rabbits can be bred without danger of transmitting the infection.

Dermatophytosis

(Ringworm)

Clinical dermatophytosis commonly affects individual rabbits, but epizootics can also occur. Ringworm is generally associated with poor husbandry, poor nutrition, and other environmental stressors. The cause is most commonly *Trichophyton mentagrophytes* and occasionally *Microsporum canis*. Transmission is by direct contact. Fomites, such as hair brushes, that evade proper disinfection can play a significant role in spreading infection. Asymptomatic carriers are very common. The lesions usually appear first on the head and may spread to any area of the skin. Affected areas are circular, raised, reddened, and capped with white, bran-like, flaky material. A negative result with a Wood's lamp illumination does not exclude dermatophytosis, because all agents do not fluoresce. Hair plucked from the edge of the lesion may be cultured on special media, such as dermatophyte test media or Sabouraud's agar. A KOH skin scraping taken from the periphery of the lesion that reveals fungal forms confirms the diagnosis. Because rabbits with active infections are infectious for people and other animals, they should be either isolated and treated or euthanized. Griseofulvin at an individual dosage of 25 mg/kg body wt/day, PO, for 4 wk, or in the feed at 825 mg/kg of feed, is effective but not approved for use in rabbits; it should not be used in rabbits intended for human consumption. Griseofulvin may be teratogenic and should not be used in pregnant does. Topical antifungal creams containing itraconazole (5 mg/kg/day, PO, for 4–6 wk), clotrimazole, or miconazole may be effective extra-label treatments. For rabbitries, treatment with either 1% copper sulfate as a dip or 8 oz of MECA (metabolized chlorous acid/chlorine dioxide compound, 1:1:10 mix of base:activator: water) sprayed on six times in a 26-day period was shown to be effective.

Tularemia

Tularemia is rare in domestic rabbits, but wild rabbits and rodents are highly susceptible and have been involved in most epizootics. Up to 90% of human cases of tularemia are linked to wild lagomorph exposure. The etiologic agent, *Francisella tularensis*, is an aerobic nonmotile, gram-negative, pleomorphic, bipolar coccobacillus prevalent in the south central USA. It is highly infectious and passed through the skin, through the respiratory tract via aerosols, by ingestion, and via bloodsucking arthropods. Tularemia causes an acute fatal septicemia. Diagnosis is based on necropsy findings of septicemic bacterial disease with numerous small, bright-white hepatic foci, congestion, and enlargement of the liver and spleen. Treatment of the animal is not indicated. Tularemia is a reportable disease. *See also* p 692.

VIRAL DISEASES

Viruses are not important causes of clinical disease of rabbits in the USA but include the infectious fibromas, papillomatosis, rabbitpox, myxomatosis, and a herpesvirus infection (virus 3). Rotaviral enteritis also has been diagnosed in the USA and seems to contribute to the overall problem of intestinal disease in rabbits. Viral hemorrhagic disease is found in almost every country that raises rabbits except the USA. In April 2000, the USDA diagnosed rabbit calicivirus in a backyard facility in Iowa. Rapid response and cooperation between federal and state agencies contained this outbreak and eliminated the source of infection. The USA is currently considered free of rabbit hemorrhagic disease.

Myxomatosis

Myxomatosis is a fatal disease of all breeds of domesticated rabbits caused by myxoma virus, a member of the poxvirus group. Myxomatosis is called "big head" and is characterized by mucinous skin lesions or myxedema of the head. Wild rabbits such as the cottontail (*Sylvilagus*) and jackrabbits (*Lepus*) are quite resistant. Myxoma virus-infected *Sylvilagus* develop fibroma-like lesions similar to those caused by rabbit fibroma virus. All other mammals are refractory to the virus. Myxomatosis has a worldwide distribution. In the USA, myxomatosis is restricted largely to the coastal area of California and Oregon, where epidemics occur infrequently but sporadic cases are common. These areas correspond to the geographic distribution

of the California brush rabbit (*S. bachmani*), the reservoir of the infection. Losses in rabbitries may be 25%–90%. Transmission occurs via mosquitoes, fleas, biting flies, and direct contact.

The initial sign is conjunctivitis that rapidly becomes more marked and is accompanied by a milky ocular discharge. The rabbit is listless and anorectic, with a fever that frequently reaches 108°F (42°C). In acute outbreaks, some rabbits may die within 48 hr after signs appear. Those that survive become progressively depressed and develop a rough coat. The eyelids, nose, lips, and ears become edematous, which gives a swollen appearance to the head. In females, the vulva becomes inflamed and edematous; in males, the scrotum swells. A characteristic sign at this stage is drooping of the edematous ears. A purulent nasal discharge invariably appears, breathing becomes labored, and the rabbit goes into a coma just before death, which usually occurs within 1–2 wk after clinical signs appear. Occasionally, a rabbit survives for several weeks; in these cases, fibrotic nodules appear on the nose, ears, and forefeet. Rabbits inoculated experimentally with laboratory strains of the virus invariably develop small nodules at the point of injection after several days; similar nodules develop later on other parts of the body, particularly the ears.

Few characteristic gross lesions are found at necropsy in the acute form of the disease. The spleen is occasionally enlarged and is almost always devoid of lymphocytes when examined histologically. In rabbits that survive longer, subcutaneous edema and nodular skin tumors are seen. The seasonal incidence of the disease, clinical signs (especially the swollen genitalia), and high mortality are all of diagnostic significance. Large, eosinophilic, cytoplasmic inclusion bodies in the conjunctival epithelial cells are also helpful in diagnosis. Outside the USA, vaccination is an option and highly recommended in endemic areas.

An attenuated vaccine prepared from a myxomatosis virus has protected rabbits infected under both field and laboratory conditions. This vaccine is not available in the USA, and because there is no effective treatment, euthanasia and burying or burning of affected rabbits is indicated. Preventive measures include protecting rabbits from exposure to arthropod vectors.

Rabbit (Shope) Fibroma Virus

Shope fibromas are found under natural conditions only in cottontails, although

domestic rabbits can be infected by inoculation of virus-containing material. Fibromas may be found in domestic rabbits in areas where they are endemic in wild rabbits and where husbandry practices allow contact with arthropod vectors.

A fibroma virus, a member of the pox-virus group, causes this tumor, which is found on the legs, feet, and ears. The earliest lesion is a slight thickening of the subcutaneous tissues, followed by development of a clearly demarcated soft swelling. These tumors may persist for several months before regressing, leaving the rabbit essentially normal. Intracytoplasmic inclusion bodies are seen when sections of the tumor are examined histologically. Because Shope fibromas are of little significance in domestic rabbits, no control measures have been developed.

Rabbitpox

Rabbitpox is an acute, generalized disease of laboratory rabbits (*Oryctolagus*) that apparently has not been recognized in wild rabbits (*Sylvilagus*). A few outbreaks have been reported in the USA since 1930. The causative virus is closely related to vaccinia virus, and some outbreaks may have been caused by a virulent strain of vaccinia. Pox lesions may be present on the skin. Most rabbits develop a fever and nasal discharge. The mortality rate varies but is always high. The most characteristic lesions seen at necropsy are a skin rash, subcutaneous edema, and edema of the mouth and other body openings. Because of the edematous condition, "poxless" rabbitpox may be confused with myxomatosis. The virus may be isolated or the infection diagnosed serologically by methods appropriate to vaccinia. (See also POX DISEASES, p 867.) Spread through a rabbitry is rapid, but rabbits inoculated with smallpox vaccine (vaccinia virus) are immune. Rabbitpox virus does not infect people.

Papillomatosis

Two types of infectious papillomas occur infrequently in domestic rabbits. The oral papilloma, caused by the rabbit oral papillomavirus, is the most important clinically. The lesions consist of small, grayish white, pedunculated nodules or warts on the undersurface of the tongue or floor of the mouth. The second type, caused by the cottontail (Shope) papillomavirus, is characterized by horny warts on the neck, shoulders, ears, or abdomen and is primarily a natural disease of cottontail rabbits. Arthropod vectors transmit the

Shope papillomavirus; therefore, arthropod control could be used as means of disease prevention. The oral papillomavirus is distinct from the Shope papillomavirus (which is also distinct from the Shope fibroma virus). Skin tumors caused by the Shope papillomavirus never occur in the mouth. Neither type of papillomatosis is treated, and the condition usually resolves spontaneously over time.

Rotaviral Infection

Rotavirus has been isolated from rabbits with diarrhea in many different countries. In serologic studies of rabbit colonies around the world, almost 100% of the adult rabbits in some rabbitries were positive for rotavirus, demonstrating its widespread nature. Rotavirus is shed in the feces of infected rabbits and, therefore, is probably transmitted by the fecal-oral route. Young rabbits of weaning age are most susceptible. It is probable that rotavirus is only mildly pathogenic, but most rotavirus infections are complicated with pathogenic bacteria such as *Clostridium* spp or *E. coli*. The mixed infection results in a much more deadly syndrome. There is no treatment, but the infection appears to be self-limiting if susceptible rabbits are not continually introduced into the population. Experimentally, the virus is shed for only 1 wk after inoculation. Therefore, cessation of breeding for 4–6 wk seems to allow the disease to run its course, because seropositive does do not infect their offspring.

Rabbit Calicivirus Disease

(Viral hemorrhagic disease)

Rabbit calicivirus disease was first reported in 1984 in the People's Republic of China, from whence it spread through the domestic and wild rabbit populations in continental Europe. The first report of the virus in the Western hemisphere was in Mexico City in 1988. Mexico successfully eradicated the virus by 1992. Outbreaks of rabbit calicivirus disease have since occurred in Australia (1995), New Zealand (1997), and Cuba (1997). In 1995, as a result of a laboratory accident in southern Australia, the virus escaped from quarantine and killed 10 million rabbits in 8 wk. Rabbit calicivirus disease was confirmed in a group of 27 rabbits in Iowa in April 2000 in the USA. The source of infection was not determined. The outbreak was contained, the virus eradicated, and the USA remains disease free. Rabbit calicivirus is a reportable disease in the USA.

Rabbit calicivirus disease is highly infectious in European rabbits (*Oryctolagus*), but cottontail rabbits and jackrabbits are not susceptible. People and other mammals are not affected. The calicivirus is highly contagious and can be transmitted by direct contact with infected rabbits or indirectly by fomites. Infection results in a peracute febrile disease causing hepatic necrosis, enteritis, and lymphoid necrosis, followed by massive coagulopathy and hemorrhages in multiple organs. Rabbits show few clinical signs and die within 6–24 hr of fever onset. Morbidity rate is often 100%, and mortality 60%–90%. A killed vaccine effectively reduced the incidence of rabbit calicivirus in Europe in the late 1980s. Rabbits are vaccinated at 10 wk, and annual boosters are recommended.

PARASITIC DISEASES

Coccidiosis

Coccidiosis is a common and worldwide protozoal disease of rabbits. Rabbits that recover frequently become carriers. There are two anatomic forms: hepatic, caused by *Eimeria stiedae*, and intestinal, caused by *E. magna*, *E. irresidua*, *E. media*, *E. perforans*, *E. flavescens*, *E. intestinalis*, or other *Eimeria* spp. Transmission of both the hepatic and intestinal forms is by ingestion of the sporulated oocysts, usually in contaminated feed or water.

Hepatic Coccidiosis: Severity of disease depends on the number of oocysts ingested. Young rabbits are most susceptible. Affected rabbits may be anorectic and have a rough coat. Hepatic coccidiosis is most often subclinical, but growing rabbits may not make normal gains. Infrequently, death may follow a short course. Rabbits usually succumb within 1 mo after a severe experimental exposure. At necropsy, small, yellowish white nodules are found throughout the hepatic parenchyma. In the early stages, they may be sharply demarcated, whereas in the later stages they coalesce. The early lesions have a milky content; older lesions may have a more cheese-like consistency. Microscopically, the nodules are composed of hypertrophied bile ducts or gallbladder. Diagnosis of this form of coccidiosis is based on the gross and microscopic changes, along with demonstration of the oocysts in the bile ducts. An impression smear of a lesion in the liver examined under light microscopy often reveals oocysts. The

oocysts may also be demonstrated by fecal flotation. It is important not to confuse the oocysts with the normal yeast (*Cyniclomyces guttulatus*), which is commonly seen in fecal examinations.

Treatment is difficult, and control rather than cure is expected. Sulfaquinoxaline administered continuously in the drinking water (0.04% for 30 days) prevents clinical signs of hepatic coccidiosis in rabbits heavily exposed to *E. stiedae*. However, it may not prevent the lesions. Sulfaquinoxaline may also be given in the feed at 0.025% for 20 days, or for 2 days out of every 8 days. A single oral dose of sulfadimethoxine at 50 mg/kg, followed by its inclusion in drinking water at 1 g/4 L for 9 days, was found to significantly reduce fecal oocyst count. Because feed-grade sulfaquinoxaline can be difficult to obtain, liquid sulfaquinoxaline is used more commonly. Withdrawal time is 10 days for rabbits used for food. Other coccidiostats that may prove to be effective include amprolium (9.6% in water or 0.5 mL/500 mL), salinomycin, diclazuril, and toltrazuril. A single oral dose of toltrazuril at 2.5 mg/kg or 5 mg/kg has also significantly reduced oocyst count. Treatment is best administered for a minimum of 5 days and repeated after 5 days. Rabbits treated successfully are immune to subsequent infections.

Treatment will not be successful unless a sanitation program is instituted simultaneously. Elimination of fecal-oral transmission of infective oocysts is achieved by preventing feed hoppers and water crocks from becoming contaminated with feces. Hutches should be kept dry and the accumulated feces removed frequently. Wire cage bottoms should be brushed daily with a wire brush to help break the life cycle of the protozoa. Ammonia (10%) solution is lethal to oocysts and is the best choice to disinfect cages or ancillary equipment exposed to fecal material.

Intestinal Coccidiosis: This form of coccidiosis can occur in rabbits receiving the best of care, as well as in rabbits raised under unsanitary conditions. Typically, infections are mild, and often no clinical signs are seen. In early infections, there are few lesions; later, the intestine may be thickened and pale. Good sanitation programs that can eliminate hepatic coccidiosis do not seem to eliminate intestinal coccidiosis. Intestinal coccidiosis is generally diagnosed by fecal flotation and microscopic identification of the oocysts (species). It is important to distinguish

coccidian oocysts from the nonpathogenic yeast *Cyniclomyces guttulatus* that can also be found in large numbers. Treatment is similar to that for hepatic coccidiosis except that sulfaquinoxaline is given for 7 days and repeated after a 7-day interval.

Larval Worm Infection

Although adult tapeworm infections are rare in domestic rabbits, the discovery of larval tapeworm cysts on the serosal peritoneum is common. Rabbits are intermediate hosts for two species of canine tapeworm, *Taenia serialis* and *T. pisiformis*. Although *T. serialis* is rare in domestic rabbits, it is somewhat more common in wild ones. The larval stage of *T. pisiformis*, a cysticercus, is found attached to the mesenteries. Before forming these fluid-filled cysts, the young larvae migrate through the liver, where they leave white, tortuous subcapsular tracts. Generally, there are no clinical signs, and diagnosis occurs at necropsy. Treatment is usually not attempted, but control is accomplished by restricting access of dogs (the final host of the tapeworm) to the area in which food and nesting material are stored. Mebendazole at 1 g/kg of feed (50 mg/kg) for 14 days is reported to be an effective treatment.

Baylisascaris procyonis has been reported in rabbits. Signs are similar to those induced by *Encephalitozoon cuniculi*. No treatment is available.

Ectoparasites

The ear mite *Psoroptes cuniculi* is a common parasite of rabbits worldwide. Mites irritate the lining of the ear and cause serum and thick brown crusts to accumulate, creating an "ear canker." Infested rabbits scratch at and shake their head and ears. They lose weight, fail to produce, and suffer secondary infections, which may

damage the inner ear, reach the CNS, and result in torticollis (see p 1945). The brown crumbly exudate should never be removed in a conscious rabbit, because this is very painful. The crusts will slowly slough off as the mites die and the tissue underneath heals. The incidence is much lower when rabbits are housed in wire cages instead of solid cages. The mite is readily transmitted by direct contact. Rabbits should be treated systemically with any of the miticides approved for use in dogs and cats. A variety of injectable ivermectin treatment regimens effective against both fur and ear mites have been reported, with the dosage of ivermectin 200–400 mcg/kg, SC, two or three treatments 10–21 days apart. Mites may also be treated with selamectin (20 mg topically every 7 days has been effective).

Fur mite infestations are common, and two genera, *Cheyletiella* and *Listrophorus*, are found worldwide. A number of different species of the genus *Cheyletiella* are found on rabbits. The most common in North America is *C. parasitovorax*. The genus *Listrophorus* has but one species, *L. gibbus*. These mites live on the surface of the skin and do not cause the intense pruritus seen with sarcoptic mange. Fur mite infestations usually are asymptomatic unless the rabbit becomes debilitated. *Cheyletiella* may be noticed as "dandruff." Scraping the dandruff onto a dark paper or background will demonstrate the "walking dandruff," as *Cheyletiella* is called. Transmission is by direct contact. Diagnosis is accomplished by skin scraping and light microscopy. *Cheyletiella* mites may cause a mild dermatitis in people, especially on the arms. Weekly dusting of animals and bedding with permethrin powder can control *Cheyletiella* mites.

Rabbits are rarely infested with either *Sarcoptes scabiei* or *Notoedres cati*. These mites burrow into the skin and lay eggs. The rabbits are extremely pruritic, and the parasites are difficult to eliminate on domestic rabbits. The condition is extremely contagious and can be transmitted to people.

Fleas of the *Ctenocephalides felis*, *C. canis*, and *Pulex irritans* species can affect rabbits and many other animals. Imidacloprid is a flea adulticide; the feline dose should be divided in two or three spots to treat rabbits infested with fleas. Fipronil is contraindicated for use in rabbits because of potential toxicity. Flea collars are also not recommended. It is important to also treat every cat and dog in the house, because the original host is not usually the rabbit.

Gross lesions of *Psoroptes cuniculi* in a rabbit. Courtesy of Dr. Louise Bauck.

Encephalitozoonosis

Encephalitozoon cuniculi is a widespread protozoal (microsporidian) infection of rabbits and occasionally of mice, guinea pigs, rats, and dogs. Usually, no clinical signs are seen, but a few rabbits develop mild, chronic renal disease. Some develop brain lesions that may result in convulsions, tremors, or head tilt. Head tilt is often caused by bacterial infection with *Pasteurella multocida*; this can be difficult to distinguish from head tilt associated with *E. cuniculi* infection, because both infections are common and can occur together. The mode of transmission is not definitively known, but the organism is shed in the urine and potentially can infect the fetus in utero. It seems to be mildly contagious in a rabbitry. At necropsy, the most significant macroscopic lesion is pitting of the kidneys. Microscopic lesions consist of focal granulomas and pseudocysts in the brain and kidneys. Sometimes a severe, focal, interstitial nephritis is seen. In some cases, an ocular manifestation is a key clinical presentation, and lesions range from phacoclastic uveitis to mature cataracts. Diagnosis is made by histologically identifying the lesions (pseudocysts) and observing the organisms when stained with Giemsa, Gram, or Goodpasture carbol fuchsin stains. Several serologic and skin tests are helpful in screening rabbits for antibodies to the organism, but positive serology only indicates past infection and does not confirm a diagnosis. Effective treatment has not been established. Some evidence suggests that oxibendazole or albendazole (20–30 mg/kg/day, PO, for 7–14 days, then 15 mg/kg/day, PO, for 30–60 days) or fenbendazole (20 mg/kg/day, PO, for 28 days) may be effective. Prevention entails good sanitation and possibly serologic screening of breeding stock with elimination of positive reactors. A differential diagnosis in rabbits with outdoor access is an aberrant migration of *Baylisascaris* spp into the nervous system. Encephalitozoonosis is an emerging disease of immunodeficient people.

Pinworms

Passalurus ambiguus, the rabbit pinworm, usually is not clinically significant but often is upsetting to owners. It is common in many rabbitries and is distributed worldwide. Transmission is by ingestion of contaminated food or water. The adult worm lives in the cecum or anterior colon. Diagnosis is made by observing the adults at necropsy or by finding the eggs during

examination of the feces. Single treatments are not very effective, because the life cycle is direct and reinfection is common.

Piperazine citrates in the water (3 g/L) for alternating 2-wk periods or fenbendazole (50 ppm in feed for 5 days) are effective treatments. Rabbit pinworms are not transmissible to people.

NONINFECTIOUS DISEASES

Broken Back

Fracture or dislocation of lumbar vertebrae with compression or severing of the spinal cord is common in both pet and commercial rabbits. The predisposition to a fractured back highlights the importance of adequate and proper restraint skills by the handler. If a rabbit struggles during restraint, it is often best to carefully release the grip and relax the rabbit instead of fighting against the forceful movements of the scared animal. Common signs include posterior paresis or paralysis and urinary and fecal incontinence due to loss of sphincter control. Initial signs of paralysis may resolve within 3–5 days as swelling around the cord diminishes. Supportive therapy includes anti-inflammatory medication to reduce damage from swelling. In acute cases, methylprednisolone sodium succinate might be beneficial. The rabbit should be hospitalized and medical treatment, including pain management, IV fluid therapy, nutritional support, and cage rest should be initiated; with this approach, the severe clinical signs of paraplegia can gradually resolve over 3 mo of conservative therapy. Although these cases may appear "hopeless," rabbits can improve to the point of being able to voluntarily move both hindlimbs and to ambulate by walking and hopping. Intense nursing and management are required.

Cannibalism

Young does may kill and eat their young for several reasons, including nervousness, neglect (failure to nurse), and severe cold. Dogs or predators entering a rabbitry often cause nervous does to kill and eat the young. Cannibalism of the dead young occurs as a natural, nest-cleaning instinct. If all management practices are proper and the doe kills two litters in a row, she should be culled.

Dental Disease

Dental disease may present as excess salivation (slobbers), teeth grinding, or anorexia. Oral examination and palpation

along the ventral surface of the jaw should be a part of routine physical examinations of rabbits. Dental abscesses may develop as a consequence of foreign bodies (eg, plant material embedded between the tooth and gum), pulp exposure after tooth trimming, inappropriate diet, or other diseases. Dental abscesses also may appear as retrobulbar abscesses. Hence, a rabbit that presents for primarily ophthalmologic signs such as epiphora or exophthalmus should receive a full dental examination. Rabbit incisors may wear differently depending on diet, and a pelleted diet may predispose the rabbit to dental disease. Multiple teeth are commonly affected. A thorough oral examination under heavy sedation or full anesthesia and diagnostic radiographs are indicated. Often, a skull CT provides significantly more information because of the complexity of the lesions and the 3D structure of the head (which is difficult to fully image with plain radiographs).

Dental extractions may be accomplished using a fine-tipped dental elevator worked along the root to free the tooth. Incisors are curved and require use of a specialized rabbit incisor luxator or similar curved instrument for removal. Curettage of the alveolus to destroy the apical germinal tissue is required to prevent regrowth of the tooth. Regrowth is unlikely if the pulp remains in the extracted tooth, but follow-up radiographs in 2–3 mo will confirm successful extraction. After lavage, infected sockets can be filled with doxycycline periccutaneous gel or antibiotic-impregnated polymethyl methacrylate (PMMA) beads. PMMA beads are sometimes available from compounding pharmacies or can be self-manufactured. Care has to be taken to choose an antibiotic that is heat stable (eg, gentamicin) in the beads. Other treatment options include leaving the surgical site open and marsupializing the skin to allow healing by secondary intention and to facilitate local antibiotic therapy. Antibiotics can be instilled into the open wound by eye drops or by packing the wound with antibiotic-impregnated gauze. Gingival tissues can be sutured closed if needed or can remain open to avoid development of an anaerobic environment. It is important to avoid any cutting of the teeth with wire cutters or even dental pliers. The pressure of such cutters can be transmitted through the tooth and fracture the whole tooth, which will result in further problems. An elongated tooth should always be drilled down by a dedicated dental burr. Defect treatment with calcium hydroxide paste results in tissue necrosis and is contraindicated.

Extraction of cheek teeth involves delicate elevation and luxation if the dental anatomy is normal. Extraction of multiple cheek teeth carries a very poor prognosis for recovery, although some pet rabbits do well with very few molars if the diet is suitably modified. Continued monitoring of the occlusal surface and followup adjustment is expected. Pain management and extended-duration (4 wk to months) systemic antibiotic therapy based on culture and sensitivity are indicated.

Dental Malocclusion: The incisors, premolars, and molars of rabbits grow throughout life. The normal length is maintained by the wearing action of opposing teeth. Malocclusion (mandibular prognathism, brachygnathism) probably is the most common inherited disease in rabbits and leads to overgrowth of incisors with resultant difficulty in eating and drinking. Dental trimming is often done with combined anesthesia of diazepam (1–5 mg/kg, IM) followed by or in combination with ketamine (10–20 mg/kg, IM), or a combination of ketamine and dexmedetomidine (*see* p 1939).

Occasionally, the cheek teeth overgrow and cause severe tongue or buccal lesions. Because malocclusion is generally considered to be inherited, rabbits with this condition should not be bred. However, young rabbits can damage their incisor teeth by pulling on the cage wire, which results in misalignment and possibly malocclusion as the teeth grow. This condition is difficult to differentiate from genetic malocclusion, and these rabbits should also be culled. Genetic malocclusion generally can be detected in rabbits 3–8 wk

Severely overgrown incisor teeth in a rabbit. If younger animals, the cause (eg, brachygnathia) is often genetic. In older animals, the cheek teeth are often part of the problem. Courtesy of Dr. Joerg Mayer.

old. If incisors are suddenly overgrown in an adult rabbit, it is not enough to trim the incisors down. The problem commonly originates in the back of the mouth, and a full assessment of the cheek teeth is warranted. The dental procedure needs to be done under full anesthesia and with special equipment. Rabbit dentistry is very different from that in dogs and cats because of the differences in anatomy and physiology. Special training and literature about rabbit dentistry is readily available, and dental procedures in rabbits should be performed only by those with specific training.

Gastric Stasis, Hair Chewing, and Hairballs

The GI tract of the rabbit is similar to that of the horse, with an anatomy and physiology that often leads to clinical complications. One of the most frequent presentations is gastric stasis, which has a variety of causes, including stress and/or pain. The initial phase of the problem commonly goes unrecognized by the owner or untrained veterinarian. Because they are a prey species, rabbits do not overtly show signs of discomfort or pain and remain quiet and inactive. Rabbits are commonly presented in an advanced state of stasis that has already led to dehydration, pain, and hepatic lipidosis. Decreased food intake has a large impact on the health of rabbits and affects many other factors of homeostasis. When food intake is decreased, water intake is also commonly decreased. The GI contents lose the typical slurry-like consistency and become pasty. As the rabbit becomes dehydrated, water is absorbed from the GI tract into the vascular space, which masks the typical hematologic signs of dehydration (eg, no increase in PCV). A decrease in energy uptake will produce hepatic lipidosis relatively quickly in rabbits, which in turn decreases food intake. It is of utmost importance to realize the seriousness of the condition and to counteract the downward spiral.

Rabbits groom themselves constantly, so the stomach contents often contain hair. When the GI contents are of normal, slurry-like consistency, the hair normally passes through the GI tract and is excreted with the fecal pellets. A high-fiber diet helps to create a fiber mesh that prevents the GI contents from becoming too dense so that hair can more easily pass through the upper GI tract along with the mesh of fiber. Hair chewing is generally a result of low fiber in the diet and can be corrected by increasing

the fiber or feeding hay along with the pellets. Adding magnesium oxide to the diet at 0.25% also may be helpful. In some cases, hair chewing is a result of boredom because of lack of fiber or chew substrate. Providing environmental enrichment often halts this behavior.

The hair becomes a problem only if excess amounts are consumed or if it accumulates in the stomach and blocks the pylorus. If this happens, the rabbit becomes anorectic, loses weight, and dies within 3–4 wk. Premortem diagnosis of pyloric obstruction can be difficult, because palpable hairballs can be an incidental finding and radiography is often nondiagnostic.

Once GI stasis affects the emptying of the stomach, gas accumulation creates further visceral distention and pain. The resulting decreased food intake and GI hypomotility cause an increased cecal pH and altered cecal microflora, creating cecal dysbiosis. Alterations in water and electrolyte balance result in systemic ketoacidosis and hepatic lipidosis. Gastric ulceration and even gastric rupture may occur.

The goals of treatment are to remove the obstruction, stimulate motility, restore GI microorganism balance, and relieve dehydration and anorexia. Most cases can be managed by aggressive fluid management (maintenance is 100–120 mL/kg/24 hr), with affected rabbits receiving double the rate of maintenance fluids (10 mL/kg/hr) IV. Pain medication (eg, oxymorphone 0.2 mg/kg every 4–6 hr) is essential to relieve the GI discomfort. With aggressive fluid and pain management, the rabbits usually feel better within 24 hr. Because the GI tract is either full or distended with contents, oral force feeding should be discouraged. Energy can be provided by adding dextrose to the IV fluids. Food should be available at all times and in different forms (eg, hay, vegetable matter, supportive care formula). Rabbits often start to eat on their own after they are properly hydrated and received analgesia for visceral pain. If the rabbit does not eat because of advanced stages of hepatic lipidosis, assist syringe feeding should be started. Once a true GI obstruction has been excluded, treatment can then include a motility stimulant such as metoclopramide (0.5 mg/kg, PO or SC, tid-qid) or cisapride (0.5 mg/kg, PO, bid-tid); however, this should not be started before hydration and pain management. Reestablishment of GI microflora may be assisted by probiotic treatment or cecotrophs from healthy rabbits.

Mineral oil and laxatives do not effectively remove the hair mass. Roughage (hay or straw) should be fed during the treatment to help carry the hair fibers through the GI tract and out with the feces. Surgical treatment should be considered only if medical management has not resulted in improvement.

Prevention of GI stasis is the best option and can be accomplished by providing a high-fiber diet, avoiding stress and obesity, providing environmental enrichment, and combing daily to remove loose hair. Rabbits also consume significantly more water when offered by bowl vs sipper bottle. Clinical research does not support routine doses of mineral oil, wetting agents, or proteolytic enzymes as effective preventives.

Heat Exhaustion

Rabbits are sensitive to heat. Hot, humid weather, along with poorly ventilated hutches or transport in poorly ventilated vehicles, may lead to the death of many rabbits, particularly pregnant does. Affected rabbits stretch out and breathe rapidly. Hutches should be constructed so that they can be sprinkled in hot, humid weather. Free access to cool water should be provided. When the environment can be controlled, optimal conditions are a temperature of 50°–70°F (15.5°–21°C) and a relative humidity of 40%–60%, with 10–20 air changes/hr. Wire cages are preferable to solid hutches. Treatment consists of immersing rabbits in cold water during the heat of the day, especially those that will kindle in the next day or two. Breeding bucks may lose a majority of viable sperm and might not breed successfully for several weeks until new sperm production replaces the sperm killed by thermal stress.

Hutch Burn

(Urine burn)

Prolonged irritation of the bladder mucosa with calcium sediment can cause a cystitis that can manifest in incontinence and soiled fur (see p 1959). A wet perianal area often causes additional problems such as fly strike and dermatitis. This condition is often referred to as hutch burn. Hutch burn is often confused with treponematosis and can be truly differentiated only by the absence of spirochetes on darkfield microscopy and by the lack of antibodies to *Treponema paraluiscuniculi*. It is caused by wet and dirty hutch floors and affects the anus and external genitalia. Also, rabbits that lack

adequate sphincter control of the bladder constantly dribble urine and may be affected. The membranes of the anus and genital region become inflamed and chapped. The area soon becomes secondarily infected with opportunistic pathogenic bacteria. Brownish crusts cover the area, and a hemorrhagic, purulent exudate may be present. Keeping hutch floors clean and dry and applying nitrofurazone or an antibiotic ointment to the lesions hastens recovery.

Ketosis

(Pregnancy toxemia)

Ketosis is a rare disorder in rabbits that may result in death of does at or 1–2 days before kindling. The disease is more common in first-litter does. Predisposing factors include obesity and lack of exercise. The probable cause is starvation. Other signs are dullness of eyes, sluggishness, respiratory distress, prostration, and death. The most significant lesions are fatty liver and kidneys. The body mobilizes fat and transports it to the liver to be broken down for energy, thus the fatty liver. Diagnosis depends on a detailed history and physical examination and clinical signs. A key clinical sign is clear urine; the urine of healthy rabbits is usually cloudy. Injection of fluids that contain glucose and assisted syringe feeding may help correct the disease. Breeding young does early, before they become too fat, is also helpful. Hairballs in the stomach are often a factor in ketosis.

Moist Dermatitis

(Wet dewlap)

Female rabbits have a heavy fold of skin on the ventral aspect of the neck. As the rabbit drinks, this skin may become wet and soggy ("slobbers"), which leads to inflammation. Contributing factors include dental malocclusion, open water crocks, and damp bedding. The hair may slip, and the area may become infected or flyblown. The area often turns green if infected with *Pseudomonas* spp. Automatic watering systems with drinking valves generally prevent wet dewlaps. If open water receptacles are used, they should have small openings or be elevated. Once the area is infected, the hair should be clipped and antiseptic dusting powder applied. In severe cases, parenteral antibiotics and analgesics are necessary.

Ophthalmologic Disease

Corneal ulceration is the most common ophthalmic problem of rabbits. Rabbits

appear predisposed to this condition for two main reasons: 1) the globe and surface of the cornea are significantly larger in rabbits than in most other domesticated pets, and 2) rabbits do not blink as frequently as other species, which leaves the cornea less moist. Many potential underlying issues should be excluded, although environmental causes and trauma are the most frequent causes. The cornea should be carefully protected during anesthetic procedures. The lack of tear production associated with keratoconjunctivitis sicca or dry eye may further increase the risk of corneal damage. Exophthalmia as a result of orbital or dental disease or facial paralysis associated with encephalito-cytozoonosis can make blinking difficult and lead to corneal damage. Superficial ulcers can be treated with broad-spectrum ophthalmic antibiotic solutions. Treatment progress should be assessed in 1–2 days. Epithelial “lips” indicate a nonhealing ulcer. Such ulcers should be debrided after application of a topical anesthetic, followed by the same treatment as for a superficial ulcer. If the ulcer does not respond to topical treatment, collagen shields or even contact lenses have been used successfully. In severe cases, surgery and placement of a conjunctival pedicle graft may be required. Differential diagnoses of corneal lesions in rabbits include corneal occlusion (overgrowth of conjunctival tissue) and limbic or corneal dermoid (skin-like tissue in an abnormal location over the cornea). Hair may protrude from a limbic dermoid. These growths do not appear painful.

Pseudopterygium, an aberrant growth of conjunctival membrane tissue, is sometimes seen in rabbits. The cause is not known, and the condition is slowly progressive. The conjunctival membrane extends from the bulbar conjunctiva and slowly grows onto the cornea, giving the eye an opaque appearance. Surgical removal of the overgrown conjunctiva is straightforward but leads to recurrence. Daily administration of topical cyclosporine 0.2% in the affected eye might help slow down recurrence.

Phacoclastic uveitis secondary to *Encephalitozoon cuniculi* (see p 1954) has been recognized to present as iridal swelling and white or pink nodules on the iris. The nodules are bacterial iridal or corneal stromal abscesses and give the typical appearance of cotton candy in the anterior chamber. Spores replicating in the lens may result in cataract formation and even lens rupture, leading to a painful uveitis. Diagnosis is confirmed by presence of the

organisms on histopathology of excised tissue or DNA probe on removed lens material. Treatment involves lens removal by phacoemulsification or enucleation. Spontaneous lens regeneration may occur. Prosthetic lens insertion is not recommended. The prognosis is guarded without surgery; glaucoma develops in most affected rabbits. Topical treatment includes NSAIDs and mydriatic and antibiotic medications. After starting topical medications, progress and intraocular pressure should be checked in 5–7 days. Monitoring should continue every 2–3 wk for the next 2 mo. Systemic therapy for *Encephalitozoon* should be started.

Inherited glaucoma is discussed below (see below).

Ulcerative Pododermatitis

(Sore hocks)

Ulcerative pododermatitis does not involve the hock but the plantar surface of the metatarsals and, less commonly, the volar surface of the metacarpal-phalangeal region. The cause is either pressure on the skin from bearing the body weight on wire-floored cages or trauma to the skin from stamping, with secondary infection of the necrotic skin. Several factors, including accumulation of urine-soaked feces, nervousness, posterior paralysis after a spinal cord injury, and the type of wire used, may influence development. Genetics are also involved. The Rex appears to be predisposed because of the lack of the longer guard hairs that usually act as a cushion over the predisposed area of the hock. Heavy-breed rabbits such as the Flemish Giant and the Checkered Giant are also susceptible. Affected rabbits sit in a peculiar position with their weight on their front feet; if all four feet are affected, they tiptoe when walking. Various debriding agents can be used to clean the lesion, followed by topical antibiotic treatment along with parenteral antibiotics. Radiographs exclude osteomyelitis with severe lesions. The rabbit must be removed from the cage or given a solid floor (board or mat) on which to sit or rest. Treatment is often difficult and time consuming, with application of bandages that need frequent changing. Low-level laser therapy has shown some benefits and is encouraged. Husbandry improvement should focus on providing soft, dust-free bedding. In many cases, weight management is also indicated. Because large feet and thick footpads are hereditary, selection of breeding stock for these traits has reduced the incidence of pododermatitis.

Urolithiasis

Urolithiasis is seen routinely in pet rabbits and occasionally in commercial rabbitries. It is generally suspected when hematuria is seen. (A dipstick can quickly exclude normal pigment causes of red urine.) The rabbit's calcium metabolism is significantly different from that in other vertebrates. Rabbits do not require vitamin D₃ to absorb calcium from the gut into the bloodstream. The vast majority of dietary calcium is readily absorbed into the bloodstream, leading to relatively higher blood calcium levels (up to 16 mg/dL [4 mmol/L] can be normal). Renal elimination of calcium is much higher in rabbits (as high as 60%) than in other vertebrates (2%–5%). This often gives the urine a cloudy appearance, which is normal. Feeding a calcium-rich diet for a prolonged time to a metabolically inactive rabbit (ie, not growing, pregnant, or lactating) can lead to an abnormal hypercalciuria, and calcium can precipitate out as bladder sludge or form uroliths. Small stones are often voided, but surgery is frequently needed to remove larger urinary stones. Uroliths are caused by calcium carbonate and triple phosphate crystals precipitating out of normal urine when the pH increases to 8.5–9.5. Normal rabbit urine has an average pH of 8.2. Several factors have been incriminated in urolithiasis, including nutritional imbalance (especially the calcium:phosphorus ratio), genetic predisposition, infection, inadequate water intake, and metabolic disorders. Short-term treatment involves surgically removing the uroliths, whereas long-term treatment focuses on reducing dietary calcium intake. Because alfalfa is high in calcium and one of the main dietary components of regular rabbit pellets, switching to timothy-based pellets and to grass or timothy hay and rolled oats helps to prevent recurrence.

Heritable Diseases

Hydrocephalus: Hydrocephalus, characterized by an enlarged head, is occasionally seen in neonatal rabbits. The top of the skull appears dome-shaped, and the fontanelle is wider than normal. Most affected rabbits are born dead; occasionally, they live for several weeks but generally exhibit neurologic signs. At necropsy, the brain is enlarged; on cut section, the ventricles are greatly enlarged and filled with CSF. The cause can either be genetic or result from dietary deficiency or excess of vitamin A. In the case of a dietary deficiency or hypervitaminosis, poor reproduction (low fertility, small litter size, abortion, etc)

also is seen in the breeding herd. A correct assessment of vitamin A becomes critical in treatment, and both serum and livers should be analyzed. In deficiency, the serum level of vitamin A is below normal (2.6–4.2 IU/mL). In toxicosis, the serum level can be normal, but the concentration of vitamin A in the liver is very high (>4,000 IU/g). Treatment of the deficiency involves increasing the carotene content of the diet or adding a vitamin A supplement. Treatment of hypervitaminosis A requires reducing vitamin A in the diet. However, reducing the amount of vitamin A stored in the liver is extremely difficult. If the doe's reproduction has been impaired, replacing the doe is probably more cost-effective than trying to decrease the vitamin A level. Because genetic hydrocephalus appears to be inherited recessively, control requires culling both parents.

Buphthalmia (Blue Eye, Moon Eye, Infantile Glaucoma): Buphthalmia is an autosomal trait with incomplete penetrance that results in variable clinical severity. Intraocular pressures begin to rise as early as 3 mo. One or both eyes may be affected. Glaucoma can be treated medically (dorzolamide 2%; 1 drop tid) or by surgical enucleation. Affected rabbits should not be bred.

Splayleg: Splayleg is presumed to be an inherited disorder presenting with abduction of one or more legs as early as 3–4 wk of age. The right rear limb is most commonly affected, although the condition may be unilateral or bilateral. Hip dysplasia can occur during postnatal development among rabbits housed on slick nest boxes or flooring.

Neoplasia

By far, the most common tumor in rabbits is uterine adenocarcinoma. The incidence can be as high as 60% in intact does >3 yr old. The disease may present with multicentric tumors that involve both horns of the uterus. The masses can often be palpated as globular polypoid structures. The tumor often metastasizes to the liver, lungs, and other organs; cystic mastitis may develop concurrently. This disease is the primary reason to recommend spaying of nonbreeding female rabbits at the age of 4–6 mo. Lymphoma and other neoplastic disorders of lymphoid tissue are common tumors that occur in all ages of pet rabbits. Malignant lymphomas (lymphosarcoma) are relatively common and may occur in rabbits <2 yr old.

The manifestation can be extremely varied, ranging from ocular lesions, to skin, to leukemic forms. Lymphosarcoma presents with a tetrad of lesions, including enlarged kidneys, splenomegaly, hepatomegaly, and lymphadenopathy. Treatment of lymphoma can be attempted by chemotherapy, but prognosis is often poor due to the often aggressive form of the disease. Rabbits can be treated with "typical" chemotherapeutic agents, and adverse effects to these drugs appear less common than in other domesticated pets. Thymoma and thymic lymphoma are the most common mediastinal masses in rabbits. Differentiation between the two is difficult and usually requires a fine-needle aspirate or a biopsy of the chest mass. The typical clinical sign for a chest mass in rabbits is intermittent

or permanent exophthalmos. Because of the impaired venous return from the head through the chest, the venous sinuses behind the globe expand and cause the exophthalmos. A chest radiograph to scan for masses should be performed in all rabbits with exophthalmos. The thymoma can sometimes be removed surgically relatively easily, because it does not involve other major structures in the chest cavity. In the case of thymic lymphoma, surgery is often less successful, because the structure is often not possible to be removed in toto. Radiation of the thorax has been described as an effective therapy, and animals have survived for years after the treatment. If no advanced therapy is an option, oral prednisolone has been used in a few cases with moderate success.

RATITES

Twelve species of birds are grouped as ratites, not including the order Tinamiformes. These include the ostrich, emu, rhea, cassowary, and kiwi. The ostrich, emu, and rhea are the ratite species primarily raised in production facilities, whereas all may be found in zoo collections. The ostrich originated in Africa and has been commercially raised since 1850 for feathers, meat, and hide products. The emu is native to Australia and has been raised for meat, oil, and leather in many countries around the world, including the USA. The South American rhea has been produced primarily for feathers.

Ostriches (*Struthio camelus*) are the largest members of the ratite group. Mature ostriches may stand 2.4–2.8 m tall and weigh up to 160 kg, although most are 65–130 kg. Males are black and white, females are brown.

Emus (*Dromaius novaehollandiae*) are second only to ostriches in size, measuring up to 2 m tall and weighing 18–48 kg. Female emus are typically larger than males. Both females and males have brown to gray-brown plumage with black feather shafts and tips. Emus are flightless but travel at a quick trot and can sprint at speeds up to 51 km/hr.

Rheas can reach 1.7 m in height and 40 kg in weight. They are native to South America and are divided into two species: the

Greater Rheas (*Rhea americana*) include five subspecies, and the Lesser Rheas (*Rhea pennata*) include three subspecies. Similar to emus, rheas have brown to gray-brown feathers.

MANAGEMENT

Physical restraint of ratites is different for each. The ostrich's head can be caught by hand or hook, and a hood can be placed over the head. Once hooded, the ostrich's head should be maintained below the level of its body to restrict it from kicking its legs forward. An ostrich kick can seriously injure a handler and, once captured, the bird will quickly try to back up and kick anyone in front of its body. Because an ostrich will back up when its head is held, an assistant should be positioned behind the bird to push as the person holding its head leads the ostrich forward. Emus must be handled from behind, grasping the wings and lifting the bird slightly upward and back. The front of the bird should be avoided to prevent being injured by the claws on the feet, because, as with all ratites, emus will kick forward to try to escape. Rheas are handled much like emus. Some handlers use hoods to facilitate handling emus and rheas, although this technique is not as effective as it is with ostriches.

Juvenile birds from 4 mo to yearlings are best handled by slowly and calmly herding them into an enclosed barn. If they cannot see out of an enclosure and are crowded into a corner, they will often sit if not startled. When calmly herded into a confined area, young birds can easily be sexed, banded, and administered antiparasitic medication, and diagnostic samples (eg, blood) can be collected. If there is no enclosed area, portable panels with plywood or plastic applied can be used to herd the birds into the desired space.

Physical and Laboratory Examination:

Before the bird is restrained, it should be examined from a distance while walking/running in its enclosure for conformation, gait, body condition, respiration rate and character, and behavior-related problems.

The enclosure should be inspected for fresh droppings and urine. Green urates may be an indication of hepatitis, whereas dry, hard fecal material is common in birds that are dehydrated or suffering from GI impaction. The droppings should be examined for tapeworm segments and collected for fecal flotation and direct parasite evaluation.

The eyes and sinuses are examined for any discharge or swelling, and the beak and oral cavity examined for any lesions. The neck is palpated, especially in the area of the thoracic inlet, for any swellings. Overall body condition should be noted and is determined by the epaxial muscle mass, rated on a scale of 1–5, with 1 being emaciated and 5 obese. The feathers and skin are examined for lesions and parasites. The thorax is auscultated, and heart rhythm and rate are determined. The abdomen is palpated from the ventriculus, which lies immediately caudal to the breastplate, to the proventriculus, located between the legs. The caudal abdomen is palpated and balloted for any evidence of coelomic fluid or retained eggs. Finally, a cloacal examination is performed to verify normal anatomy. When indicated, samples for microbial culture can be collected from the trachea, cloaca, and caudal oviduct, and blood can be collected for a CBC and serum chemistry panel. (For hematologic and serum biochemical reference ranges for ostriches, see TABLES 6 and 7, pp 3176 and 3178). Sodium heparin is the preferred anticoagulant for both the CBC and serum chemistry panel. A slide should be prepared immediately for cytologic evaluation.

Recommended sites for venipuncture and catheterization in ostriches and rheas are the cutaneous ulnar veins on the ventral

side of the wings and the medial metatarsal veins. In emus, the jugular vein and medial metatarsal vein are the blood collection sites of choice. Venipuncture of the jugular vein is more difficult in ostriches because of their size and because sudden movement by the bird can result in lacerations and exsanguination. In debilitated ratites, catheterization (adults, 14-gauge, 13-cm catheter) of the jugular vein is easy and provides a readily accessible port to the vascular system. The right jugular vein is more developed than the left.

Anesthesia: Chemical restraint for handling and surgical procedures in ratites use typical veterinary drugs. Anesthesia may be induced in younger birds with isoflurane or sevoflurane using the same procedures as with small animals. Intubation for maintenance is recommended, but the cuff should not be inflated because of the possibility of pressure necrosis (birds have complete tracheal rings that do not expand with the tracheal cuff). Xylazine and ketamine combinations are commonly used for short procedures on induction, followed by intubation and gas anesthesia. Xylazine administered at 2.5 mg/kg, IV, followed, after sedative effect is noticed, by ketamine at 1 mg/kg, is an effective protocol. However, xylazine has significant cardiorespiratory depressant effects and should not be used in severely ill birds. Also, xylazine is not recommended as a premedication for inhalation anesthesia, because it may greatly enhance the cardiodepressant effects of gas anesthetic agents. Recovery may be smoother if diazepam is given at 0.2 mg/kg, IV or IM. Tiletamine/zolazepam is an induction alternative for ratites, dosed at 2–10 mg/kg, IM, or 1–3 mg/kg, IV, with the higher end of the dose range recommended for emus and rheas. Once the bird has been induced, padding should be placed under the body during the entire procedure to minimize neuropathy and myositis. Ostriches may develop peroneal nerve paralysis when placed in lateral recumbency, without padding, for <1 hr. Sternal recumbency does not appear to interfere with respiration while anesthetized, but the large body size of ratites may restrict their ability to breathe. Therefore, manual or mechanical respiration is recommended during general anesthesia to reduce the cardiorespiratory depressant effects of both gas anesthetic agents and physical compression of air sac volume. The neck should be straight and the head elevated slightly above the body during

general anesthesia. Vital signs of ratites should be monitored while under anesthesia along with body temperature (esophageal) to maintain normothermia; intravenous access should be established for drug and fluid administration. During recovery, the bird should be placed in a dark, quiet, preferably padded enclosure in sternal recumbency. Wrapping the body with the legs immobilized under the animal while in sternal recumbency will often allow the bird to recover with minimal struggle.

Surgical Procedures: Surgical procedures in ratites generally are related to the GI tract, orthopedics, and trauma repair. Proventriculotomy for foreign body removal and impactions in ratite species is a common surgical procedure. In young birds, incisions should be made carefully, because the abdominal wall is very thin. To perform a proventriculotomy, the bird is positioned in right lateral recumbency with the left pelvic limb abducted and supported caudally in a stand. In ostriches, the ventriculus is located caudal to the proventriculus in the coelomic cavity; therefore, the surgical incision to access this part of the GI tract should be through a left paramedian approach beginning ~15 cm caudal to the keel. Yolk sac removal due to nonabsorption and/or infection is common. Egg retention in hens is addressed surgically, and often multiple eggs are removed. Orthopedic surgeries are addressed as in other species with pins, plates, and transfixation casting as needed for fracture repair. Laceration repair is performed as in other species. Upper esophageal tears from attempted hooking (capture) will often heal by second intention and, unless severe, do not require surgical repair.

As in all production animals, the cost of surgical correction of many conditions might be greater than the commercial value of the individual animal presented. Producers should be made aware of cost considerations.

Nutrition: To date, there has been little reliable research on ratite nutrition. The formulations of commercial diets available are based on studies in Africa and Australia, as well as extrapolations from available poultry information. Current trends are to feed 14%–20% protein from the time chicks hatch to 3 mo of age, reducing the protein level after 3 mo of age. Ostriches and rheas are hindgut fermenters and have the ability to digest fiber from a young age. For optimal

health and production results, appropriate ratite feed formulated for ostriches, emus, and rheas is recommended. Ostriches, emus, and rheas have significantly different digestive systems and specific nutritional requirements for optimal growth, reproduction, and health. High-quality grass can be used as a grazing supplement for ostriches and rheas. Chicks allowed to hatch in the nest are coprophagous, eating feces from the parents for the first few weeks of life.

Vaccination: When indicated in a specific flock, autogenous bacterins for *Salmonella*, *Escherichia coli*, and clostridial diseases have been used; however, this is not a common practice, and these products may be difficult to obtain. For emus, equine encephalitis vaccination is recommended. Tissue-culture propagated, inactivated bivalent Eastern and Western equine encephalomyelitis (EEE, WEE) vaccine prepared and licensed for use in horses, and that may contain equine tetanus antitoxin, has effectively protected emus against EEE and WEE infection. A vaccination protocol is to administer IM an initial full equine dose at 6 wk of age, followed by booster vaccinations at 10 wk of age and at 5- and 6-mo intervals thereafter and before and after breeding season (April and September). A booster should be administered when EEE or WEE is identified within 10 miles of the production facility or before transfer to an endemic area. The recommended vaccine protocol (emus) for *Clostridium chauvoei* (blackleg) using the ruminant vaccine with or without tetanus antitoxin is to administer an initial vaccine at 2 mo of age, followed by a booster vaccination at 3 mo and then annually after the end of breeding season in April.

REPRODUCTION

Anatomy: All female ratites have a single left ovary and oviduct. The oviduct consists of 1) the infundibulum, where fertilization occurs; 2) the magnum, where the thick albumin is put on; 3) the isthmus, where the inner and outer shell membranes are added; 4) the uterus, where the shell is added; and 5) the vagina. The opening of the vagina into the cloaca is on the left side of the cloaca at the ten o'clock position.

The male ratite has two intra-abdominal testicles located near the kidneys. During the breeding season, the testicles increase 200%–300% in size. The rooster does not pro-

Ostrich semen. Courtesy of Dr. Karen Hicks-Alldredge.

duce sperm when not in season. Roosters in the ratite family all have a phallus that serves to transport semen from the ejaculatory ducts in the cloaca of the male to the cloaca of the female. The phallus is shaped differently in ostriches, emus, and rheas; however, the function is similar. All ratite phalluses have a dorsal groove through which the semen travels.

Breeding: Ostriches and rheas are long day breeders. The season is controlled by the photoperiod (length of daylight) as well as the ambient temperature; in North America, the breeding season is spring and summer. The emu is a short day breeder and lays in the late fall and winter. Once the breeding season has started, the cock and hen become reproductively active. The ostrich cock develops external “breeding” colors and begins to display; the hen begins to flutter. This behavior continues for days to weeks before egg laying begins. In general, females become reproductively active before the males. Therefore, early eggs are often infertile. This is also true for emus and rheas. Ostrich hens lay every other day during the proper season if the eggs are collected daily. In the wild, normal clutch sizes for ratites are 15 to 25 eggs, whereas 30 is average in a captive production facility. The range is from 0 to 167 consecutive eggs.

Hatching: If eggs are gathered and stored for “batch setting,” they should be cooled, if possible, to 60°F (15.6°C). Physiologic zero—or the point at which the embryo stops developing—is 72°F (22.2°C). The egg is laid with the embryo in the 60,000 cell stage, and cooling the egg before incubation ensures that all cells develop in synchrony. In general, hatching eggs should not be washed if they are clean.

If eggs are wet or dirty, they should be washed in a warm 110°F (43.3°C) disinfectant solution (eg, chlorhexidine, sodium hypochlorite, quaternary ammonia) before cooling.

Commercial incubation of eggs is performed in forced air incubators. Ostrich eggs generally are incubated at 97°F (36.1°C) for 40–42 days and moved to the hatcher at 40 days or when the chick “pips” (breaks the egg). Emu eggs are incubated at 97°–98°F (36.1°–36.7°C) for 54–58 days and moved to the hatcher at 50–52 days or at “pipping.” Rhea eggs are incubated at 98°F (36.7°C) for 40 days and moved to the hatcher at 38 days or at “pipping.” While temperature in the hatcher is the same as incubation, the humidity should be higher.

For optimal performance of hatchery operations, excellent basic management and biosecurity practices must be followed, including “all-in/all-out” management. Groups of newly hatched birds should be placed in an area of adequate space (to run and exercise their rapidly growing legs and bodies), heat, and ventilation, with fresh water and feed. Mixing groups of young birds should be avoided (to reduce stress) until chicks are at least 3 mo old.

Reproductive Diseases: Many diseases can result in reproductive failure, either through failure to produce eggs or through production of abnormal or contaminated eggs. Bacterial salpingitis or metritis is common. The etiologic agents vary, as does the severity of the infection. In mild cases, only the uterus or shell gland is affected (metritis), and clinical signs range from abnormal shells to no egg production at all. Infection may result from retrograde bacterial invasion (from breeding or uterine fatigue), extension of an airsacculitis, or perforation of the abdominal cavity by a foreign body. Affected hens generally have a history of erratic egg production, malformed or odoriferous eggs, or a sudden stop in production. On physical examination, temperature and respiration are variable, there may be a discharge below the cloaca, and hens may have a fetid odor. Affected hens have WBC counts ranging from 8,000 to >100,000/μL. Ultrasonography and radiology are useful to assess the amount and consistency of exudates in the oviduct. If a bacterial salpingitis is diagnosed through a caudal oviductal (vaginal) culture, subsequent treatment is based on organism isolation and sensitivity.

CHICK MANAGEMENT

The basic principles of animal husbandry and aviary management, including an "all-in/all-out" system of management, biosecurity of the flock and facility, and a stress-free environment, are inherent to successful ratite production. Generally, the level of identifiable infectious or contagious disease among chicks is low, and most clinical signs are produced by stress factors such as poor ventilation, over crowding, excessively high ambient temperatures, overuse of antibiotics, improper incubation or hatching procedures, improper nutrition, and other management-related disease. When considering the sick chick, it is important to evaluate the population at risk and take appropriate steps to prevent spread of disease. This often means elimination of clinically ill chicks by appropriate quarantine or euthanasia. If an infectious disease is involved, treating the individual chick in its environment places the other birds within the group at risk.

Ratite chicks do well on a wide range of substrates (including sand, grass, alfalfa, or native pasture) if they are introduced to the substrate at hatch and have adequate space, ventilation, and sufficient feeders and waterers. Ostrich chicks up to 3 mo old grow best and have the fewest management-related diseases (eg, proventricular impaction, leg problems, and feather picking) if 100–133 sq ft of pen space per bird is available. Ostrich chicks do not do well when confined to concrete floored housing. Adequate exercise is an important consideration for normal leg growth and digestive function.

Musculoskeletal abnormalities of the coxofemoral joint, stifle joint, femur, and tibiotarsus are common physical problems of ratite chicks. Spraddle leg is an abnormality of the coxofemoral joints that prevents normal adduction of the limbs. Lack of exercise and excess weight due to edema at hatch or overfeeding are the main underlying causes of spraddle leg and progressive lateral rotation of the tibiotarsus and the tarsometatarsus. Limb musculoskeletal abnormalities are progressive and have an extremely poor prognosis; management practices must be in place to prevent their occurrence, including maintenance of an appropriate growth rate and provision of acceptable substrate and opportunity to exercise. Rolled toes are diagnosed more often in young ostriches and can be treated by splinting the affected toe(s) in a normal position.

INFECTIOUS DISEASES

Infectious diseases are primarily a problem in chicks <6 mo old. Infective agents associated with disease in chicks include bacterial, fungal, viral, and parasitic agents. However, the isolation of disease agents in a sick chick must be considered in conjunction with a review of nutritional, environmental, management, and genetic factors.

Diarrhea is the most common clinical sign in ratite chicks. Many chicks will have diarrhea when the yolk sac is absorbed and the chick starts eating well, at 8–12 days of age. If the chicks are alert and active, no treatment is needed. Chicks will also develop diarrhea after a sudden change in diet for which treatment with probiotics is indicated. Bacterial causes of diarrhea include *Escherichia coli*, *Salmonella* spp, *Pseudomonas* spp, *Campylobacter jejuni*, *Klebsiella* spp, *Clostridium perfringens*, *Clostridium colinum*, *Mycobacterium* spp (adults), *Streptococcus* spp, and *Staphylococcus* spp. The appropriate antibiotic should be determined by culture and subsequent microorganism isolation and sensitivity, and the source of bacteria identified (eg, barn, hatcher, inadequate hygiene, airborne vectors). Viral agents (suspected pathogens) that may cause diarrhea include paramyxovirus, reovirus, herpesvirus, bima-like virus, enterovirus, adenovirus, and coronavirus. Treatment for viral diarrhea is supportive only, and any potential source of the virus (eg, wild birds, infected hens, people) should be eliminated. GI obstruction is another cause of diarrhea; treatment is surgical, and any changes in environment or feed should be made slowly to prevent recurrence. In cases of fungal candidiasis, antibiotic treatment should be discontinued and a dry environment maintained. Although the pathogenicity of protozoa relating to diarrhea diagnosed in ostrich chicks is unknown, metronidazole is considered the treatment of choice. Enteritis may also be caused by management errors, including overmedication and excess electrolyte supplementation in drinking water during hot weather.

The incidence of **yolk sac infection and retention** generally is low in naturally hatched chicks. However, this condition often occurs when owners assist to hatch a chick or tie off the omphalomesenteric vessels and bandage the abdomen. The yolk sac may also be contaminated through the ostium at the ileal opening when absorption of the yolk material by the vitelline membrane (yolk sac lining) is delayed. Bacteria commonly isolated from the yolk

sac are gram-negative; however, yolk sac retention secondary to noninfectious causes also occurs.

Poxvirus infections are more frequent in ostrich chicks and produce typical, crusty granulomatous lesions on the face, ears, and neck. Poxvirus is transmitted by insect vectors, primarily mosquitoes. The disease is self-limiting, and mortality is low. Vaccination of a flock during an outbreak with fowlpox vaccine may stop the spread of disease. The vaccine is a cutaneous fowlpox vaccine administered by dipping a large needle with reservoirs near the tip that allow inoculation when a puncture is made through the propatagium. Staphylococcal dermatitis occurs as a secondary problem in debilitated chicks, especially when external parasites disrupt the epithelial integrity.

Eastern equine encephalomyelitis can cause death in ostrich chicks as a fading chick syndrome and as a violent and fatal gastroenteritis in emus of all ages. Vaccination of emus for this disease is necessary in areas where the virus exists.

Avian influenza has been diagnosed in rheas and other ratite species. Routine testing for avian influenza is required for most intrastate shipments of ratites.

Parasitic Diseases

Protozoa: A number of intestinal protozoa, including *Hexamita*, *Giardia*, *Trichomonas* spp, *Cryptosporidium*, and *Toxoplasma* spp, have been isolated from ratite chicks. The pathogenicity of these parasites in all ratite species is unknown, and immunosuppression may be required for disease to develop. Metronidazole at 10 mg/kg, PO, bid, is recommended for protozoal parasite infections diagnosed in ratite species. Coccidiosis is common, and although not believed to be pathogenic, it can be treated with sulfa drugs. If coccidiosis is causing clinical signs (eg, diarrhea), the underlying immunosuppressive disease condition(s) must be diagnosed to effectively treat the protozoal disease.

Cestodes: The tapeworm *Houttuynia struthionis* is common in Africa but rarely diagnosed in the USA. The intermediate host is not known. Treatment is fenbendazole, PO, at 15 mg/kg/day for 5 days, used at regular intervals.

Nematodes: The wireworm *Libiostrongylus douglassii* is the most economically significant GI parasite of ostriches. Mature worms and late larval stages live in the crypts of the glandular portion of the stomach. Diagnosis is based on finding

trichostrongyloid-type eggs in the feces. The recommended treatment for the ostrich wireworm is ivermectin at 0.2 mg/kg or fenbendazole at 15 mg/kg. Another nematode with clinical significance for ratite species is *Baylisascaris* spp, which is transmitted from skunks or raccoons through feed. This neurotropic parasite causes CNS lesions and signs. Restricting exposure to raccoon and skunk feces is the best prevention. *Chandlerella quiscali* is a nematode identified in emus that results in cerebral larval migrans. The common grackle is the definitive host for *C quiscali*, and emus are exposed to the parasite through the bite of *Culicoides crepuscularis*. Birds infected with *C quiscali* develop profound torticollis and incoordination that leads to emaciation, scoliosis, and death. Ivermectin is the treatment of choice for *C quiscali* infections in emus.

Arthropods: Three types of arthropods can affect ratites: lice, ticks, and quill mites. Lice can be a problem, especially in ostriches. Biting lice (*Struthioliperurus struthionis*) cause skin and feather damage. Treatment with permethrin spray (poultry concentration) is effective, as is injectable ivermectin at 1 mL/110 lb, IM. Several species of ticks have been identified on ratite species; their main significance is as vectors of disease. Feather mites live in the vein on the underside of the feather and feed on blood. Ratite feather mites can be visualized as small, reddish, dust-like particles in the feather vein. Treatment for ticks and mites is ivermectin at 0.2 mg/kg at 30-day intervals.

DIGESTIVE SYSTEM DISORDERS

Impaction of the proventriculus and ingestion of foreign bodies are management-related problems. Chicks are at high risk of impaction for the first 2 wk after movement to a new environment, with or without a change in substrate or diet. Proventricular impactions are also diagnosed as a sequela of diseases involving ileus of the GI tract. Impactions with sand and concentrated feed can be managed medically with psyllium laxatives and supportive therapy. Impactions with forages or ingestions of foreign material (eg, hardware, rocks, jewelry, etc) require proventriculotomy surgery for removal and subsequent resolution of the problem.

Cloacal prolapses are common in young chicks. Frequently, the chick has diarrhea or an impaction within the GI tract that causes straining and subsequent prolapse of the

cloaca. The prolapse is easily reduced and a purse-string suture is placed for 24–48 hr, making sure there is adequate room for the bird to defecate/urinate while the suture is in place.

Intestinal torsion or volvulus, primarily involving the colon, occurs in ostriches of all ages. It can present as a flock problem when the diet is suddenly changed, especially if the new diet has a high fiber content. Clinical signs include scant to no feces, slight diarrhea, abdominal enlargement, and vomiting. Abdominocentesis and radiographic imaging of the coelom are diagnostic. When an early diagnosis is achieved, surgical intervention is corrective but often not economically feasible.

MUSCULOSKELETAL DISORDERS

Exertional myopathy results from capture, transport, attack by predators, or fighting; it can occur in birds of all ages. Borderline nutritional deficiencies may exacerbate stress-related myopathy. Clinically, birds are often unable to stand but are otherwise bright, alert, and responsive. Fluid therapy to correct metabolic acidosis and to effect diuresis, combined with anti-inflammatory and antibiotic therapy to prevent clostridial disease, are indicated. Administration of vitamin E at 5 mg/kg, with or without selenium at 0.06 mg/kg, is recommended. If nutritional deficiencies are expected, correcting the diet by adding oral vitamin E to the diet or drinking water is indicated.

Various treatments, including slinging the bird to exercise the legs and swimming, have been tried for myositis secondary to overexertion or trauma. However, handling the bird in this manner is very stressful; it is preferable to allow the bird to sit until it can stand on its own, which may take up to 90 days. The prognosis remains guarded, even if the bird is alert and has a good appetite.

TOXICITIES

Many different disease toxicoses have been documented in ratites. Exogenously administered selenium has resulted in acute selenium toxicity in ostriches, leading to pulmonary edema and congestion. The feed additive monensin has been associated with myositis and malabsorption syndrome in ostriches and emus. Gossypol in commercial ostrich feed contaminated with cattle feed resulted in a malabsorption syndrome. Cantharidin from blister beetles has resulted in hemorrhagic gastritis and enteritis in emus. Young chicks are sensitive to insect stings, and death is common when chicks

eat and are stung in the oral cavity by red ants or wasps. Nicotine from cigarette butts has resulted in CNS signs. Toxic plants that contain solanine (eg, silverleaf, nightshade) result in vomiting and diarrhea, whereas plants that contain high levels of nitrates result in dyspnea and CNS signs. Anomonia toxicity is seen in birds housed in poorly ventilated barns and results in clinical signs of corneal edema, epiphora, and dyspnea.

TRAUMA

Wing luxations and fractures can result from hauling or breeding accidents. Most cases of wing luxation are actually a radial paralysis rather than a true luxation of the joint. However, a true humeral luxation from the shoulder can occur. Treatment for both injuries is the same and involves taping the wings up over the back. Maintaining the wings in this position for 1–2 wk generally resolves the problem. Fractured wings, depending on the location of the fracture, can be repaired with a half-Kirschner apparatus or splints (or both). Occasionally, intramedullary pinning is required. With minor wing fractures in emus, taping may be sufficient to treat the injury.

Lacerations of the neck skin and musculature may involve the trachea and esophagus of ratites that are injured due to contact with fences. Primary closure of the trachea and esophagus in acute injuries is recommended. If the esophageal injury is old, the esophagus will often heal through secondary intention. With severe neck injuries, an esophagotomy tube, placed in the distal third of the cervical portion of the esophagus, may be required for alimentation.

Lower leg injuries commonly occur in ratites that contact cable fencing at a high rate of speed. Standard principles of wound management (see p 1701) should be applied, including debriding and bandaging the wound. If bone is exposed in a lower leg injury, radiographic imaging of the affected area, at weekly intervals, is recommended, because stress fractures and sequestra can occur. Often, the soft-tissue injury shows normal healing 3 wk after trauma, but the bird may still have a fracture of the tarsometatarsus. Luxation of the phalanges is common, especially if the bird's enclosure has icy or muddy areas. If the luxation is not treated promptly, casting the foot in a normal flexed position for 5–6 wk generally allows enough soft-tissue fibrosis and repair to maintain the luxated joint in place. When casting alone is unsuccessful, arthrodesis of the joint according to standard equine procedures can be performed.

REPTILES

The class Reptilia includes >8,000 species, but only a few dozen are likely to be encountered in general practice. All the Crocodylia, front-fanged poisonous snakes (but not all backed-fanged poisonous species) and both species of poisonous lizard (*Hemiderma* spp) are considered to be dangerous animals and are usually covered by federal and/or state legislation. These species are not generally kept as pets and will therefore not be discussed here. The class Reptilia includes four orders: Crocodylia (crocodiles, alligators, gharials), Testudines (turtles and tortoises), Squamata (lizards and snakes), and Rhynchocephalia (tuataras).

Reptiles are vertebrates with organ systems similar to those of mammals. However, they are ectothermic and rely on environmental temperature and behavior to control their core body temperature. They possess both renal and hepatic portal circulations, and predominantly excrete ammonia, urea, or uric acid depending on their evolutionary adaptations. Their RBCs are nucleated, and their metabolic rates are lower than those of mammals. All reptiles exhibit ecdysis—a normal process by which the outer skin is periodically shed. Diurnal species require broad-spectrum light for vitamin D₃ synthesis and calcium homeostasis. Fertilization is internal, and females may produce eggs (oviparous) or live young (ovoviviparous).

Reptiles are not considered highly social creatures, and multiple-male groups can lead to intraspecies aggression. Single-male, multiple-female groupings can work well for certain species, but the solitary reptile is often the healthiest pet. The life span of many reptiles can exceed 10–20 yr, requiring a longterm commitment from owners.

Anatomy: Reptiles possess a common cloaca, which receives the lower GI, reproductive, and urinary tracts. In addition, lungs are simpler and composed of vascular pockets, more like a cavitated sponge than alveoli.

Lizards and chelonians are quadrupeds and have a familiar pentadactyl limb arrangement. Reptiles lack a true diaphragm; in many species, all organs are contained within a single coelomic cavity. Some lizards (eg, tegus and monitors) have thin postpulmonary and/or post-hepatic

membranes that divide the coelom into compartments. Snakes' organs are distributed in a longitudinal arrangement. Boas and pythons are primitive snakes and have both left and right lungs; however, other snakes lack a developed left lung. Squamates have incomplete tracheal rings, and males have paired copulatory organs (hemipenes).

The chelonians are characterized by their shell, which comprises a dorsal carapace and ventral plastron. The internal organs are separated by two thin membranes. The heart is located within a cardiac membrane, while the lungs are dorsad and separated from the remaining viscera by a postpulmonary membrane (or septum horizontale). Chelonians have complete tracheal rings, and males have a single copulatory phallus.

Physiology: Reptiles rely on environmental temperature and behavior to maintain their body temperature within their preferred optimal temperature zone (POTZ). Within this species-specific POTZ, a reptile is able to achieve the preferred body temperature for specific metabolic activities, which may vary diurnally and seasonally and by age and gender. The metabolic rate of reptiles is lower than that of mammals and birds. Consequently the K constant to determine energy expenditure, nutritional requirements, and allometric drug doses is given by the equation $BMR = K(\text{body wt} [\text{in kg}]^{0.75})$, in which BMR = basal metabolic rate in Kcal/day and $K = 10$ (the energy constant for reptiles).

All snakes, lizards, and chelonians have a three-chambered heart (two atria and one ventricle), whereas crocodilians have a four-chambered heart. All reptiles have both pulmonary and systemic circulations (similar to mammals). In noncrocodilian reptiles, functional separation of venous and arterial blood is largely maintained via a muscular ridge within the ventricle. Peripheral blood cell types include erythrocytes, heterophils, eosinophils, basophils, lymphocytes, monocytes (including azurophils), and thrombocytes. Renal and hepatic portal circulations exist, and intra- and extracardiac vascular shunts may be present, especially in aquatic species.

Reptilian skin is usually heavily keratinized and protected by scales. The chelonian

shell is composed of both dermal bone plates and keratinized epithelial scutes. Reptiles do not have extensive skin glands, and their skin is essentially dry. However, many male lizards have a series of pre-anal or femoral pores located cranial to the vent or along the craniomedial aspect of the hindlimbs. In some species, both sexes have these glands, but they are more pronounced in the male. Chromatophores are common and enable many species, most notably the Chamaeleonidae, to change color. Bony skin structures, osteoderms, are found in the crocodilians and some lizards. These structures may interfere with radiographic interpretations and surgery. Certain species of snakes have heat-sensitive receptors located around the maxilla that are used to locate prey. Skin characteristics (eg, crests, spines, dewlaps) are often used for species or gender identification in those species that exhibit dimorphic variation.

All reptiles shed their skin. The frequency of ecdysis depends on species, age, nutritional status, environmental temperature and humidity, reproductive status, parasite load, hormonal balance, bacterial/fungal skin disease, and skin damage. The entire process can take 7–14 days.

Reproduction: Most species require some form of conditioning before breeding (eg, hibernation, seasonal nocturnal cooling). Many species are sexually dimorphic. Male lizards are generally larger, have pre-anal or pre-femoral pores, have hemipenial bulges at the tail base, and often are more brightly colored. The gender of snakes is determined by probing for the hemipenes with a blunt, lubricated probe. In males, the probe will enter to a depth of 6–14 subcaudal scales, whereas in

Green iguanas, male (left) displaying a larger dewlap and jowls than the female (right).

Courtesy of Dr. Stephen Divers.

females it enters a cloacal gland only to a depth of 3–6 scales. Sexual dimorphism in chelonians is usually obvious in adults; males often have a concave plastron and a longer tail. Many reptiles, especially lizards and chelonians, are territorial and will fight conspecific males, causing severe injuries. In addition, overzealous and unrelenting males may ardently pursue females, causing repeated harassment. Fertilization is internal, and reproduction is either oviparous (egg production) or ovoviviparous (live bearing). Gender determination may be genetic (most snakes, many lizards) or related to incubation temperature (most chelonians, some lizards).

MANAGEMENT

Veterinarians must not only be familiar with common reptile species and their management but also be able to extract clinically relevant husbandry information from the owner in a timely manner. The

TABLE 22 RECOMMENDED MINIMUM SPACE REQUIREMENTS FOR REPTILES

Reptile Group	Minimum Space Requirement
Tortoises and terrapins	0.4 m ² /0.1 m carapace length
Purely aquatic chelonians	0.25 m ³ /0.1 m carapace length
Terrestrial lizards	0.2 m ² /0.1 m total length
Arboreal lizards	0.4 m ³ /0.1 m total length
Boas and pythons	0.6 m ² /meter of snake
Kingsnakes and rat snakes	0.6 m ² /meter of snake
Whipsnakes and racers	1.2 m ² /meter of snake
Arboreal snakes	0.8 m ³ /meter of snake

use of a history form can greatly facilitate this process and ensure that nothing is overlooked.

Species: Different species from different locations must not be mixed. Ideally, only a single species should be kept in any enclosure, and care must be exercised to avoid competition for resources such as food, basking areas, and retreats. In general, the solitary reptile pet is often the healthiest. Most nonbreeding pet snakes and aquatic turtles are best maintained as a single pet, because trauma while feeding is common in groups. Some lizards, notably the chameleons (*Chameleo* spp.), are so territorial that isolation is often essential for longterm survival in captivity.

Enclosure: The size of the enclosure is important, and although many breeders and retailers may be able to intensively manage stock, pet owners should be advised on minimum enclosure sizes (see TABLE 22), the importance of providing the largest enclosure possible, and correct cage furniture. The type of enclosure (arboreal, terrestrial, subterranean, or aquatic) should be appropriate for the species (see TABLE 23).

Glass aquaria are commonly used, but the greater visualization perceived as an advantage to the owner may be stressful to the reptile. Glass is also a poor insulator, and greater heat loss may lead to dramatic temperature fluctuations. Even if the entire top of the enclosure is covered by mesh, ventilation may be severely hampered. Plastic or fiberglass enclosures are more expensive but more versatile.

Newspaper, artificial turf, and organic particulates (eg, bark chips) are suitable materials to line cages and vivaria, but they must be completely replaced regularly. Soil, sand, and natural leaf litter can also be used, but oven baking is recommended to sterilize before use. Gravel and pebbles are not recommended for terrestrial species, because they are difficult to clean and often ingested by reptiles. Other essential items include a water bowl (large enough for the reptile to bathe) and various retreats (eg, cardboard boxes, cork bark, shredded paper). Clean, secure branches are required for arboreal species. Soap and water is generally all that is required to clean cages, but bleach can be used as long as rinsing is thorough. Some cleansers (eg, phenolic disinfectants) are toxic. In certain areas, the climate may permit keeping reptiles in outdoor enclosures, which is highly

desirable, although theft, predators, and wildlife carriers of disease should be considered.

Heating: A variety of heaters can be used, including incandescent bulbs, infrared ceramics, heating pads or mats, warming cables, tubular heaters, radiators, convector heaters, and natural sunlight radiation. Heaters of an appropriate size should be thermostat controlled, screened from the animals, and positioned toward one end of the enclosure to provide a thermal gradient. "Hot rocks" frequently result in burns in larger animals and should be avoided. Light bulbs cannot be used to provide nocturnal heat.

Environmental Lighting: All reptiles benefit from broad-spectrum lighting. However, UVB light (290–300 nm) is especially important for most diurnal lizards and chelonians for vitamin D₃ synthesis and calcium regulation. The best source of lighting is unfiltered sunlight. However, many artificial fluorescent strip-lights, compact fluorescent, and mercury halide bulbs are available. Almost every light marketed for reptiles has the term "broad" or "full" or "natural" on its packaging, creating confusion for veterinarians and owners alike. Appropriate lights must be labeled as providing UVB or, better still, be examined and tested using a spectrometer. Even suitable fluorescent lights must be placed relatively close to the reptile and replaced every 9–12 mo. Most transparent plastic and glass barriers filter out UVB wavelengths. A photoperiod of 12 hr/day is suitable for general maintenance.

Humidity: Humidity that is too high or low can create serious problems. Humidity is seldom directly controlled, although the advent of dedicated humidifiers and sprinkler systems makes this practical. Decreasing ventilation to maintain temperature and humidity is ill advised and frequently causes skin and respiratory disease.

Quarantine and Record Keeping: Although the incubation period of many reptile disorders is unknown, quarantine periods of 3–6 mo are recommended. Owners should also be encouraged to keep detailed records of any changes in husbandry or nutrition, breeding activity, in-contact animals, disease outbreaks, health issues, and previous treatments.

Nutrition: Species identification is essential to critically appraise captive

TABLE 23

IMPORTANT HUSBANDRY REQUIREMENTS FOR SELECTED REPTILES

Species	Habitat/Vivarium Type
Corn/rat snake	Terrestrial, scrubland
Boa constrictor	Terrestrial, rain forest (semi-arboreal/aquatic)
Ball python	Terrestrial, scrubland
Leopard gecko	Terrestrial, arid scrub
Green iguana	Arboreal, rain forest
Bearded dragon	Terrestrial, desert
Water dragon	Arboreal, rain forest
Savannah monitor	Terrestrial, arid scrub
Greek tortoise	Terrestrial, temperate to subtropical
Box tortoise	Terrestrial, temperate to subtropical
Leopard tortoise	Terrestrial, tropical
Red-footed tortoise	Terrestrial, tropical
Red-eared slider	Temperate to subtropical gravel bottom or bare, water depth 30 cm min, land area $\frac{1}{4}$ of tank

^a P $\odot$ TZ = preferred optimal temperature zone. Temperature requirements shown are air temperature gradients. In general, basking temperatures should be 5°C warmer, whereas at night these temperatures should fall by 5°C.

^b BS = broad-spectrum lighting (UVB 290–300 nm) essential, NS = no special lighting requirements

^c I or i = insectivorous, H or h = herbivorous, C or c = carnivorous; upper case indicates major food preference, lower case minor food preference.

^d Humidity requirements are significantly greater during ecdysis.

diets (see TABLES 24 and 25). Rodent-eating carnivores such as most snakes present few problems as long as the rodent is recognizable to the snake as food. Obese rodents that have been frozen for prolonged periods may contain fewer nutrients. Feeding live rodents is not advised (and is illegal in some countries) because of the dangers of prey-induced trauma to sedate reptiles and the welfare implications for the live prey. Insectivorous reptiles can be well catered for with a variety of commercially available crickets, waxworms, tebos, locusts, mealworms, cockroaches, and flies. Feeding insects a nutritional diet high in calcium and dusting the insects with a high-calcium reptile supplement immediately before feeding is required to prevent deficiencies.

Providing herbivorous reptiles with a varied and nutritious diet can be difficult. Foods with a high calcium:phosphorus ratio should be selected with due regard given to the species-specific requirements for vegetables and fruits. Human nutrient databases can be useful (see

<http://ndb.nal.usda.gov> for the USDA National Nutrient Database for Standard Reference). Calcium or vitamin D₃ deficiency (generally due to poor quality lighting and low-calcium diets) leads to secondary nutritional hyperparathyroidism in insectivores and herbivores. A variety of commercially available foods are available in moist, canned, and dry pellet forms. These may help provide a balanced diet, but they have not been critically evaluated.

Although some species will drink from a water bowl, others will only imbibe water droplets on plants and décor. Poor water quality has been implicated as a cause of stomatitis in snakes. Lack of appropriate water delivery has been implicated as a predisposing cause of renal disease in green iguanas. The advent of timer-controlled sprinkler systems makes regular water provision possible for many of these more fastidious drinkers.

Physical Examination

The successful diagnosis and treatment of reptile diseases requires proper restraint and performance of a variety of clinical techniques. Although the principles are similar to those used for domestic animals, there are a number of reptile-specific peculiarities. It may be possible to observe calm specimens unrestrained, permitting an assessment of demeanor, locomotion, and obvious neurologic disorders such as lameness, paralysis, paresis, and head tilt. Observation of reptiles within their usual environment is particularly valuable and should be done whenever possible. Nervous or aggressive species are best restrained at all times using towels, snake hooks, clear plastic containers, and restraint tubes. Gauntlets severely reduce the clinician's tactile sensation but may be required when dealing with large lizards or small to medium-sized aggressive crocodilians. Careful consideration should be given to the safety of veterinary staff, zoo keepers, and private owners when dealing with large or otherwise potentially dangerous reptiles. In many cases, chemical agents can expedite procedures and considerably reduce risks to both the reptile and human handlers. Given the improvements in reptile anesthesia, even manageable reptiles may be preferentially sedated or anesthetized for procedures that would otherwise take

longer to accomplish and cause unnecessary stress or discomfort to the animal. It is possible that sedatives and anesthetics may affect clinical pathologic results, especially hematology.

The decision to examine a potentially dangerous reptile should be made with due regard to legislative and safety requirements. No species of *Chelonia* is legally considered dangerous, but several species (eg, snapping turtles, *Chelydra* spp) have a ferocious bite that makes them a formidable opponent. In addition, the Convention on the International Trade of Endangered Species of Fauna and Flora (CITES) may also have implications for Appendix 1 and 2 reptiles kept as pets. Even some common pet species (eg, corn snake) may be illegal in some endemic areas, whereas native venomous snakes may be freely collected because they are considered "vermin."

The risks of reptile-borne zoonoses are probably no greater than for other animal groups, and basic personal hygiene after handling reptile patients will minimize these risks. The major zoonoses include *Salmonella*, *Pseudomonas*, *Mycobacterium*, *Cryptosporidium*, and *Rickettsia* spp and pentastomids (arachnid lung parasites). Major public concern centers on the commensal reptile *Salmonella* spp, and clinicians are advised to obtain a copy of the statement policy and client brochure on this subject produced by the Association

of Reptilian and Amphibian Veterinarians (www.arav.org/special-topics/).

Every reptile must be accurately weighed; an accurate weight is important to avoid deaths associated with drug overdose, particularly anesthetics and aminoglycosides. In addition, serial weight measurements permit an appraisal of growth and captive management, response to treat-

ment, and disease progression or resolution. Relating body weight to length and conformation gives an assessment of body condition. The snout-vent length of lizards and especially snakes is worth noting, because organ position and growth can be calculated as a result. Chelonian body condition relies on relating total weight to straight carapace length or body volume.

Transillumination of the coelom using a cold light source can be used to visualize the internal structures of small lizards and snakes and is particularly useful to confirm suspected impactions and foreign bodies. Care must be exercised if a hot light source (eg, incandescent spotlight) is used, because of the possibility of burns.

Auscultation of reptiles is difficult and often unrewarding. Electronic stethoscopes

with moistened gauze between the shell or scales and the stethoscope diaphragm can be helpful. Doppler ultrasound is particularly useful to determine heart rates.

Snakes: The head of an aggressive snake or a snake of unknown disposition should be identified and restrained before opening the transportation bag to remove the animal. In general, the head of the snake is

^a The poor Ca:P ratio of these commonly used items may make them less suitable as a staple component of a reptile diet.

held behind the occiput using the thumb and middle finger to support the lateral aspects of the cranium. The index finger is placed on top of the head. The other hand is used to support the body. Restraining the snake's head in this manner supports the cranial-cervical junction, which, having only a single occiput, is prone to dislocation. When dealing with large boids, a second, third, or even fourth handler is required to support the body during the examination. It is usually safer and more convenient to sedate a large, pugnacious snake than to risk injury to the snake, owner, or staff.

Nonvenomous species should be supported using one or two hands, depending on size. Nervous or aggressive snakes can be restrained using plexiglass tubes or sedated before examination. The clinician should attempt to gauge muscle tone, proprioception, and mobility. Systemically ill serpents will often be limp, lack strength, and be less mobile. Head carriage,

body posture, cloacal tone, proprioception, skin pinch, withdrawal, and papillary and righting reflexes can be used to assess neurologic function.

The entire integument, particularly the head and ventral scales, should be thoroughly examined for evidence of dysecdysis (poor shedding), trauma, parasitism (especially the common snake mite, *Ophionyssus natricis*, and ticks), and microbiologic infection. Any recently shed skin should also be examined, if available, for evidence of retained spectacles. Skin tenting and ridges may indicate cachexia ("poverty lines") or dehydration; ticks and mites may congregate in skin folds, infraorbital pits, nostrils, and corneal rims. The infraorbital pits (where present) and the nostrils should be free from discharges or retained skin. The eyes should be clear, unless ecdysis is imminent. The spectacles covering the eyes should be smooth; any wrinkles usually indicate the presence of

a retained spectacle. The spectacle represents the transparent fused eyelids, and therefore the cornea is not normally exposed. The subspectacular fluid drains through a duct to the cranial roof of the maxilla. When blocked, the buildup of fluid causes a subspectacular swelling that often becomes infected. Damage to the underlying cornea can result in panophthalmitis and ocular swelling. Retrobulbar abscessation results in protrusion of a normal-sized globe. Other ocular pathologies can include uveitis, corneal lipidosis, and spectacular foreign bodies, including slivers of wood or other vivarium materials.

Working from cranial to caudal, the head and body are palpated for swellings, wounds, and other abnormalities. The position of any internal anomalies, noted as a distance from the snout and interpreted as a percentage of snout-vent length, enables an assessment of possible organ involvement. Recently fed snakes have a midbody swelling associated with the prey within the stomach; handling such individuals may well lead to regurgitation. Preovulatory follicles, eggs, feces,

enlarged organs, and masses may be palpable. The cloaca can be examined using a dedicated otoscope or by digital palpation.

Examination of the oral cavity is often left until last, because many snakes object to such manipulation. However, even before the mouth is opened, the tongue should be seen flicking in and out of the labial notch with regularity. The mouth can be gently opened using a plastic or wooden spatula to permit an assessment of mucous membrane color and the buccal cavity for evidence of mucosal edema, ptialism, hemorrhage, necrosis, and inspissated exudates. White deposits may indicate uric acid deposition due to visceral gout. The pharynx and glottis should be examined for hemorrhage, foreign bodies, parasites, and discharges. Open-mouth breathing is a reliable indicator of severe respiratory compromise. The patency of the internal nares and the state of the polyphyodontic teeth should be noted.

Lizards: Lizards vary considerably in size, strength, and temperament; therefore, a variety of handling techniques are required.

The tegus and monitors are renowned for their powerful bites, whereas other species, particularly the green iguana, are much more likely to use their claws and tail. The main problem when handling small lizards is restraining them before they flee. The lizard should be transported in a securely tied cloth bag, so that the position of the lizard can be identified and the lizard held before the bag is opened. Large lizards are best restrained with the forelimbs held laterally against their coelom and the hindlimbs held laterally against the tail base. The limbs should never be held over the spine, because fractures and dislocations can occur. Nervous lizards can be wrapped in a towel to aid restraint. Smaller lizards can be restrained around the pectoral girdle, holding the forelimbs against the coelom, although care is required not to impair respiratory movements. A lizard should never be grasped by the tail, because many species can drop the tail (autotomy) in an attempt to evade capture. Restricting the vision of a lizard (eg, a towel placed over the head) is often the simplest way to facilitate handling and examination. A useful restraint technique for iguanid or monitor lizards uses the vasovagal response: gentle digital pressure applied to both orbits causes many lizards to enter a state of stupor for up to 45 min (or until a painful or noisy stimulus is applied). This technique enables the mouth to be gently opened without the need for excessive force. If possible, the lizard should be observed unrestrained to check for neurologic problems. Calm lizards may be permitted to walk around the examination table or on the floor. However, if in any doubt, the lizard should be placed in a large plastic enclosure to prevent escape during observation.

The integument should be examined for parasites (essentially mites and ticks) and trauma due to fighting, mating, and burns. Lizards tend to shed their skin in stages. Classically, dysecdysis and skin retention occurs around the digits and tail, causing ischemic necrosis. Extensive skin folding and tenting may indicate cachexia and dehydration.

The head should be examined for abnormal conformation. The mouth can be opened using a blunt spatula or, in iguanas, by gently applying pressure to the dewlap. The buccal cavity and glottis should be examined thoroughly for evidence of trauma, infection, neoplasia, and edema, especially pharyngeal edema. The internal extent of any rostral abrasions should be evaluated. The nostrils, eyes, and tympanic

scales should be clean and free of discharges. The presence of dry, white material around the nostrils of some iguanid lizards is normal, because some species excrete salt through specialized nasal glands. The rostrum should be examined for trauma, often caused by repeated attempts to escape from a poorly designed vivarium or to evade cagemates. The head, body, and limbs should be palpated for masses or swellings, which can be abscesses or metabolic bone disorders. Lizards suffering from severe hypocalcemia and hyperphosphatemia may exhibit periodic tremors and muscle fasciculations. The coelomic body cavity of most lizards can be gently palpated. Food and fecal material within the GI tract, fat bodies, liver, ova, and eggs are usually appreciable. Cystic calculi, fecoliths, enlarged kidneys, impactions, retained eggs or ova, and unusual coelomic masses may also be noted.

The cloaca should be free from fecal staining, with visual and digital examination considered routine. In the green iguana, renomegaly can be appreciated by digital cloacal palpation. The high incidence of dystocia necessitates a need to identify gender during examination. Many species of lizards are sexually dimorphic, although sexing juveniles can be difficult.

Tortoises, Turtles, and Terrapins:

Small to medium-sized tortoises are not difficult to handle, although their strength and uncooperative nature can hinder examination. Patiently holding the tortoise with its head down will often persuade a shy individual to protrude the head from the shell. Placing the thumb and middle finger behind the occipital condyles prevents retraction of the head. However, with larger species, it may be physically impossible to prevent a strong individual from pulling free. In such cases, sedation or use of a neuromuscular blocking agent may be necessary. The more aggressive aquatic species should be held at the rear of the carapace. Some species (eg, snapping turtles) have long necks and an extremely powerful bite, necessitating great care. Certain species also have functional hinges at the front and/or back of the plastron, and care should be exercised not to trap a finger when the hinge closes.

Examination of the head should include the nostrils for any discharges and the beak for damage and overgrowth. The eyelids should be open and not obviously distended or inflamed, and the eyes should be clear and bright. Conjunctivitis, corneal

ulceration, and opacities are frequent presentations. The tympanic scales should be examined for signs of swelling associated with aural abscessation. Applying steady distractive pressure to the maxilla and mandible can open the mouth, and a mouth gag can be inserted to prevent closure. Aggressive chelonians, generally aquatic species, often threaten by open-mouth displays, which provide a good opportunity to examine the buccal cavity with minimal handling. Mucus membrane coloration is normally pale; hyperemia may be associated with septicemia or toxemia. Icterus is rare but may occur with biliverdinemia due to severe liver disease. Pale deposits within the oral membranes may represent infection or urate tophi associated with visceral gout. The glottis is positioned at the back of the fleshy tongue and may be difficult to visualize; however, it is important to check for any inflammation and glottal discharges consistent with respiratory disease.

The integument should be free of damage. Subcutaneous swellings are usually abscesses. Aquatic species appear more susceptible to superficial and deep mycotic dermatitis, especially around the head, neck, and limbs. The withdrawn limbs can be extended from the shell of small to medium-sized chelonians by applying steady traction. Because the coelomic space within the shell is restricted, gently forcing the hindlimbs into the shell will often lead to partial protrusion of the forelimbs and head, and vice versa. A wedge or mouth gag can be used to prevent complete closure of a hinge. No chelonian will close a hinge on an extended limb. The integument should be examined for parasites (particularly ticks and flies), dysecdysis, trauma, and infection that may arise due to predator attacks. Aggressive conflicts and courting trauma must also be considered in the communal environment. Limb fractures are less common in chelonians than in other reptiles, but when they do occur they are often associated with rough handling and secondary nutritional hyperparathyroidism. Focal subcutaneous swellings are usually abscesses, but grossly swollen joints or limbs are more often cases of fracture, osteomyelitis, or septic arthritis.

The prefemoral fossae should be palpated with the chelonian held head-up. Gently rocking the animal may enable palpation of eggs, cystic calculi, or other coelomic masses. The shell should be examined for hardness, poor conformation, trauma, or infection. Soft, poorly mineralized shells are usually a result of secondary nutritional

hyperparathyroidism resulting from dietary deficiencies of calcium, excess phosphorus, or a lack of full-spectrum lighting. Pyramiding of the shell appears to be more associated with inappropriate humidity than dietary imbalances. Shell infection may present as loosening and softening of the scutes with erythema, petechiae, purulent or caseous discharges, and a foul odor.

Prolapses through the vent are obvious, but it is necessary to determine the structure(s) involved. Prolapses may include cloacal tissue, shell gland, colon, bladder, or phallus. Internal examination using digital palpation and an endoscope is recommended.

Anesthesia and Analgesia

For some minor procedures (eg, blood sampling), simple restraint may be all that is required. This can be enhanced by temporary immobilization techniques such as dorsal recumbency, reduced light intensity, or gentle ocular pressure (vasovagal response). For more invasive and painful procedures, general anesthesia must be used. Although considerable anatomic, physiologic, and pharmacologic differences exist between reptiles, some general guidelines are applicable. The following is therefore intended as a practical approach, rather than an exhaustive review of reptile anesthesia.

Preanesthetic Assessment and Stabilization:

All reptiles should be hospitalized and maintained at their preferred optimal temperature zone at all times to minimize physiologic disturbance, facilitate recovery, and maintain immunocompetence. Although hypothermia will reduce movement, it does not provide analgesia and is therefore unacceptable as a means of anesthesia on welfare grounds. It can also dramatically affect the pharmacokinetics of any drugs administered and greatly prolong recovery.

A full clinical examination should be performed and the animal accurately weighed, although this may not be practical or possible in some cases. The hydration status of all reptiles should be assessed, especially if debilitated or post-hibernation. For elective procedures (eg, neutering), underweight, dehydrated, or debilitated animals should be nursed for days, weeks, or months until their condition improves. For nonelective surgery, dehydration should be corrected before anesthesia. Even the most moribund egg-bound reptile will

usually benefit from stabilization for 24–48 hr before surgery is performed. Reptiles that have not been stabilized before surgery tend to succumb intra- or postoperatively. Although oral fluids are least invasive to administer and provide the most physiologically normal method of rehydration, they are sufficient only for mildly dehydrated animals and are contraindicated immediately before surgery because of the risks associated with regurgitation. Intracoe-lomic fluids are more suitable, but uptake can take many hours and their use is problematic if coeliotomy or coelioscopy is planned. For dehydrated surgical candidates, IV or intraosseous fluid therapy should be administered before, during, and after surgery as necessary.

Reptiles should be fasted before all elective surgery to avoid the compression of lung(s) associated with large meals and potential regurgitation. Fasting depends on the feeding regimen of the reptile, but in general one feeding cycle should be skipped before surgery. Premedication with sedatives such as acepromazine and atropine is generally rare in reptiles, although midazolam has been advocated in large chelonians. However, presurgical administration of analgesics should be considered routine (see TABLE 26).

Anesthetic Induction: IV or intraosseous propofol provides a rapid, controlled mode of induction. It is relatively nontoxic, and there is reduced risk of thrombophlebi-

TABLE 26

ANALGESICS, SEDATIVES, AND ANESTHETICS USED IN REPTILES

Drug	Dose and Route	Comments
Morphine	1.5 mg/kg, IM, SC 10 mg/kg, IM, SC	Chelonians (red-eared sliders) Lizards (bearded dragons) Not analgesic for snakes. Causes pronounced respiratory depression in turtles.
Hydromorphone	0.5 mg/kg, IM, SC	Chelonians: appears to cause less respiratory depression than morphine
Tramadol	5 mg/kg/day, PO, SC; 10 mg/kg, PO, every 4 days	Chelonians (red-eared sliders); less respiratory depression than morphine
Butorphanol	20 mg/kg, SC	Snakes (cornsnakes) at high doses. Not analgesic for bearded dragons or red-eared sliders. May cause respiratory depression, and high-dose volume may be impractical. May be able to partially antagonize opiate agonists like morphine.
Meloxicam	0.2 mg/kg, IV, IM, SC, every 24–48 hr	
Ketamine	10–40 mg/kg, IM 40–60 mg/kg, IM	Sedation, prolonged hangover effects Deeper sedation but not sufficient for painful procedures and care in debilitated individuals
	Ketamine 10 mg/kg, combined with medetomidine 0.1–0.2 mg/kg (or dexmedeto- midine 0.05–0.1 mg/kg) and morphine 1.5 mg/ kg or hydromorphone 0.5 mg/kg, IM (or 50% dose, IV)	Deep sedation/anesthesia in many chelonians. Reversed using atipamezole (0.5 mg/kg, IM) and, if necessary, naloxone (0.2 mg/kg, IM)

TABLE 26

ANALGESICS, SEDATIVES, AND ANESTHETICS USED IN REPTILES (continued)

Drug	Dose and Route	Comments
Midazolam	2 mg/kg, IM	Premedication, or can be given with ketamine to increase sedative effects or promote similar effects at lower ketamine doses.
Dexmedetomidine	0.05–0.1 mg/kg, IV or IM	Often used in combination with ketamine and opiates as a sedative to light anesthetic. Useful when IV access is difficult.
Atipamezole	10 × mg dose of dexmedetomidine, IM	Used to reverse dexmedetomidine
Tiletamine/zolazepam	3–12 mg/kg, IM	Tortoises, lizards, snakes. Low dose useful to facilitate intubation. Higher doses associated with prolonged recoveries.
Propofol	3–10 mg/kg, IV, intraosseous	Low dose rate for larger reptiles. Subanesthetic doses produce variable short-term sedation.
Alfaxalone	5–10 mg/kg, IV 10–20 mg/kg, IM	Similar effects to those of propofol IV, but higher doses effective IM. Larger IM dose volumes may warrant dividing into two or more injections.
Isoflurane	1%–5%	Routine gaseous agent; subanesthetic levels provide short-term sedation. Mask down or conscious (sedated) intubation possible in some species.
Sevoflurane	2%–7%	Very similar effects to those of isoflurane but recoveries appear to be faster. Preferred agent for critical or large reptiles.

tis if it is injected perivascularly. This is of particular concern, because IV access may be relatively difficult, especially in active animals undergoing elective procedures. Alfaxalone has been licensed in the USA; it is an excellent IV induction agent and is also effective when used IM.

If IV access is impractical or dangerous to attempt, IM agents can be used to induce sufficient chemical restraint for intubation. For IM injections in lizards and chelonians, the forelimb muscles are preferred, whereas for snakes, the epaxial muscles are used. An IM combination of ketamine, medetomidine (or dexmedetomidine), and morphine or hydromorphone has proved effective for a variety of chelonians; this can be readily reversed using atipamezole and, if necessary, naloxone or naltrexone.

Squamates can also be induced by inhalation agents in an induction chamber

or by mask. However, breath holding tends to occur in turtles and crocodilians, which can respire anaerobically for prolonged periods. Induction may take 10–30 min in cooperative lizards and snakes. Intubation of conscious patients has been suggested after local lidocaine spray, but the adverse effects of increased stress and catecholamine release should always be considered. There is also the potential danger of being bitten.

Maintenance of Anesthesia: Isoflurane or sevoflurane are the agents of choice for maintenance of anesthesia. These volatile inhalation agents have faster modes of action, are more controllable, and facilitate faster recoveries than most alternatives. Furthermore, their lack of reliance on hepatic metabolism or renal excretion reduces the anesthetic risk to debilitated

reptiles or those with questionable renal or hepatic function.

Intubation of reptiles is relatively simple. Small-gauge endotracheal tubes or catheters are easily inserted through the glottis immediately caudal to the tongue; this may be aided by forcing the tongue up and forward by pressing a finger into the intermandibular space from under the jaw. The reptilian glottis is actively dilated, and therefore its movement will often be abolished in anesthetized animals; a guiding stylet can be useful to facilitate endotracheal tube placement. The bifurcation of the trachea may be far cranial in some chelonians, and gaseous exchange has also been reported within the tracheal lung of some snakes; care should be taken to use a short endotracheal tube that is securely taped in position.

Noncrocodilian reptiles lack a diaphragm; skeletal intercostal muscles (Squamata) or limb movements (Chelonina) control breathing. The action of these muscles is abolished at a surgical plane of anesthesia, and intermittent positive-pressure ventilation is required. Ventilation rates should initially mirror preanesthesia evaluations and then be adjusted to maintain end-tidal capnography readings of 15–25 mmHg. Electrical ventilators enable precise control of ventilation rates and pressures.

Monitoring anesthesia in reptiles differs considerably from doing so in mammals. Palpebral and corneal reflexes are reliable in those species in which they can be elicited (ie, all chelonians, all crocodilians, most lizards, but no snakes). However, corneal reflexes are abolished at toxic doses, and pupillary diameter may bear little relation to the depth of anesthesia (unless fixed and dilated, which indicates excessive anesthetic depth or brain anoxia and death). Jaw tone and withdrawal reflexes (tongue, limb, or tail) are abolished only at a surgical plane of anesthesia. This also correlates with full loss of the righting reflex, loss of spontaneous movement, and complete muscle relaxation.

Heart rate may be monitored by auscultation or by visualization or palpation of the heart beat in most snakes and some lizards. Pulse oximetry, using either an esophageal or cloacal reflectance probe, is useful to monitor pulse rate and strength. Although the blood oxygen saturation (SpO_2) readings are often low and have not been validated for reptiles, monitoring the trend in SpO_2 is often helpful. Doppler ultrasonography can also be used over peripheral arteries or the heart. Blood gas estimations are often affected by

intracardiac or pulmonary shunts, especially in aquatic species. However, end-tidal capnography has proved effective.

Toward the end of surgery, the anesthetic gas should be discontinued while maintaining ventilation for another 5–10 min to facilitate excretion. At this point, oxygen should be discontinued in favor of room air delivered by bag-valve mask to encourage spontaneous respiration.

Postoperative Support: Once it is breathing spontaneously, the reptile can be returned to an incubator or vivarium to fully recover. Continued monitoring is essential until righting reflexes return and the animal is ambulatory. Additional analgesia, fluid, and nutritional support should be provided as indicated.

Diagnostic Techniques

Radiology: Several anatomic differences make it difficult to obtain quality radiographs in reptiles. The relatively small size of most pet reptiles and the lack of diffuse body fat often produce images of poor contrast. Thick, highly keratinized scales, osteoderms, or shells can severely hinder the x-ray beam, necessitating greater power and a subsequent loss of fine soft-tissue detail.

Despite these difficulties, most high-capacity units can be set to produce quality radiographs of reptiles. High-detailed screen/film combinations (eg, mammography film) are essential to obtain sufficient detail and contrast, especially in smaller animals. Various agents can be used to improve contrast. Barium sulfate (30%) can be used for GI studies. Water-soluble iodine compounds such as iohexol can be used for GI, urogenital, and IV techniques. The injection of air into the coelom of a lizard can greatly improve the appreciation of preovulatory follicles.

Snakes: Snakes can be difficult to position and restrain for radiographic examinations unless anesthetized. If the purpose of the examination is simply to exclude radiodense foreign bodies, the snake may be allowed to coil in its natural position. If detailed examination of the skeletal, respiratory, and digestive system is desired, the snake must be extended. A plastic restraint tube can be used for this purpose; however, this may produce some radiographic artifact. In larger snakes, several films will be needed to radiograph the entire length of the body. Lateral views are best taken using horizontal beams to avoid displacement artifact of the viscera. However, standard laterals with the

snake taped in lateral recumbency can be useful, especially when horizontal beams are not possible or safe to undertake. The interpretation of dorsoventral views are hindered by the spine and ribs but can still be useful when dealing with obvious lesions including eggs and mineralized masses.

Lizards: Small lizards can often be restrained by taping them to the radiography film or table for a dorsoventral view. Placing cotton balls over the eyes, and wrapping them with self-adhesive tape will often produce a calm, motionless lizard. A dorsoventral view can help identify foreign bodies, intestinal impaction, or coelomic masses. A horizontal x-ray beam provides the best lateral imaging in lizards, especially when evaluating the respiratory system. The positioning for this view involves rotating the x-ray tube 90° and placing the film vertically behind the lizard. Elevating the body of the lizard on rolled towels or foam pads helps prevent superimposition of the limbs with the coelomic cavity. The positioning for, and interpretation of, crocodilian radiographs are similar to those used for lizards.

Radiograph of a Greek tortoise demonstrating several abnormal eggs, including one within the bladder and encased by uric acid, forming a large urolith. Courtesy of Dr. Stephen Divers.

Chelonians: Most chelonians are fairly easy to position and restrain. For vertical beam dorsoventral radiographs, most conscious animals will remain motionless long enough to permit exposure. Ideally, the head and limbs should be extended from the shell to reduce superimposition of the limb musculature on the coelomic viscera. More active animals can be restrained by taping them to the cassette or by placing them in a radiolucent container, although this should be avoided with smaller specimens (and lower exposures), because material artifacts may appear. For lateral horizontal beam radiographs, the chelonian is best placed on a central plastron stand to encourage extension of the limbs and head while the tortoise remains immobile. Both left and right lateral projections should be taken with the lateral edge of the shell touching (or as close as possible to) the cassette. The third basic coelomic view is the horizontal craniocaudal (or anterior-posterior) view. The chelonian is positioned on a central plastron stand, with the caudal edge of the carapace touching (or as close as possible to) the cassette; the head should be facing the x-ray tube and the beam centered on the midline of the cranial rim of the carapace. Radiology of the head and limbs requires exteriorization from the shell usually under general anesthesia. The use of sandbags, foam, and tape aid positioning. Standard interpretation requires that both true lateral and dorsoventral views should be taken—even slight rotation makes interpretation more difficult.

Ultrasonography: A useful and often underrated technique, ultrasonography has gained popularity as a diagnostic technique for reptiles. It is particularly useful for examining tissue parenchyma, guiding biopsy needles, and, with color flow Doppler, investigating cardiac disease. Unfortunately, the equipment tends to be expensive, and several probes with small footprints are required, given the variation in reptile size and ultrasound applications. Ultrasound waves cannot penetrate through mineralized tissue or air and, therefore, ultrasonography has obvious limitations to investigate respiratory and GI diseases.

The giant species require a 5-MHz probe, whereas a 7.5-MHz probe suffices for most reptiles. When examining very small specimens (or for ultrasonography of eyes), a 10–20 MHz probe is more appropriate. Good contact and imaging generally require copious quantities of gel or a water bath. It is helpful to maintain the animal in a normal position or, failing that, at least appreciate

the complications associated with organ displacement. Ultrasonography can be a useful adjunct to radiography, especially to assess the reproductive tract (evaluating ovarian activity and distinguishing between pre- and postovulatory egg stasis), liver and gallbladder, urinary system, soft-tissue masses, and heart. Ultrasonography has been used to guide liver biopsy, although iatrogenic trauma has been reported in snakes.

CT and MRI: CT offers excellent, high-resolution, detailed images. Potentially, it would be the diagnostic imaging technique of choice for the respiratory system and skeleton of reptiles. MRI produces primarily high-detailed images of soft-tissue structures and is useful to diagnose neurologic, hepatic, renal, and reproductive diseases in reptiles. Disadvantages of these techniques are the need for general anesthesia to completely eliminate motion, equipment availability, and cost.

Endoscopy: Endoscopy has proved to be a most useful diagnostic tool in reptile medicine, and given the small and delicate nature of many species, continued development of minimally invasive techniques is likely. Flexible endoscopes are useful for respiratory endoscopy in snakes or GI endoscopy in many species. The main disadvantage of the flexible, fiberoptic endoscope is the poorer image quality than for those obtained using rigid scopes of a similar diameter. However, the continued development of smaller videoscopes looks likely to redefine flexible endoscopy in reptiles. The compact body size of most pet reptiles, coupled with their coelomic body design, makes rigid endoscopy useful in many situations. Although equipment must be matched to size of the reptile, in general the 1.9-mm and 2.7-mm telescope and sheath systems work well for most pet species, enabling gas insufflation, fluid irrigation, and biopsy capability.

Insufflation is essential to provide the lens-organ distance required for visualization. For GI endoscopy, air and/or saline is used; for coelioscopy, medical grade CO₂ or saline is preferred. Coelomic pressures seldom need to be >5 mmHg. When performing endoscopy in small neonates or within a hollow viscus (eg, bladder, oviduct, cloaca, stomach), warmed sterile saline irrigation often provides better clarity than gas insufflation.

General anesthesia is recommended for all endoscopy procedures. Certain

examinations (eg, buccal cavity and cloaca) may be possible in a conscious or sedated animal using a mouth gag or other appropriate restraint, but complete immobilization is preferred to avoid risking damage to patient, staff, or equipment. Anesthesia is mandatory for coelioscopy.

Blood Collection: Venipuncture is generally a blind technique in reptiles. Up to 0.5 mL/100 g may be safely collected from healthy reptiles, less in debilitated animals. There is a relative lack of hematologic or biochemical data for most reptiles. In addition, blood values can vary dramatically with species, environment, nutrition, age, breeding, and hibernation. Given this variability, published ranges may be of limited value. More reliance should be placed on establishing an individual's observed range and using serial sampling to monitor the progress of hematologic and biochemical changes. The use of a toenail clip to obtain blood may result in fecal or urate contamination, increased tissue enzymes, and hemogram and electrolyte changes due to the peripheral nature of the sample and the crushing artifact of collection. Of even greater concern are the ethical and welfare issues associated with toenail clipping.

The two common sites for venipuncture in snakes are the caudal vein and the heart. The caudal vein is accessed caudal to the cloaca, between 25% and 50% down the tail, and avoiding the paired hemipenes of males. In lizards, the most clinically useful vessel is the ventral midline caudal vein, best accessed 20%–80% down the tail. The most clinically useful vessels in chelonians appear to be the jugulars, subcarapacial sinus, and dorsal coccygeal veins. The left and right jugular veins are preferred because of the reduced risk of lymphatic contamination.

Necropsy: A detailed necropsy should be undertaken whenever possible, because it often provides a definitive diagnosis. When managing a disease outbreak in a population, elective euthanasia and necropsy of one or more individuals is often the most efficient and cost-effective means of diagnosis. Fresh necropsies can provide organ biopsies, blood, and other bodily fluids for laboratory examination. The submission of microbiology samples, especially bacteriology, from reptiles that have died and remained within a heated enclosure must, however, be interpreted with caution.

Surgery

In general, performing surgery on a reptile patient should be approached with the same principles as those used for domestic animals. However, there are some specific anatomic considerations, as well as unique aspects of patient preparation, positioning, and equipment. Only a basic discussion follows here, and consulting other sources on reptile anatomy, physiology, husbandry, anesthesia, and surgery, as well as domestic animal surgery literature, is essential before performing surgery on any reptile.

For truly giant reptiles, such as giant tortoises, the use of stronger, large animal instruments is recommended. For reptiles weighing 5–50 kg, most instruments used for small animals are appropriate. However, most pet reptiles weigh <1 kg, and microsurgical instruments are often required. These instruments are not miniaturized versions of standard instruments but rather balanced instruments with fine, small tips. Because microinstruments can be costly, ophthalmologic instruments can be useful alternatives. Plastic, self-retaining retractors can be adjusted to fit different sizes of incisions and do not compromise ventilation. Smaller versions of standard abdominal retractors can also be used but are significantly heavier. Eyelid retractors can be useful to retract coelomic incisions in small lizards and snakes. Epoxy resins or low-temperature veterinary acrylics are used for many chelonian plastron closures and shell repairs.

Rapidly absorbable suture materials are recommended for internal soft-tissue applications. For prolonged internal durability, polydioxanone or nylon are preferred. Poliglecaprone, monofilament nylon, and polydioxanone are favored for skin suturing, although wire may be necessary for giant tortoises or monitor lizards.

Because most reptile patients that require surgery are significantly smaller than mammalian patients, some degree of magnification is generally recommended. Headband or frame-mounted operating loupes (2–4 × magnification) with a dedicated halogen or xenon light source are affordable, versatile, comfortable, and simple to use. While operating, microscopy telescopes can provide magnification with selected rigid endoscopy systems.

A healthy reptile can generally tolerate 0.4–0.8 mL/100 g body wt of blood loss. Reptiles in need of surgery are often compromised, and diagnostic blood

samples may have been collected before surgery. Therefore, the amount of blood a reptile can afford to lose during surgery may be considerably less. Careful consideration must be given to minimizing hemorrhage using cotton-tipped spears or applicators, vascular clips, and radiosurgery.

Patient positioning will depend on the species and the nature of the surgery. Consideration should be given to ensuring that head and neck position does not interfere with ventilation; avoiding excessive compression of the head, limbs, or coelom to prevent pressure necrosis, visceral rupture, or hypoventilation of the lungs; avoiding extreme and prolonged hyperextension or hyperflexion of any joint; and ensuring that the surgical site is easily accessible and does not require surgeon positioning that will result in fatigue. Sand-bags, bean-bags, foam supports, and adhesive tapes can be used to maintain patient position.

When reptile skin is incised, it tends to invert. Therefore, everting suture patterns (eg, horizontal mattress) are recommended to ensure opposition of tissue without future dysecdysis. The skin suture materials should be monofilament. Wire suture may be required for repairs involving shell or thickly keratinized skin containing osteoderms. Staples have also been advocated, because they cause mild eversion of the skin. Given the length of time it takes for reptile wounds to heal, sutures should not be removed until 6–8 wk after surgery.

The primary factors to consider postoperatively are analgesia and continued vigilance concerning hydration, temperature, nutrition, and hygiene. It is widely understood and accepted that reptiles can feel pain. Pain slows the healing process and depresses the normal function of the immune system in mammals. There is no evidence to suggest this process would not be similar in reptiles. Clinically, reptiles that receive postoperative analgesia appear to recover better than those that do not. The continuation of preemptive analgesia using opioids and/or NSAIDs should be a routine part of postoperative care.

Few drugs are approved by the FDA for use in reptiles. Medications can be given by a variety of routes, including PO, SC, IM, IV, intracardiac, intracoelomic, intrasosseous, intrasynovial, or intratracheal injection. Certain drugs can be applied topically, given per cloaca, by inhalation (nebulization), or by direct intralesional administration. Because reptiles are ectotherms, temperatures outside the preferred optimal temperature zone (POTZ) can have

profound influences on drug distribution, metabolism, excretion, and elimination half-life. Some therapeutic regimens state a fixed temperature at which the reptile should be held during treatment. If there are pharmacokinetic data on the drug, then the elimination of the drug will be known and constant. However, if this stated temperature is below or above the POTZ for the species being treated, then stress and debilitation may ensue. Even when the stated therapeutic temperature is within the POTZ for the species being treated, constant exposure to a fixed temperature is likely to be stressful.

Reptiles have a well-developed renal portal system; blood from the caudal half of the body passes through the kidneys before reaching the systemic venous circulation. Drugs injected into the caudal half of the body may have a significantly reduced half-life if excreted via tubular secretion. However, studies have demonstrated that these effects are unlikely to be clinically significant. Of potential concern is the caudal injection of nephrotoxic drugs that may reach renal tissue in high concentration. Also, the large bladder of chelonians may act as a drug reservoir and lead to a secondary therapeutic peak many hours after drug administration. The shell of tortoises, turtles, and terrapins is largely living tissue; therefore, all chelonian medication should be based on total body weight.

Drug Dosage and Allometric Scaling:

Numerous pharmacokinetic studies have been published for reptiles, and these should be considered the most reliable source for information on drug dosages. When species-specific information is not available, it is possible to extrapolate from closely related species. If there are no pharmacokinetic data or reliable clinical experience for a particular species, it may be necessary to extrapolate pharmacokinetic data from other animals. Allometric scaling calculates the drug dose and dosing frequency using metabolic rate rather than body weight. The basic allometric equations are shown below, in which W = body weight (kg) and K = energy constant, which is 10 for reptiles. These equations can be used to calculate a dose and dose frequency for a species for which no data are available, by using pharmacokinetic data from a known species (control), whether another reptile or mammal or bird:

$$\begin{aligned}\text{Minimum energy cost} &= K (W^{0.75}) \\ \text{Specific minimum energy cost} &= K (W^{-0.25})\end{aligned}$$

Antimicrobials: Many bacterial infections in reptiles are caused by gram-negative bacteria, particularly *Pseudomonas*, *Aeromonas*, *Citrobacter*, *Klebsiella*, and *Proteus* spp. Bacterial resistance to many commonly used antibacterials is seen, and many gram-negative bacteria can have unexpected sensitivity to particular antibacterials; therefore, sampling for Gram stain, cytology, culture, and sensitivity testing should be done before starting therapy. Antibacterial therapy must usually be given while awaiting the results of bacterial sensitivity tests. In these circumstances, amikacin, ceftazidime, and enrofloxacin or ciprofloxacin are often preferred (see TABLE 27). In severe infections, amikacin may be combined with ampicillin or amoxicillin for respiratory tract infections or with ceftazidime for generalized or systemic infections. Chloramphenicol in combination with neomycin may be given for GI infections. Penicillin, metronidazole, lincomycin, or clindamycin can be used for anaerobic infections.

Fungal and yeast infections commonly occur in reptiles. GI and skin mycoses are particularly common in reptiles maintained on inappropriately long-term broad-spectrum antibacterials. Cutaneous mycoses can often be treated by debridement and topical application of antifungals. GI infections can be treated with nystatin, whereas systemic infections may require itraconazole or fluconazole. In cases of pulmonary mycoses, antifungal medication may be given by nebulization or intratracheal or intrapulmonary injection.

Herpesviruses can cause severe morbidity and mortality in chelonians. Acyclovir has been used with some success during the early stages.

Parasiticides: Parasiticides used commonly in reptiles are listed in TABLE 28. Parasiticide overdose may lead to drug toxicity, which may be seen as neurologic signs, including seizures. Ivermectin is contraindicated in chelonians, and adverse reactions have been reported in some iguanid lizards, skinks, and indigo snakes. Milbemycin has been successfully used in box tortoises and terrapins, but it is recommended that ivermectins and milbemycins be avoided in all chelonians because safer alternatives are available. Permethrin is licensed for use in reptiles and appears safe and effective against mites and ticks.

TABLE 27 ANTIMICROBIAL DRUGS USED IN REPTILES

Drug	Dosage	Comments
Acyclovir	80 mg/kg/day, PO; topical cream 12 times daily	Antiviral
Amikacin	Corn snake: loading dose 1.7 mg/kg, IM, followed by 26 mcg/kg/hr via osmotic infusion-pump implant Gopher snake: initial dose 5 mg/kg, IM, then 2.5 mg/kg, IM, every 3 days Gopher tortoise: 5 mg/kg, IM, on alternate days American alligator (juvenile): 2.25 mg/kg, IM, every 3–4 days Ball python: 3.5 mg/kg, IM, every 4–5 days 50 mg/10 mL saline × 30 min nebulization bid	Maintain hydration
Amoxicillin	22 mg/kg, PO, bid 10 mg/kg/day, IM	Often ineffective unless given in combination with aminoglycosides
Amphotericin B	0.5–1 mg/kg, intracoelomic, IV, 1–3 days for 14–28 days Tortoise: 0.1 mg/kg/day, intrapulmonary, for 28 days 5 mg/150 mL saline for 1 hr of nebulization, bid for 7 days	Aspergillosis; fluid therapy recommended Pulmonary candidiasis
Ampicillin	Most species: 10–20 mg/kg, SC, IM, 1–2 times/day Tortoises: 50 mg/kg, IM, bid	
Azithromycin	Ball python: 10 mg/kg, PO, every 3–7 days (3 days for skin infections, 5 days for respiratory tract, 7 days for liver and kidneys)	
Carbenicillin	200–400 mg/kg/day, IM	
Cephalexin	20–40 mg/kg, PO, bid	
Ceftazidime	20–40 mg/kg, SC, IM, IV, every 2–3 days	
Ceftiofur	Tortoises: 2.2–4 mg/kg/day, IM Snakes: 2.2 mg/kg, IM, on alternate days Lizards: 5 mg/kg/day, IM, SC	
Cefuroxime	100 mg/kg/day, IM, for 10 days at 30°C	
Chloramphenicol	Indigo snake: 50 mg/kg, IM, bid Midland water snakes: 50 mg/kg, IM, every 4 days Most species: 20–40 mg/kg, IM, once to twice daily	
Ciprofloxacin	10 mg/kg, PO, on alternate days	
Clarithromycin	Desert tortoise: 15 mg/kg, PO, every 2–3 days	<i>Mycoplasma</i>
Clindamycin	5 mg/kg, PO, bid	
Clotrimazole	Topical	Fungal dermatitis

TABLE 27 ANTIMICROBIAL DRUGS USED IN REPTILES (continued)

Drug	Dosage	Comments
Doxycycline	Most species: 5–10 mg/kg/day, PO Hermann's tortoise: 50 mg/kg, IM, then 25 mg/kg, every 3 days	
Enrofloxacin	Most species: 5–10 mg/kg/day, IM, PO Nasal flush 50 mg/250 mL sterile water; 1–3 mL/nares daily to every other day Burmese python (juvenile): 10 mg/kg, IM, initial dosage, then 5 mg/kg, IM, every 48 hr. <i>Pseudomonas</i> : 10 mg/kg, IM, every 48 hr Hermann's tortoise: 10 mg/kg/day, IM Monitor lizards: 10 mg/kg, IM, every 5 days Indian star tortoise: 5 mg/kg, IM, once to twice daily Crocodilians: 5 mg/kg IV every 2–3 days	IM injection likely causes necrosis, and consideration should be given to single injection followed by oral administration IM injection likely causes necrosis, and consideration should be given to single injection followed by oral administration IM injection likely causes necrosis, and consideration should be given to single injection followed by oral administration IM injection likely causes necrosis, and consideration should be given to single injection followed by oral administration
Fluconazole	Lizards: 5 mg/kg/day, PO Sea turtles: 21 mg/kg, SC, once; then 10 mg/kg, SC, 5 days later	
Gentamicin	American alligator: 1.75 mg/kg, IM, every 3–4 days at 22°C Painted turtle: 10 mg/kg, IM, on alternate days at 26°C Red-eared terrapin: 6 mg/kg, IM, every 25 days Gopher snake: 2.5 mg/kg, IM, every 3 days at 24°C	Maintain hydration, nephrotoxicity reported Maintain hydration, nephrotoxicity reported Maintain hydration, nephrotoxicity reported Maintain hydration, nephrotoxicity reported
Itraconazole	Chameleon: 5 mg/kg/day, PO Spiny lizard: 23.5 mg/kg/day, PO, for 3 days, with persistent drug concentration for 6 days Snakes: 10 mg/kg/day, PO Sea turtles: 5 mg/kg/day, PO, or 15 mg/kg, PO, every 72 hr	Fungal dermatitis
Kanamycin	10 mg/kg/day, IM, at 24°C	Fluid therapy recommended

TABLE 27 ANTIMICROBIAL DRUGS USED IN REPTILES (*continued*)

Drug	Dosage	Comments
Ketoconazole	Crocodylians: 50 mg/kg/day, PO Most species: 15–30 mg/kg/day, PO, for 14–28 days	
Lincomycin	10 mg/kg/day, PO; 5 mg/kg, IM, once to twice daily	
Marbofloxacin	Ball python: 10 mg/kg, PO, every 48 hr	
Metronidazole	Bacterial infections, 20–50 mg/kg, PO, every 1–2 days	Maximal dose for tricolor snake, king snake, indigo snake, or Uracoan rattlesnake, is 40 mg/kg
Neomycin	10 mg/kg/day, PO	Oral only, not to be given systemically
Nystatin	Enteric fungal conditions in turtles: 100,000 U/kg/day, PO, for 10 days	
Oxytetracycline	Most species: 5–10 mg/kg/day, IM, PO American alligator: 10 mg/kg, IV, IM, every 4–5 days	Pain, irritation, and inflammation at injection site Mycoplasmiasis
Piperacillin	50–100 mg/kg, IM, every 12 days	Fluid therapy recommended
Polymixin B	Topical	Abrasions, wounds
Silver sulfadiazine	Topical every 24–72 hr	Broad spectrum for skin infections
Sulfamethoxydiazine	80 mg/kg, SC, IM, then 40 mg/kg/day, for 5–7 days	Coccidial infections
Tobramycin	Chelonians: 10 mg/kg, IM, every 1–2 days Most species: 2.5 mg/kg, IM, every 1–3 days	Potentially nephrotoxic, fluid therapy recommended
Tylosin	5 mg/kg/day, IM	Mycoplasmiasis
Voriconazole	10 mg/kg, PO	

TABLE 28 PARASITICIDES USED IN REPTILES

Drug	Dosage	Parasite	Comments
ENDOPARASITICIDES			
Fenbendazole	25–100 mg/kg, PO every 14 days for up to 4 treatments 50 mg/kg/day, PO, for 3–5 days	Roundworms, <i>Hexamita</i>	Can cause leukopenia
Ivermectin	200 mcg/kg, PO, IM, SC, repeat after 14 days		Not in chelonians; care in skinks and indigo snakes

TABLE 28 PARASITICIDES USED IN REPTILES (*continued*)

Drug	Dosage	Parasite	Comments
Levamisole	5–10 mg/kg, SC, intracoelomic, repeat after 14 days	Lungworms and other nematodes	Snakes, lizards, care in tortoises (use 5 mg/kg)
Mebendazole	20–25 mg/kg, PO, repeat after 14 days	Strongyles and ascarids	
Metronidazole	20–40 mg/kg, PO, every 1–2 days for 2–5 treatments	Protozoa	
Oxfendazole	68 mg/kg, PO, as a single dose	Nematodes	
Paromomycin	35–100 mg/kg/day, PO, for 28 days	Amoebas, cryptosporidia	Does not eliminate cryptosporidia
Ponazuril	Bearded dragons: 30 mg/kg, PO, every 2 days for two treatments	Coccidiosis	
Praziquantel	8 mg/kg, PO, SC, IM, repeat after 14 days and 28 days	Tapeworms, flukes	
Pyrantel	5 mg/kg, PO, repeat in 14 days	Nematodes	
Spiramycin	160 mg/kg/day for 10 days, then twice weekly for 3 mo	Snakes with cryptosporidiosis	May reduce clinical signs but does not clear infection
Toltrazuril	5–15 mg/kg, PO, repeat in 14 days 15 mg/kg, every 48 hr for 10 days; discontinue for 2 wk; repeat every 48 hr for 10 days, and repeat as necessary	Bearded dragons, coccidiosis Tortoises, intranuclear coccidiosis	Safety, efficacy, and pharmacokinetic data lacking
Trimethoprim-sulfa	30 mg/kg/day, PO, for 10–28 days	Coccidia	
ECTOPARASITICIDES			
Dichlorvos-impregnated strip	1 cm ² of strip/30 cm ³ vivarium for 28 days or 2.5 cm ² of strip/25 cm ³ vivarium for 2–3 days every week		Toxic, vivarium should be emptied; keep out of direct contact of animals
Fipronil	By spraying, every 7–10 days	Mites and ticks	
Ivermectin (10 mg/mL)	By spraying, 1–2 mL/L water every 7–10 days 200 mcg/kg, IM, every 7–14 days	Mites and ticks	Should not be used in chelonians; use care in skinks and indigo snakes
Permethrin (10%)	Topical spray	Mites and ticks	Licensed product available for reptiles in the USA

Other Medications: Dosages for medications used for a variety of other disorders of reptiles are listed in TABLE 29.

Fluid Therapy: Dehydration in reptiles is usually associated with prolonged anorexia and water loss, deprivation, or an inability to drink, rather than mixed

electrolyte losses through frequent vomiting or diarrhea. Water balance in reptiles differs from that in mammals, because, per unit body weight, reptiles have a higher percentage of total body water (63.0%–74.4%) and a higher percentage of intracellular water (45.8%–58.0%). These values appear to be highest in freshwater species,

TABLE 29 MISCELLANEOUS DRUGS FOR REPTILES

Drug	Dosage	Condition
Allopurinol	20–25 mg/kg/day, PO	Gout, reduces uric acid production
Aluminium hydroxide	100 mg/kg, PO, every 12–24 hr	Reduces blood phosphorus levels
Aminophylline	2–4 mg/kg, IM	Respiratory disease when bronchodilation required
Argipressin (vasopressin)	0.01–1 mcg/kg	Egg binding (more potent than oxytocin)
Ascorbic acid	10–200 mg/kg, IM, as required	Ulcerative stomatitis
Calcitonin	1.5 units/kg, SC, tid 50 units/kg, IM, repeat after 2 wk	Hypercalcemia, fluid therapy also recommended Secondary hyperparathyroidism
Calcium gluconate (10 mg/mL)	100 mg/kg, IM, qid, or 400 mg/kg, IV, intraosseous, given over 24 hr	Hypocalcemia in iguanas; high phosphorus concentration may cause soft-tissue mineralization
Cimetidine	4 mg/kg, PO, tid-qid	Regurgitation, vomiting, gastritis, GI ulceration
Cisapride	0.5–2 mg/kg/day, PO	GI motility modification; not recommended to use with clarithromycin in tortoises
Cholecalciferol	100–1,000 units/kg, IM, as a single dose	Hypocalcemia, fibrous osteodystrophy in iguanas
Cyanocobalamin	50 mcg/kg, SC, IM	Appetite stimulation
Dexamethasone	30–150 mcg/kg, IM, IV, intraosseous	Inflammation, shock, beware of immunosuppression
Dinoprost (prostaglandin)	500 mcg/kg, IM, as a single dose	Egg binding in snakes
Doxapram	5–10 mg/kg, IV, intraosseous	Respiratory stimulation
Flunixin	100–500 mcg/kg, IM, IV, once to twice daily	Inflammation, pain
Furosemide	2–5 mg/kg, IM, IV, once to twice daily	Diuresis (effective despite lack of loop of Henle in reptiles)
Iodine	2–4 mg/kg, PO, every 7 days	Prophylaxis for goitrogenic diets
Iron	12 mg/kg, IM, every 7 days (alligators)	Anemia in alligators
Levothyroxine	20 mcg/kg, PO, on alternate days	Hypothyroidism in tortoises

TABLE 29 MISCELLANEOUS DRUGS FOR REPTILES (*continued*)

Drug	Dosage	Condition
Metoclopramide	60 mcg/kg/day, PO, for 7 days	Stimulation of gastric emptying in tortoises
Prednisolone	1–2 mg/kg, PO	Anti-inflammatory, reduction of nephrocalcinosis, beware of immunosuppression
Selenium	25–500 mcg/kg, IM	Deficiency in lizards
Sucralfate	0.5–1 g/kg, PO, tid-qid	Gastric irritation/ulceration
Thiamine	50–100 mg/kg, IM	Thiamine deficiency
Vitamin A	5,000 units/kg, PO, every 7 days	Hypovitaminosis A (iatrogenic hypervitaminosis A may result from repeated treatment)

lower in terrestrial reptiles, and lowest in marine reptiles, with the concentration of isotonic saline in nonmarine reptiles being 0.8%. This has led to the conclusion that normal 0.9% saline may be too concentrated for most reptiles. Balanced crystalloid fluids containing dextrose (260–290 mOsm/L) appear to be effective. As a general guide, maintenance requirements are about 5–15 mL/kg/day, and rehydration should proceed at 35–40 mL/kg/day, although in cases of shock, rates of 3–5 mL/kg/hr can be used for several hours.

In many instances, simply permitting a reptile to bathe in shallow, warm water within a vivarium maintained at the species-specific preferred optimal temperature zone will promote drinking. Such a method is acceptable when reptiles are able and willing to drink voluntarily. However, in many cases oral fluids must be delivered via a stomach tube. For oral rehydration, mammalian electrolyte solutions can be used but are best diluted by a further 10%–15% to produce a slightly hypotonic solution. Significant amounts of water may also be absorbed via the cloaca when chelonians (and possibly other species) bathe. Oral fluid therapy works well to provide maintenance requirements, rehydrate mildly dehydrated reptiles, and as a vehicle to give oral medications and food. For alert and active reptiles, this method is preferred because it facilitates GI activity, and fluids are rapidly absorbed when the reptile is maintained at correct temperatures. Repeated stomach tubing is stressful and can be difficult in strong chelonians; therefore, esophagostomy tubes are recommended for longterm oral therapy. Small fluid volumes can be given SC, but in

moderate to severe cases, intracoelomic, IV, or intraosseous routes are favored.

Intracoelomic administration of fluids is faster, less stressful, and allows delivery of a larger volume than stomach tubing. Large volumes of intracoelomic fluid could compromise lung function and may be slowly absorbed; however, IV catheterization is not easy, and cut-down procedures are often required. In emergencies with larger snakes, it is possible to place an intracardiac catheter. Fluid infusion is best controlled by a syringe driver or infusion pump. If such devices are not available, the total daily fluid volume can be divided into three or four bolus injections, each given slowly over 10–20 min. IV catheters can usually be left in place for up to 72 hr; intracardiac catheters up to 24 hr. Intraosseous infusion is an easier technique in lizards, small crocodilians, and chelonians. The needle is directed into the medullary cavity of a long bone, and aspiration of marrow or radiography can verify correct positioning. Great care must be exercised when dealing with osteodystrophic lizards to avoid limb fractures. Infusion rates for IV and intraosseous administration are similar. As a general guide, 0.8–1.2 mL/kg/hr is suitable for rehydration purposes, but in cases of severe dehydration or shock or during surgery, 3–5 mL/kg/hr can be given for 2–3 hr.

Colloids are less frequently used in reptiles because much of the water loss is from the intracellular space rather than plasma, but they can be used in cases of acute hemorrhage. If severe hemorrhage occurs (ie, PCV <5%), whole blood may be given by IV and intraosseous routes. Cross-matching does not appear necessary,

at least for a single transfusion. Ideally the donor and recipient are of the same species.

BACTERIAL DISEASES

Bacterial diseases are common in reptiles, with most infections caused by opportunistic agents that infect immunosuppressed hosts. A comprehensive approach is required to ensure the success of a therapeutic plan. It is important not only to determine the causative agent but also to correct predisposing factors. Appropriate therapy in the absence of appropriate husbandry and nutrition will ultimately fail.

Culture and sensitivity are recommended to determine appropriate therapy. Most bacterial infections involve gram-negative bacteria, many of which are considered commensal. Anaerobic infections are not uncommon, but organisms can be difficult to culture. Gram-positive bacteria on smears, in conjunction with a negative culture, may indicate an anaerobic infection. Alternatively, if a therapeutic choice was based on aerobic culture and sensitivity and response is poor, then the presence of an anaerobe should be considered.

Septicemia: A number of infectious conditions are similar in appearance, regardless of species. Septicemia is a common cause of death. The systemic disease may be preceded by trauma, local abscessation, parasitism, or environmental stress. *Aeromonas* and *Pseudomonas* spp are frequently isolated; the former may be transmitted by ectoparasites. Death may be peracute or follow a protracted course. Common terminal signs are respiratory distress, lethargy, convulsions, and incoordination. Petechiae may be found on the ventrum, and chelonians develop erythema of the plastron. Sanitation and husbandry can be significant factors in reducing outbreaks. Affected reptiles should be isolated, and antibiotic therapy initiated.

Septicemic Cutaneous Ulcerative Disease (SCUD): Classically, SCUD is a shell disease of aquatic turtles caused by *Citrobacter freundii*; however, various bacteria have been isolated from diseased skin and shell. *Serratia* spp may act synergistically by facilitating entry of *C. freundii*. The scutes are pitted and may slough with an underlying purulent discharge. Anorexia, lethargy, and petechial hemorrhages on the shell and skin are seen; liver necrosis is also common. Systemic

antibiotics are recommended. Good sanitation is paramount for prevention.

Another shell disease of turtles is caused by *Beneckeia chitinovora*, a common infectious agent of crustaceans. Erythema and pitting of the shell with ulceration is seen. Septicemia is uncommon. Topical iodine is recommended in addition to antibiotics. The practice of feeding crayfish is often implicated in this condition and should be discouraged.

Ulcerative or Necrotic Dermatitis:

Ulcerative dermatitis (scale rot) is seen in snakes and lizards kept in unhygienic conditions with excessive humidity and moisture. Moist, contaminated bedding allows bacterial and fungal growth that, when coupled with exposure to fecal degradation products, can predispose to small cutaneous erosions. Secondary infection with *Aeromonas* spp, *Pseudomonas* spp, and a number of other bacteria may result in septicemia and death if untreated. Erythema, necrosis, and ulceration of the dermis, and an exudative discharge are common. Although lesions are often sequelae of skin injuries, they more often develop from within, as is the case with classic necrotic dermatitis in the ball python. The disease can develop even when these animals are maintained under pristine conditions, so it is not simply a matter of excessive moisture and poor hygiene. The condition starts with hemorrhage into scales, followed by pustules that eventually lead to open and ulcerated lesions. Treatment with systemic antibiotics, topical antibiotic ointment, and excellent hygiene and husbandry are essential.

Blister disease has traditionally been considered a separate entity but is simply an early stage of ulcerative (necrotic) dermatitis. The cutaneous involvement is characterized by pustules or blisters that may resolve without development of ulcerative lesions if treatment is started early. A low-grade thermal injury may mimic blister disease because of the potential development of fluid-filled vesicles.

Abscesses: Focal infections caused by traumatic injuries, bite wounds, or poor husbandry are seen in all orders of reptiles. Subcutaneous abscesses are seen as nodules or swellings. Differential diagnoses include parasitic nodules, tumors, and hematomas. Isolates of the anaerobic organism *Peptostreptococcus* and of the aerobes *Pseudomonas*, *Aeromonas*, *Serratia*, *Salmonella*, *Micrococcus*,

Erysipelothrix, *Citrobacter freundii*, *Morganella morganii*, *Proteus*, *Staphylococcus*, *Streptococcus*, *Escherichia coli*, *Klebsiella*, and *Dermatophilus* have been recovered from reptilian abscesses, often in combinations. Small, localized abscesses should be completely excised to avoid recurrence, which is frequent. Larger abscesses should be marsupialized, followed by aggressive local wound treatment. The lining of the abscess must be aggressively scraped to remove as much material as possible. Appropriate systemic antibiotics may also be indicated but are seldom necessary after complete excision. Anaerobic bacteria are common in these lesions, and an appropriate antimicrobial agent (eg, metronidazole, ceftazidime, or a potentiated penicillin product) may need to be used or added to a current regimen.

Visceral abscessation may occur as a result of hematogenous infection. Abscesses of the female reproductive system are common and may result in coelomitis. Surgical intervention is indicated; systemic antibiotics alone are rarely, if ever, successful.

Subspectacle abscessation is seen in snakes, and conjunctivitis is seen in the other orders. Severity ranges from mild inflammation to panophthalmitis and may occur as a result of ascending infectious stomatitis (see below). Topical antibiotic ointments are used in turtles, lizards without spectacles, and crocodilians. In snakes and lizards with spectacles, drainage is achieved by surgically removing a small wedge from the spectacle and flushing the subspectacular space and lacrimal duct with an antibiotic solution (eg, gentamicin). Some affected reptiles, especially turtles, may need supplemental vitamin A.

Infectious Stomatitis: Infectious stomatitis is reported in snakes, lizards, and turtles and characterized early by petechiae in the oral cavity; caseous material develops along the dental arcade as the condition worsens. In severe cases, infection extends into the mandible and maxilla. *Aeromonas* and *Pseudomonas* spp, common oral inhabitants, are most frequently isolated, along with a variety of other gram-negative and gram-positive bacteria. Respiratory or GI infection may develop in poorly managed cases. Surgical debridement, irrigation with antiseptics, systemic antibiotics, and supportive therapy are indicated. In severe cases with ulceration or granuloma formation, aggressive surgery may be indicated. Vitamin supplementation,

especially with vitamins A and C, has been advocated but does not always affect the disease course.

Pneumonia: Respiratory infections are common; the incidence can be influenced by respiratory or systemic parasitism, unfavorable environmental temperatures, unsanitary conditions, concurrent disease, malnutrition, and hypovitaminosis A. Open-mouth breathing, nasal discharge, and dyspnea are frequent signs. *Aeromonas* and *Pseudomonas* spp are frequently isolated, but many respiratory infections are mixed. Septicemia may develop in severe or prolonged cases. Treatment consists of improving husbandry and initiating systemic antibiotics. Nebulization therapy with antibiotics diluted in saline, in combination with acetylcysteine, has been used together with parenteral antibiotics. Reptiles with respiratory infections should be maintained at the mid to upper end of their preferred optimal temperature zone. Increased temperatures are important not only to stimulate the immune system but also to help mobilize respiratory secretions. Turtles often have an underlying vitamin A deficiency and require dietary correction. Many turtles treated for pneumonia do not improve completely until after treatment for vitamin A deficiency.

Mycoplasmosis: Mycoplasmosis is a known cause of rhinitis and upper respiratory tract disease in chelonians and polyserositis in crocodilians. In chelonians, the disease has been associated with population declines, and the disease is often chronic and/or intermittent. In American alligators, mycoplasmosis results in severe systemic disease and frequently death. A

Aural abscesses represent middle ear infections in turtles and chelonians. In box turtles, these abscesses are commonly associated with vitamin A deficiencies.

Courtesy of Dr. Stephen Divers.

variety of *Mycoplasma* species have been isolated. PCR and serologic diagnostic aids have been developed, and treatment using fluoroquinolones, clarithromycin, and oxytetracycline has been advocated.

Otitis: Ear infections occur frequently in turtles, especially box turtles and aquatic turtles. Marked swelling is seen at the tympanic membrane, and caseous material is present. *Proteus* spp, *Pseudomonas* spp, *Citrobacter* spp, *Morganella morganii*, *Enterobacter* spp, and other bacteria have been isolated. The tympanic membrane must be incised, and aggressive curettage of the area performed. Surgical removal of the abscess is usually curative as long as all infection is removed and the Eustachian tube is patent. The open area should be flushed with diluted povidone-iodine or a similar product for a few days to prevent premature closure and to keep the area clean. Systemic antibiotics are rarely required. Ear infections may be secondary to hypovitaminosis A; dietary supplementation of vitamin A may be beneficial.

Cloacitis: Often traumatic in origin, infectious cloacitis is characterized by edema and hemopurulent discharge. Cloacal calculi may form in vitamin or mineral imbalances and should be manually removed and followed by dietary correction. In pericloacal abscesses, the infection often migrates cranial. Ascending urinary or genital tract infections are common sequelae. Aggressive therapy, including surgical debridement, local wound treatment, and appropriate systemic antibiotics, is indicated. Fecal examinations should be performed to identify potential parasitic causes.

Spinal Osteopathy/Osteomyelitis:

Although previously reported in the reptile literature as Paget disease, this condition is now thought to be a chronic bacterial osteomyelitis of the spine. Traditionally, Paget disease is characterized by repeated episodes of osteoclastic bone resorption and deposition, leading to dense, brittle bones. Commonly reported in snakes, these proliferative and progressive spinal lesions have been investigated and are thought to be associated with chronic bacterial infections, most commonly involving *Salmonella* spp in snakes. Diagnosis is by biopsy or blood culture. Longterm antibiotic therapy may be helpful, but the prognosis is guarded to poor.

Mycobacteriosis: Mycobacterial infections are often associated with chronic wasting in wild, imported reptiles and are seen as granulomatous lesions at necropsy. Chelonians generally exhibit pulmonary involvement, whereas lizards, snakes, and crocodilians commonly show visceral granulomas. The species isolated are *Mycobacterium ulcerans*, *M chelonae*, *M haemophilum*, and *M marinum*. All are cultured at reduced temperatures and may require long periods for growth. Rifampin and isoniazid are hepatotoxic, and the longterm administration required is unlikely to be safe. There are no reports of successful treatment.

Salmonella Arizonae and Edwardsiella Infection:

These bacteria have been isolated from clinically healthy reptiles. The zoonotic nature of these commensal organisms must be considered when handling or treating reptiles. Attempts to eliminate these microorganisms from reptiles and their eggs have been unsuccessful and are not recommended. Veterinarians and reptile owners should be aware of the informational brochures available from the Association of Reptile and Amphibian Veterinarians.

MYCOTIC DISEASES

Excessively high humidity, low environmental temperature, concurrent disease, malnutrition, and other stressors may predispose reptiles to development of various mycoses. Little is known about the pathogenesis of systemic mycoses, which can develop over a long period, but maintaining good sanitation and husbandry reduces the frequency of infection. *Aspergillus*, *Candida*, *Cladosporium*, *Metarhizium*, *Mucor*, *Paecilomyces*, *Penicillium* spp, and the *Chrysosporium* anamorph of *Nannizziopsis vriesii* are a few of the organisms associated with systemic disease. Reports of successful treatment of systemic mycoses in reptiles are few. Suggested treatments for deep fungal respiratory infections include amphotericin B, itraconazole, fluconazole, and voriconazole. For superficial or localized mycotic infections, surgical removal of the granuloma with local wound treatment is advised. *Basidiobolus* spp, pathogenic for mammals, are found in feces of healthy reptiles.

Dermatophytosis has been described in all orders of reptiles. *Geotrichum*, *Fusarium*, and *Trichosporon* are the

genera most frequently isolated. In most cases, cutaneous injury precedes a secondary fungal infection. Chelonians with fungal infections of the shell can be treated by local debridement and topical application of Lugol solution or povidone-iodine. Exposure to ultraviolet light also may be beneficial.

Ulceration of GI tissues has been associated with infections by *Mucor* and *Fusarium* spp. Chronic visceral granulomatous disease of liver, kidneys, and spleen has been caused by *Metarhizium* and *Paecilomyces* spp. Few signs other than weight loss are seen before death. Animals may continue to feed until a few days before death.

The most frequent sites of mycotic infection are the skin and respiratory tract. *Metarhizium*, *Mucor*, and *Paecilomyces* spp are frequent isolates. *Aspergillus* and *Candida* spp have been isolated from pulmonary lesions of lizards and chelonians. Most infections involve granuloma or plaque formation with resultant signs of respiratory distress before death. Candidiasis in large snakes has been treated with nystatin (100,000 U, PO, for 10 days).

VIRAL DISEASES

Few viruses have been clearly proved as etiologic agents of disease in reptiles, but several have been linked strongly enough for them to be considered the causative agent until proved otherwise. A number of viral PCR and serology tests are available.

Inclusion Body Disease (IBD) of Boid Snakes: Boa constrictors and several species of pythons are most commonly affected by IBD, which was originally thought to be caused by a retrovirus but recently an arenavirus has been implicated. Boas are considered a more typical host because so many are infected, and they can harbor the virus for years with few to no clinical signs. Early signs, possibly precipitated by any factor causing immunosuppression, include a history of unthriftiness, anorexia, weight loss, secondary bacterial infections, poor wound healing, dermal necrosis, and regurgitation. In essence, IBD should be considered in every sick boa. Typical findings in the acute phase of the disease include leukocytosis and a normal chemistry panel. As the disease progresses, WBC counts tend to decline to subnormal levels. Blood chemistry results vary depending on how debilitated and dehydrated the boa becomes, but organ damage may occur.

As the disease becomes chronic, some boas exhibit neurologic symptoms ranging from mild facial tics and abnormal tongue flicking to failure of the snake to right itself when placed in dorsal recumbency and severe seizures.

Pythons are thought to be a more abnormal host for the IBD virus, because the course of disease is more acute and neurologic symptoms more profound. Most pythons present with severe neurologic disease. Although the active disease can linger for months or more in boas, most pythons die within days or weeks of the onset of clinical signs.

Exposure to this retrovirus/arenavirus appears to be due to a transfer of body fluids. Breeding, fight wounds, fecal/oral contamination, and snake mites have been implicated as common ways of transfer. A tentative diagnosis is based on history and clinical signs. Blood work varies depending on the stage of the disease, but few diseases in snakes will cause such increased WBC counts in the early stages. On blood smears, inclusion bodies are frequently found in the cytoplasm of leukocytes. A definitive diagnosis is obtained via biopsy of internal tissues in which the characteristic eosinophilic inclusion bodies are found, eg, the liver, kidney, esophageal tonsils, and stomach.

IBD is not curable, and many owners choose euthanasia. However, individuals may elect to isolate their snakes and treat with supportive and palliative measures. It is essential to educate owners not to sell infected specimens or their offspring, because this has caused the disease to spread worldwide.

Retroviruses: Retroviruses have also been found in Russell vipers, corn snakes, and California kingsnakes in association with malignant tumors. A retrovirus isolated from a sarcoma in a Russell viper was designated as viper virus. A related virus was isolated in a corn snake from a rhabdomyosarcoma and designated cornsnake retrovirus.

Adenoviruses: Adenoviruses have been implicated in fatal hepatic or GI diseases in snakes (gaboon vipers, ball pythons, boa constrictors, rosy boas, and rat snakes), lizards (Jackson chameleons, savannah monitors, and bearded dragons), and crocodilians.

In bearded dragons, the route of transmission appears to be fecal/oral contamination. Clinical signs are more commonly noted in juvenile dragons but can affect adults,

usually to a lesser extent. Signs are vague and include lethargy, weakness, weight loss, diarrhea, and sudden death. The morbidity is high in young bearded dragons, but survival is increased with supportive care. Fluid administration, force feeding, and antibiotics for secondary infections are useful.

Because the signs of disease in bearded dragons are vague and similar to those caused by coccidia and nutritional disorders, it is important to confirm the diagnosis. Characteristic intranuclear inclusion bodies are found in several internal organs, primarily the liver. When working with a large breeding group of lizards, it is practical to sacrifice a failing specimen to make a diagnosis. Premortem diagnosis can be accomplished by liver biopsy. Identification of adenovirus from fresh feces may be possible in the future.

Recovered lizards should be quarantined for at least 3 mo. Duration of viral shedding after recovery is unknown, so owners should be discouraged from selling or trading previously infected animals.

Herpesviruses: Herpesviruses have been isolated from freshwater turtles, tortoises, and green sea turtles. In freshwater turtles, the virus may be associated with hepatic necrosis. In tortoises, the virus may cause necrosis of oral mucosa accompanied by anorexia, regurgitation, and oral and ocular discharge. Treatment in tortoises includes isolation, supportive care, and application of 5% acyclovir to oral lesions. Oral acyclovir appeared to improve the lesions in a desert tortoise. Herpesvirus is diagnosed by the presence of intranuclear inclusion bodies and electron microscopic demonstration of viral particles.

Herpesvirus infection of farmed green sea turtles have been associated with gray patch disease and lung-eye-trachea disease, whereas fibropapillomas plague certain free-ranging populations. Gray patch disease (chelonian herpesvirus 1) causes epizootics of small, circular papular skin lesions that coalesce into patches and is associated with young turtles maintained in crowded, warmer, stressful situations. Biopsies of the skin reveal basophilic intranuclear inclusion bodies in epidermal cells; viral particles are noted in the cytoplasm by electron microscopy. There is no specific treatment, but reduction of crowding and stress appears to decrease the incidence. Lung-eye-trachea disease causes harsh respiratory sounds, with ulcerations and caseous debris over the globe and throughout the oropharynx and trachea.

Buoyancy problems and high mortality are reported.

Fibropapillomatosis has been reported from free-ranging sea turtles, especially around Hawaii. The route of transmission is not known. The light gray to black masses range in size up to 20 cm in diameter. The location of the masses seems to dictate the severity of signs. Masses occurring on periocular tissue can obscure vision. Growths on the flippers can interfere with swimming and the ability to forage for food. Internal masses also are seen, primarily in the lungs, liver, kidneys, and GI tract. Diagnosis is made by characteristic lesions and histology. Treatment consists of surgical removal, with wide margins to help reduce recurrence. Some turtles recover spontaneously, whereas those with internal lesions usually perish. It is suspected that fibropapillomas are caused by a herpesvirus, and infected specimens should be isolated from healthy turtles.

Paramyxovirus: Paramyxovirus infections are more common in viperid snakes but have been reported in non-venomous snakes as well. This highly contagious virus causes predominantly respiratory signs; transmission appears to be from respiratory secretions. Secondary bacterial infections are common because of the severe inflammation initiated by the virus, and it is not unusual to note nasal discharge, open-mouth breathing, caseated pus in the oral cavity, and labored breathing. Neurologic involvement, including tremors and opisthotonos, is occasionally noted.

Paramyxovirus should be suspected in any respiratory infection that does not respond to treatment with supportive care, antibiotics, and nebulization. Endoscopic biopsies and postmortem samples of lung can be submitted to detect viral particles by histology and electron microscopy. A hemagglutination inhibition test is available to measure antibodies against ophidian paramyxovirus in zoos and private collections; a positive titer should be used as a screening tool to help eliminate infected animals and prevent carriers from entering noninfected collections.

There is no specific treatment, but supportive care and antibiotics may prove useful. Affected specimens should be isolated and strict hygiene practices followed. Although a vaccine is under development, it is currently not effective.

West Nile Virus: West Nile virus has resulted in epizootic outbreaks in farmed

alligators, with the virus causing multi-organ necrosis, heterophilic granulomas, heterophilic perivasculitis, and lymphoplasmacytic meningoencephalitis. Very high viremia titers have been reported in various reptiles, suggesting that reptiles may play a role as an amplification host.

Papillomas: Viral particles appear to be transmitted from one European green lizard to another via bite wounds. The resulting papillomas are 2–20 mm in diameter and may be single or multiple. Although there are no signs in the initial phase, affected lizards may become lethargic and anorectic and die. Diagnosis involves detection of viral particles by electron microscopy. Treatment consists of surgical removal of single masses, although regrowth is common. Isolation of affected lizards is perhaps the only way to prevent spread.

A papilloma-type virus also appears to affect Bolivian side-neck turtles and appears as white, oval skin lesions distributed over the head. Ulcerative shell lesions are also seen, primarily on the plastron. Diagnosis is made by identifying viral particles on electron microscopy. Treatment is supportive and palliative, and affected animals should be isolated.

Iridoviruses: Iridoviruses have been reported in various chelonians, snakes, and lizards. An iridovirus was found in a Hermann's tortoise, which died without prior signs of disease. Progressive anemia in Australian geckos has been linked to an iridovirus. Clinical signs range from none to stomatitis, rhinitis, conjunctivitis, tracheitis, edema, and cutaneous abscessation. In some cases, the recovered iridoviruses have been closely related to amphibian ranaviruses. Although the clinical importance of several of these viruses remain unclear, iridoviruses deserve close attention, especially in chelonians.

Other Viruses: Many other viruses continue to be isolated from reptiles, but little information exists regarding disease, diagnosis, control, and treatment. Two nonpathogenic rhabdoviruses were isolated from *Ameiva* sp lizards. In addition to herpesviruses and adenoviruses, parvoviruses and picornaviruses have been found in the intestinal tract of snakes, but their exact role is unknown. A poxvirus-like virus has been isolated from circumscribed cutaneous lesions in a caiman and from dermal lesions in a tegu. A reovirus isolated from Chinese vipers was associated with death without prior signs of illness.

PARASITIC DISEASES

Ectoparasites: A limited number of ectoparasites are seen, except on wild and newly acquired reptiles. Mites are distributed worldwide, and most reptilian species are affected. Reduced vitality and, in heavy infestations, death due to anemia may occur. Skin of affected reptiles appears coarse, and dysecdysis is frequent. The common snake mite (*Ophionyssus natricis*) and lizard mite (*Hirstiella* spp) are generally <1.5 mm long and are often found around the eyes, gluttal folds, or any other indentation on the reptile. Mites may also be associated with mechanical transmission of *Aeromonas hydrophila*, a variety of other bacteria, rickettsial agents, and probably viruses. Mites are visible to the naked eye but are hard to see in small numbers. If mites are suspected, gently rubbing the reptile while it is standing over a piece of white paper will allow the mites to be seen after they have fallen off. Affected reptiles often spend an inordinate amount of time soaking to drown the mites. Examination of the water dish can reveal the drowned remains of many mites. The gluttal folds, involutions around the face, and the space between the eye and its orbit are favored areas and should be inspected carefully.

There are many methods of treatment; however, a permethrin is specifically licensed for use in reptiles, and ivermectin is also frequently effective in squamates.

Ticks are common on reptiles, and heavy infestations may result in anemia. Argasid ticks may cause paralysis, with muscle degeneration at the site of the bite. The transmission of green-lizard papilloma-associated virus, several hemogregarines, and the filarid worm *Macdonaldius oscheri* have been associated with ticks. Ticks can transmit *Ehrlichia ruminantium*, the cause of heartwater, and consequently the importation of African reptiles has been controlled. Ticks can be removed manually or by using permethrin spray. Systemic antibiotics are often indicated because of systemic infections associated with multiple cutaneous bite wounds and, potentially, with transmission of pathogenic bacteria.

Leeches have been found on the legs, head, neck, and in the oral cavity of a variety of turtles and crocodilians.

Chelonians frequently have cutaneous myiasis. Bot flies (including *Cuterebra* sp) create a cutaneous wound in which to lay their eggs, which hatch into bots that live in cyst-like structures until mature enough to

leave the wound. These lesions are characterized as a lump under the skin; on closer inspection, they have an opening often lined by a black, crusted material. Treatment consists of slightly expanding the natural opening and manually removing the bot with a forceps. The wound is then flushed with povidone-iodine, chlorhexidine, etc, and an antibiotic ointment is instilled. Systemic antibiotics are indicated in reptiles that have multiple lesions. Cutaneous myiasis also occurs secondary to existing wounds, and maggots must be manually removed and the underlying lesion treated with topical and systemic antibiotics as needed. During heavy fly season, turtles often are housed indoors or with screens over their enclosures to offer some protection.

Ectoparasite infestations are best prevented by thorough screening and quarantine of all new animals entering a collection.

Helminths: The stress of captivity coupled with a closed environment predisposes to heavy burdens of parasites with direct life cycles. Every effort must be taken to rid reptiles of parasite burdens and the environment of intermediate hosts.

Pathogenic trematodes infect the vascular system of turtles and infect the oral cavity, respiratory system, renal tubules, and ureters of snakes. Chemotherapeutic agents have not effectively eliminated these parasites, although praziquantel has shown some promise.

Tapeworms are found in all orders of reptiles but are rare in crocodilians. Reptiles may act as the definitive, paratenic, or intermediate hosts for a large number of species. Although most species of tapeworms are generally nonpathogenic in wild reptiles, weight loss and death have been reported. The complex life cycle of cestodes and restricted geographic range of intermediate hosts limit the number of cases in captive reptiles. When present, proglottids may be found around the cloaca, or typical cestode ova may be isolated from feces. Treatment is with praziquantel, repeated in 2 wk. Plerocercoids of the genus *Spirometra* may be found as soft swellings in the subcutis. These larval stages may be removed surgically.

Nematodes are found in all orders of reptiles, and several genera are important. *Strongyloides* spp frequently inhabit the intestinal tract of reptiles; larvae are seen in the respiratory tract and respiratory exudate. In snakes, the larvae have been seen within granulomas distributed

throughout the body wall, suggesting that the larvae may be able to penetrate the skin. Overwhelming parasitism is common when poor hygiene results in highly contaminated environments. *Rhabdias* and related species have been found in the lungs of a variety of snakes; embryonated ova may be found in the oral cavity and in lung aspirates. Embryonated ova and free larval forms may be seen in the feces. Larvae resembling *Rhabdias* also have been seen in the gingiva of snakes with stomatitis. Infections often are subclinical but may be associated with secondary bacterial pneumonia. In severe cases, death may result.

Stomach worms of the genus *Physaloptera* are seen in lizards. Gastric ulceration may occur in severe infections. Ova are elliptical and may be embryonated. Numerous snakes are infected by *Kalicephalus* spp. This hookworm, capable of transcutaneous infestation, prefers the upper GI tract and causes erosive lesions at sites of attachment. Ova are similar to those of *Physaloptera* spp. Large granulomas caused by the above species have also caused GI obstruction in snakes.

Ascarids frequently infect reptiles. Ova are similar to those of ascarids from mammalian hosts. Severe lesions and death may be seen in infected snakes. Clinically infected snakes frequently regurgitate partially digested food or adult nematodes and are anorectic. The major lesions are large granulomatous masses in the GI tract; they may abscess and perforate the intestinal wall.

Many other nematode species may be found in reptiles. Capillarid, trichurid, and oxyurid ova may be found on fecal examination. The nonpathogenic larval and oval forms of parasites of prey items (eg, *Syphacia obvelata*, the mouse pinworm) may be found when infected prey is consumed. Treatment should be attempted when evidence of parasitism is present.

Some larval forms of nematodes are suspected or confirmed to penetrate the skin (eg, *Strongyloides* and *Kalicephalus*), bypassing the oral reinfection route. The subtle nature of reinfection by this route often goes unnoticed until the reptile is overwhelmed by parasites. Close attention to the immediate removal of excreta and fastidious sanitation help reduce parasite burdens in captivity.

Dermal lesions caused by the spirurid worm *Dracunculus* spp may be seen. Numerous species of spirurids infect the mesentery, coelomic cavity, and blood vessels. These worms require a mechanical

vector, so their incidence is reduced in captive-bred reptiles or in reptiles that have been in captivity longterm. Treatment consists of increasing the environmental temperature to 95°–98°F (35°–37°C) for 24–48 hr. However, some “cool-adapted” reptiles may not tolerate this treatment.

Pentastomes: Pentastomes are found in a wide variety of reptiles, with variable pathogenicity. Pentastomid infections are occasionally associated with pneumonic signs, but these primitive arthropods can inhabit any tissue, and symptoms will vary with their migration path and tissues responses. Pentastomes were initially found primarily in tropical poisonous snakes; however, as more necropsies on reptiles were performed, more were found. Necropsy results from 88 bearded dragons showed that 11 were infested with pentastomes. No truly effective treatment has been reported, but praziquantel at dosages of 8 mg/kg and ivermectin at 5–10 times normal dosages have been shown to reduce ova numbers being shed but have not eliminated the worms. The most novel approach has been to endoscopically locate and mechanically remove all the adult pentastomes. Recognition of pentastomal infestations is important, because these parasites are thought to present a zoonotic risk.

Protozoal Diseases: Numerous protozoans are found on reptiles; most are harmless commensals. The most serious protozoal pathogen of reptiles is *Entamoeba invadens*. Clinical signs are anorexia, weight loss, vomiting, mucoid or hemorrhagic diarrhea, and death. Entamoebiasis may be epidemic in large snake collections. Herbivores appear less susceptible than carnivores; a number of reptiles that seldom become affected or

die can serve as carriers, including garter snakes, northern black racers, and box turtles. Although most turtles are resistant, the giant tortoises are susceptible. Other resistant groups include eastern king snakes, crocodiles, and cobras (possibly as an adaptation that allows them to eat snakes). Most boas, colubrids, elapids, vipers, and crotalids are highly susceptible. Transmission is by direct contact with the cyst form. Hepatic abscesses containing numerous *E. invadens* trophozoites are common in chronic cases. At necropsy, gross lesions may extend from the stomach to the cloaca. The intestine shows areas of ulceration that tend to coalesce, caseous necrosis, edema, and hemorrhage. Multifocal abscesses in a swollen, friable liver are seen in the hepatic form. Identification of trophozoites or cysts in a wet preparation of fresh feces or tissue impressions, or in histologic sections, is diagnostic. Turtles and snakes should not be housed together.

E. invadens is best treated with metronidazole. Tetracycline and paromomycin have been used but are considered ineffective against the hepatic form. Strict sanitation and hygiene measures should be observed.

Flagellates, especially *Hexamita* spp, have been reported to cause urinary tract disease in chelonians and intestinal disease in snakes. The “Giardia” seen in some cases of enteritis in snakes may actually be *Hexamita* or one of the relatively nonpathogenic flagellates that inhabit the intestinal tract of snakes. Differentiation between the species requires expertise, and special preservatives and stains are required to identify most of these organisms. Metronidazole has been used to treat flagellates. Indigo snakes, king snakes, and uracoan rattlers should be treated at the low end of this dosage range. Early studies with benzimidazoles are very encouraging and should also be considered as a viable therapy.

Several coccidial organisms have been reported: *Klossiella* from the kidney, *Isospora* from the gallbladder and intestine, and *Eimeria* from the gallbladder. The severity of disease varies with the coccidia and affected species. Because of their direct life cycle, these parasites can increase to tremendous numbers, especially in immunosuppressed reptiles. Oocysts are not fragile and can survive for weeks in a dessicated condition. Fastidious, daily cleanings are necessary to remove all feces and feces-contaminated food and water. Insects and other food items must be removed on a daily basis, because they are

Entamoeba invadens trophozoite (left) and cyst (right) (1,000× oil immersion). Courtesy of Dr. Stephen Divers.

another source of contamination (eg, crickets may eat the oocysts while gathering fluid from the feces). Persistent treatment using sulfadimethoxine is required until infection is resolved, often taking 2–4 wk; success should be measured by serial fecal samples.

Trimethoprim-sulfa is another useful drug to treat coccidia. Care should be taken when using sulfa in reptiles with dehydration or renal compromise. If in doubt, a balanced electrolyte solution should be administered PO at appropriate dosages. Even under the best conditions, treatment will eliminate coccidia in only 50% of cases. Treatment resulting in a reduction of coccidia is still important, and coccidial numbers should be periodically monitored.

Plasmodial (malarial) organisms, as well as other intracellular blood protozoans, have been reported in reptiles. Their significance is unknown, and treatment is not considered necessary.

Cryptosporidiosis is frequently reported in association with postprandial regurgitation (snakes, *Cryptosporidium serpentes*), diarrhea (lizards, *Cryptosporidium saurophilum*), marked weight loss, and chronic debilitation. The organism affects the GI mucosa, resulting in marked thickening of the gastric rugae and loss of segmented motility. A mass in the gastric region is often, but not always, palpable in snakes, and contrast radiographs or endoscopic examination reveals rugal thickening. Many lizards, including Old World chameleons and savannah monitors, are affected primarily in the intestine. Mucosal thickening develops as a result of invasion by numerous cryptosporidial organisms. Diagnosis can be made using acid-fast stains on fresh feces or on the coating from regurgitated items or endoscopic gastric biopsies, which will identify the tiny oocysts. Although several treatments have been suggested, none (except for hyperimmune bovine colostrum) have been consistently effective. Intensive supportive care will often stabilize and help prolong the life of the affected reptile. Euthanasia is a valid option for infected reptiles. Cryptosporidiosis was previously considered a zoonotic disease; however, it now appears that the species commonly found in reptiles do not affect mammals.

ENVIRONMENTAL DISEASES AND TRAUMATIC INJURIES

Beak anomalies in chelonians inhibit feeding and are often associated with secondary nutritional hyperparathyroidism

leading to hypocalcemia, distortion of the skull, and abnormal occlusion and wear. Increased levels of dietary protein may contribute to accelerated growth of these tissues, while a lack of abrasive food items limits natural wear in captivity. Treatment consists of trimming or grinding the beak into a more normal conformation. The condition usually recurs because of primary malocclusion, and longterm maintenance may be required.

Males of many species can be highly territorial and exhibit **aggression** toward other males or toward females during mating periods. Injuries to cagemates can be severe and are best avoided by separating animals at feeding and reducing the number of animals allowed in a breeding group. When separated individuals are placed together for breeding, they should be carefully monitored. If reptiles must be kept together, it is vital the enclosure is large enough to avoid competition for resources, especially basking areas, and retreats. Food and water is best placed in multiple locations to prevent dominant cohabitants from intimidating the others.

Fractures due to trauma are commonly seen in all species. They are often associated with secondary nutritional hyperparathyroidism in chelonians and lizards. Long bones may be repaired with lightweight external coaptation. A simple way of splinting the legs of lizards is to tape the injured leg to the body (front legs) or the tail (rear legs). These splints are tolerated well and protect the injured limb from further injury.

Injury to the spinal column must be assessed individually; when clear displacement is not evident, radiographic evaluation should be performed. Spinal injuries caudal to the vent may be tolerated, but injuries cranial to the vent frequently result in constipation and retention of urates, with variable limb movement. Environmental changes (eg, low branches, shallow water dish, nonabrasive substrates) and teaching the owner how to empty the cloacal content will allow the lizard to survive. Because these fractures are often secondary to secondary nutritional hyperparathyroidism, a thorough history of the reptile's husbandry may also reveal the need for nutritional changes.

Aggressive iguanids may frequently lash out with their tails and damage them against the vivarium glass or other furniture. Continual damage can lead to **ischemic necrosis** of the tail. Secondary infection may follow and progress to osteomyelitis. In some cases, septic emboli may lead to tail infection. In either scenario, tail

amputation, in addition to investigation and correction of predisposing factors, is required. Radiography should precede surgery, because osteomyelitis may appear more cranial than the external lesion. Tail amputation in iguanids should be performed under anesthesia, taking advantage of the lizard's ability to perform autotomy. The tail is simply bent and twisted sharply to cause a fracture through a fracture plane. Muscle fibers are trimmed, but the tail is left unsutured to encourage regeneration. Clean postoperative conditions are essential, but antibiotics are not. Tail necrosis in reptiles that do not exhibit autotomy requires a more traditional surgical amputation with primary closure of the wound.

Burns are generally associated with unscreened incandescent lights or other heat sources. Fluid loss, dehydration, and septicemia are common sequelae. However, many can be treated by cleansing the site, applying antibiotic ointment, providing analgesics, and placing the reptile in a clean, dry environment. Silvadene cream is the preferred topical dressing, because it is water miscible and is effective against yeast and bacteria, including *Pseudomonas* spp. In uninfected burns, sterile skin protectants can be applied to the area to act as a "second skin." These products allow access to the water and help keep contaminants out. In severe burn cases, fluids are given to offset fluid losses, and systemic antibiotics are required to prevent secondary infection. Pain management and assisted feeding techniques may also be applied.

Traumatic injuries to turtles may result in fractures to the plastron, the carapace, or both. Repairs should be delayed in anything other than fresh wounds. Contaminated tissues should be gently debrided, flushed, and appropriately bandaged using a wet-to-dry technique. Holes in the bandages can be created to allow the legs to remain exposed. If obvious infection is present, samples should be submitted for microbiology before systemic antibiotics are started. Once stable, the wounds should be cleaned again, and the fractures realigned under general anesthesia and repaired using zip ties. These injuries also can be repaired using epoxy resin or a quick-setting, epoxy glue layered over fiberglass screen. Dental and orthopedic cements have also been used to stabilize fractured tissues. Healing is slow and may require 4–6 mo or longer.

Dysecdysis, or incomplete or inadequate skin shedding, may be caused by low humidity, ectoparasitism, nutritional deficiencies, infectious diseases, lack of suitable abrasive surfaces, or even decreased thyroid

function. Often, eyecaps or annular bands on the tail or digits are retained. Eyecaps are best treated by application of an ophthalmic ointment bid for several days until they either fall off or can be grasped with a pair of fine forceps and carefully removed. Patience is advised—eyecaps should never be forced off because of the possibility of damaging the spectacle.

Recalcitrant, retained sheds are best treated by soaking the reptile in warm (77°–85°F [25°–29°C]) water for several hours and then pulling gently with a gauze sponge. A humidity chamber also works well and can be as simple as a 10-gal. aquarium with an undertank heater in which wet bath towels are placed. The top can be covered with a light cloth to increase humidity levels, but excessive heat must be avoided and can be relieved by allowing more ventilation if needed.

Prey-induced trauma, caused by live, uneaten invertebrate and vertebrate prey, can frequently cause severe trauma, with secondary infection and abscessation. Whenever possible, rodents that have been freshly killed or frozen and thawed should be offered to prevent injury to the reptile (dead prey should be discarded after 12 hr if uneaten). The feeding of live prey is illegal in many countries. Fresh bite wounds may be treated by cleansing with povidone-iodine (diluted 1:10). Parenteral antibiotics, based on results of culture and sensitivity tests, should be used. Untreated wounds frequently abscess and are seen as a soft or hard swelling. The abscess, including the fibrous capsule, should be removed surgically, and the defect sutured. Open or draining abscesses should be curetted, flushed with povidone-iodine, and parenteral antibiotics administered. Antibiotic ointments with proteolytic enzymes may be helpful. (See also ABSCESSES, p 1991.)

METABOLIC AND ENDOCRINE DISEASES

Gout: Gout is seen in all orders of reptiles; visceral and articular forms have been reported. Radiographs often reveal mineralized tophi in affected organs and joints. Primary visceral gout is the accumulation of urate microcrystals in organs secondary to a chronic hyperuricemia and is generally caused by excessive protein in the diet. Secondary visceral gout is due to chronic hyperuricemia from such causes as dehydration and renal insufficiency. Gout can be very debilitating, causing discomfort to the point that some reptiles refuse to move, eat, or drink.

Primary visceral gout is treated by correcting the diet. Secondary visceral gout is treated by attempting to correct the underlying problem, be it dehydration or renal disease. The prognosis is poor in advanced cases. Allopurinol is effective at reducing blood uric acid levels. Drug administration usually must be longterm, because signs typically recur if treatment is discontinued. Euthanasia must be considered in reptiles in which movement is painful and appetite becomes suppressed.

Metabolic Bone Diseases: Secondary nutritional hyperparathyroidism is the most common bone disease seen in reptile practice. It relates to poor diet (low calcium to phosphorus ratio, vitamin D₃ deficiency) or poor husbandry (lack of UVB light, inadequate thermal provision). Affected reptiles are generally rapidly growing herbivorous and insectivorous lizards and chelonians. Signs include anorexia; lethargy; an inability to walk normally; swollen/distorted mandible, maxilla, and/or long bones; limb and spinal pathologic fractures; cloacal prolapse; muscle fasciculations; and tetany. Diagnosis requires radiography to document generalized demineralization of the skeleton and low plasma levels of 25-dihydroxycholecalciferol. Findings in the late stages include hyperphosphatemia and low total and ionized calcium. Treatment of critical cases requires fluid therapy, nutritional support, and parenteral calcium therapy if hypocalcemic. Correction of the diet and husbandry are the mainstays of successful therapy.

Secondary renal hyperparathyroidism occurs in adult reptiles and is associated with hyperphosphatemia, soft-tissue calcification, osteodystrophy, and hypocalcemia. Provisional diagnosis generally rests on history, radiography, and plasma biochemis-

try, although a definitive diagnosis requires demonstration of reduced renal function (eg, iohexol clearance) and renal pathology (eg, renal biopsy).

Reports of **hypertrophic osteopathy** are uncommon and currently appear to be limited to lizards with extensive periosteal proliferation beginning in the distal long bones and progressing proximally. The pathogenesis is unknown, but theories include chronic anoxia, toxins, and vagal neurologic pathways.

Miscellaneous Endocrine Disorders:

Endocrine diseases are not often documented in reptiles. **Diabetes mellitus** has been reported in chelonians; glucosuria and hyperglycemia are the primary findings, and polyphagia may or may not be apparent. The etiology is often undetermined but has been associated with gastric neuroendocrine carcinomas in bearded dragons. Pancreatectomy in lizards may result in hypoglycemia, implying that other hormones, such as glucagon or somatotropin, may play a role in the pathogenesis of diabetes mellitus in reptiles.

Hypothyroidism and thyroid hyperplasia have been reported in Galapagos Islands tortoises. It has been speculated that high amounts of dietary iodine in the natural diet may play a significant role. Feeding goitrogenic foods to tortoises has been incriminated in development of this condition. The primary clinical sign is subcutaneous edema.

Hyperthyroidism has been reported in a female green iguana that presented with polyphagia, loss of the dorsal spines, hyperactivity, increased aggression, tachycardia, and a bilobate mass palpable anterior to the thoracic inlet. Surgical thyroidectomy returned the lizard to a euthyroid state.

REPRODUCTIVE DISEASES

Dystocia (Egg Retention): Sterilization is rarely performed in reptiles, and therefore reproductive disease remains a common presentation. In oviparous reptiles, eggs (demonstrating various degrees of shell mineralization) may be retained, whereas in (ovo)viviparous species unfertilized ova or fetuses may be seen. In some cases, abnormal and persistent preovulatory follicles may also be diagnosed as spherical masses that fail to ovulate or resorb. Dystocia is generally not an acute presentation as in mammals or birds, and reptiles may retain eggs/fetuses for weeks or even months after the normal timing of laying/birth. Coupled with imprecise details of copulation, this

Secondary nutritional hyperparathyroidism in a green iguana. Note the swollen, fibrous long bones and maxilla (insert). Courtesy of Dr. Stephen Divers.

can often make the distinction between normal gravidity and dystocia difficult in otherwise clinically healthy reptiles. Certainly, severe metabolic disturbance and infection can exacerbate the issue. In general, a presumptive diagnosis can be achieved through palpation and diagnostic imaging, especially radiography and ultrasonography. Hematology and plasma biochemistry may also help identify inflammatory/infectious changes and metabolic disturbances, especially hypercalcemia.

Unless there is evidence of acute disease, medical management may be tried, although it frequently fails. Improvements in husbandry (especially provision of solitude and a suitable substrate), corrections of any metabolic disturbances, subcutaneous dilute oxytocin/vasotocin, and potentially prostaglandin ($\text{PGF}_{2\alpha}$ and PGE) may be helpful. In most cases, surgical ovariohysterectomy is required (unless a valuable breeding animal) after medical stabilization.

Vent Prolapse: A variety of prolapses may be seen emanating from the vent of reptiles, including cloaca, colon, oviduct, hemipenes/phallus, and (if present) bladder. Common causes include dystocia, copulation trauma, cloacitis, bacterial/fungal/parasitic infection, metabolic disease (especially secondary hyperparathyroidism), cystic calculi, renal disease, neoplasia, or any space-occupying lesion within the coelom causing tenesmus. It is important to identify the prolapsed organ, because some (eg, phallus/hemipenes) can be amputated, whereas others (eg, cloaca, colon, bladder) cannot. The prolapse should be gently

cleaned, and the application of hyperosmotics may help reduce swelling and facilitate replacement. However, it is also important to determine the cause to prevent recurrence.

Prolapses of the hemipenes and phallus can be amputated after induction of general anesthesia or intrathecal (caudal spinal) block; this will render the animal infertile. If the prolapsed tissue is viable and can be replaced, purse-string sutures of the vent should be avoided, because they tend to deform the vent and may interfere with the urogenital openings. In such cases, it is preferable to use a transcutaneous cloacopexy technique. If the tissue is not viable, then careful and detailed surgery is required when attempting debridement and resection-anastomosis of the cloaca, colon, or bladder and often necessitates both cloacal and coeliotomy approaches.

NEOPLASTIC DISEASES

Neoplasia is becoming increasingly common as captive reptile populations age, and it should always be included in the differential diagnosis of disease. In addition to spontaneously developing neoplastic diseases, tumors have been associated with parasitism and oncogenic viruses. Surgical or endoscopic biopsies are preferred for diagnosis. Techniques such as radiography, CT, MRI, ultrasonography, endoscopy, cytology, histopathology (biopsy), and viral isolation provide improved diagnostic capabilities. Once neoplasia is diagnosed, treatment protocols similar to those used in other animals could be considered.

RODENTS

The order Rodentia, with ~2,020 living species placed in 28 families (approximately half of all mammalian species), is the largest order of mammals. They are found worldwide except in Antarctica and on some oceanic islands. Ecologically, they are remarkably diverse. Some species spend their entire lives above the ground in the canopy of rainforests; others rarely emerge from beneath the ground. Some species are aquatic, whereas others are equally specialized for life in deserts. Many rodents are to some degree omnivorous; others are

highly specialized, eating, for example, only a few species of invertebrates or fungi.

Despite their morphologic and ecologic diversity, all rodents share one characteristic: a highly specialized dentition for gnawing. Rodents have a single pair of upper and a single pair of lower incisors. Between each incisor and the first cheek tooth is a toothless interval called the diastema. The incisors are rootless and grow continuously. Enamel is deposited on the anterior and lateral incisor surfaces; the posterior incisor surface is dentin. During

gnawing, as the incisors chisel against each other, they wear away the softer dentin, leaving a sharp enamel edge. This "self-sharpening" system is very effective and is one of the keys to the enormous ecologic success of rodents.

Using the incisors together to chisel away at a surface requires muscle that forcefully brings the lower jaw forward. The masseter muscle does this in rodents. Rodents are traditionally divided into three groups based on how the masseter attachments evolved: sciurormorphs (eg, squirrels, beavers), hystricomorphs (eg, New and Old World porcupines, guinea pigs, jerboas), and myomorphs (eg, New and Old World rats and mice, hamsters, gerbils, voles).

Most modern rodents have adapted to eat seeds, which links them to the evolution of modern grasses. All rodents evolved from shrewlike carnivorous or insectivorous ancestors and have since diverged into various families and subfamilies.

Despite the large number of rodents, only a few species are owned as pets. The common pet rodents are chinchillas, gerbils, guinea pigs, hamsters, mice, and rats. Less common pet rodents are African giant pouched rats, degus, prairie dogs, spiny mice, and voles.

As prey animals, rodents do not show obvious signs of pain or disease until near death. Consequently, sick rodents are often presented late in disease progression when the prognosis is more guarded. Dermatologic conditions make up 25% of rodent cases presented for small animal consultation. Traumatic injuries are also frequent and seen in rodents of all ages. Although some diseases are caused by shortcomings

in husbandry, often rodents subjected to "benign neglect" live long, healthy lives. The adverse effects of overfeeding pet rodents are seen in the early development of many spontaneous tumors and degenerative diseases.

CHINCHILLAS

Chinchillas are slender-bodied, medium-size rodents with short forelimbs and long muscular hindlimbs that give the animal a rabbitlike appearance. The head, eyes, and ears are relatively large, and the bullae are greatly expanded. Chinchillas have long gestation periods and deliver fully furred young with open eyes.

In the wild, chinchillas live in relatively barren areas of the Andes of Northern Chile at elevations of 3,000–5,000 m. Chinchillas live in burrows or rock crevices but are well adapted for running. They dust bathe, are vegetarian, and are active throughout the year. They are gregarious, living in groups of several hundred. All domestic (USA) chinchillas are descendants of 13 individuals brought to the USA in 1927.

Biology

Chinchillas come in a variety of colors. The original chinchilla fur color in the wild was mottled yellow-gray. Through selective breeding, the most common color seen is dark blue grey (the dominant fur color). Other colors have emerged and include the dominant colors of beige, white, and ebony, and the recessive colors of sapphire, violet, charcoal, and velvet. Eye color may be black, pink, or red due to fur color genes.

TABLE 30 BIOLOGIC DATA OF PET RODENTS

	Chinchilla	Gerbil	Guinea Pig	Hamster	Mouse
Life span ^a (yr)	4–15	2.5–4	4–8	1–2	1–2
Adult male body wt (g)	400–500	45–130	800–1,600	85–140	20–30
Adult female body wt (g)	400–600	55–135	700–1,300	95–120	18–35
Sexual maturity (wk)	32–36	9–12	10–12	4–7	6–8
Gestation (days)	111	24–26	63–69	16	19–21
Litter size (average)	2	1–12	3–4	6–10	5–12
Weaning (days)	42–56 ^b	21	30 ^b	21–30	21–23

^a Life span data is for typical life span range in pet rodents. Life spans exceeding these times have been recorded for rodents in research studies.

^b Guinea pigs and chinchillas have precocious young that can eat some solid food at 7–14 days. Early weaning results in lower body wt and social maladaptation in later life.

Ten different sounds comprise the vocal repertoire of chinchillas, depending on the behavioral context. Different sounds are made during exploratory behavior, predator avoidance, sexual behavior, and social behavior, including social contact and agonistic (defensive and offensive) behavior. In addition, chinchillas can raise and lower the tones of the calls they make. All chinchillas have a similar cry that is used commonly from birth.

The female chinchilla has an estrous cycle of 38 days. Females are seasonally polyestrous, and the breeding season is November to May in the northern hemisphere. The gestation period averages 111 days. Generally, the female will have two litters a year with 1 to 6 young (average 2) per litter. Young become sexually mature at 8 mo of age. Chinchillas have a long life span, reported to be up to 20 yr.

Sexing chinchillas (and guinea pigs) can be difficult. In females, a vaginal closure membrane seals the vaginal orifice at all times except estrus and parturition. The vaginal orifice is U-shaped and situated between the anus and the mound-shaped urethral orifice. It is difficult to distinguish when closed and is indicated by a slightly raised, semicircular area. When its closure membrane covers the vaginal orifice, the urethral orifice can be mistaken as a genital opening. The well-developed clitoris of female chinchillas (and guinea pigs) can be manually extruded through the urethral orifice and mistaken for a penis. The vagina is open during estrus. During these times, the vaginal closure membrane dissolves and then repairs. During estrus, there is no vulval swelling. Instead, the perineum changes color, going from a dull pink to a deep red. The perineal color increases dramatically at the time of vaginal perforation and remains intense throughout most of the luteal phase of the estrous cycle.

Male chinchillas do not have a true scrotum. The testes are contained within the inguinal canal or abdomen, and two small, moveable scrotal sacs are next to the anus, into which the caudal epididymis can drop. The external appearance of the scrotal sacs is similar to the nonpendulous scrotum of pigs and cats. The penis is readily apparent below the anus, from which it is separated by an expanse of bare skin. The penis can be manually extruded 1–2 cm when flaccid. The tip of the erect penis extends to the level of the axilla, a distance of ~11 cm.

As with other rodents, the anogenital distance gives the best initial indication of the animal's sex. In males, the anogenital

distance is greater. Extrusion of the penis from the urethral orifice will confirm the sex of the chinchilla, as long as the clitoris is not mistaken for a penis. There are two major differentiating features: the penis is significantly larger than the clitoris, and the extruded penis can be separated and distinguished from the prepuce (whereas the extruded clitoris tends to evaginate, and the clitoral prepuce is not apparent).

Husbandry

Chinchillas are very tolerant of cold but sensitive to heat. The ambient temperature range to which chinchillas are adapted is 65°–80°F (18.3°–26.7°C). Exposure to higher ambient temperatures, especially in the presence of high humidity, can result in heatstroke. A good general rule is to add the unit values of the temperature (Fahrenheit) and humidity, and consider any value >150 to be dangerous. For example, 85°F + 65% humidity = 150. Chinchillas will develop matted fur if kept in a warm (>80°F [26.7°C]), humid environment.

Chinchillas are easily housed in either wire mesh-bottom or solid-bottom cages, although solid-bottom cages are recommended for pregnant females about to have young. Wire mesh spacing in cages should be narrow, because tibial fractures commonly occur in young chinchillas that catch a hindleg in wide floor mesh grating. Chinchillas are shy animals and need a place to hide when in captivity. In the wild, chinchillas conceal themselves in rock crevices. Polyvinyl chloride (PVC) plumbing pipes, especially elbow, Y, and T sections, make ideal hiding places. The pipes should be 4–5 in. in diameter and are easy to sanitize by placing in a dishwasher.

Because chinchillas have a habit of dust bathing, a box containing a mixture of silver sand and Fuller's earth (9:1), 2–4 in. deep should be placed in the cage daily. Dust baths should be provided for ~30 min/day. If dust baths are left in the cage for long periods, they become soiled with feces. When chinchillas do not have access to a dust bath in captivity, the fur becomes matted from oily secretions. Dust bathing often causes irritation of the eyes, resulting in conjunctivitis without associated clinical signs of upper respiratory infection. Excessive dust bathing has been reported to result in pulmonary epithelial hyperplasia and granulomas.

Chinchillas have a high requirement for dietary fiber. Their diet should mainly consist of high-quality grass hay. Pelleted chinchilla diets are commercially available

and should be used to supplement the diet. Guinea pig or rabbit pelleted diets have also been used successfully to supplement the diet. Like rabbits and guinea pigs, chinchillas produce two types of fecal pellets: one nitrogen-rich intended for cecotrophy, and one nitrogen-poor delivered as fecal pellets.

Urinary calculi, urolithiasis, metastatic renal calcification, and nephritis are reported occasionally. Calculi are typically composed of calcium carbonate. Such conditions are often associated with feeding a diet high in calcium and low in phosphorus, such as alfalfa hay.

Polygamous breeding colonies are common among chinchilla ranchers, and a system of individual female housing has been devised that allows a single male to serve 12 females. A variety of breeding techniques have been used successfully, and mating is facilitated by observing changes in the vaginal closure membrane and performing vaginal cytology. Pregnant females do not make a nest.

Chinchillas possess well developed and anatomically elaborate male accessory reproductive glands. The secretions from these glands form a hard plug that remains in the female tract after copulation. In chinchillas, the vesicular gland provides the bulk of the accessory gland secretions, and the fluid hardens or gels when mixed with prostatic secretions. A 2–3 in. long, 1-in. diameter, irregularly shaped, firm, waxy plug is often found in the female's cage after mating.

Physical Examination

The chinchilla's overall appearance and behavior should be noted. Sick chinchillas may show weight loss, hunched posture, abnormal gait, scruffy fur, or labored breathing. They may be lethargic or unresponsive to stimulation. Chinchillas should be handled calmly and gently to minimize stress. Docile, nonpregnant animals can be removed from a cage by grasping and lifting the base of the tail while using the opposite hand to support the body. Routine restraint can be accomplished by wrapping a towel around the body. Small chinchillas may be grasped gently around the thorax, taking care not to restrict breathing. Pregnant females should not be handled unless necessary. Pregnancy is detectable by palpation at 90 days gestation and may be determined by regular weighing. By day 42 of gestation, weight gain in pregnant chinchillas will increase rapidly.

A protective reaction in chinchillas known as fur slip results in the release of a

large patch of fur, revealing smooth, clean skin underneath. It may also occur with improper handling, fighting, or situations that overexcite a chinchilla. The fur can take several months to regrow and frequently is a different shade. To prevent fur slip, chinchillas should always be handled gently with minimal stress.

Infectious Diseases

Nearly all significant reports on infectious diseases of chinchillas over the past 60 yr come from colonies of chinchillas raised for fur, and most reports of bacterial disease in colonies are ≥30 yr old. Reviews of chinchilla disease often give the false impression that these animals are highly susceptible to infectious disease. However, the incidence of infectious disease in pet chinchillas is low.

Bacterial Infections: Historically, *Pseudomonas aeruginosa* infections, yersiniosis, and listeriosis occurred frequently among fur-ranching chinchillas. Estimates of fur-ranching chinchilla numbers in the USA in 1954 were >100,000 animals. By the mid-1960s, these numbers were reduced significantly to only a few thousand. Reports since 1980 of yersiniosis and listeriosis in chinchillas come almost exclusively from fur-ranching chinchillas in Hungary, Poland, Slovakia, and Croatia. These four European countries supply almost 50% of the 200,000 chinchilla pelts produced annually worldwide.

● Opportunistic bacterial infections in chinchillas can cause disease, localized either to one organ or as septicemia. Affected animals usually are immunocompromised by age, underlying disease, nutritional status, or husbandry-related factors (eg, poor hygiene, poor ventilation, contaminated feed). Members of the family Enterobacteriaceae and *P. aeruginosa* have been associated with significant morbidity and mortality in chinchillas. However, Enterobacteriaceae and *P. aeruginosa* can also be isolated from clinically healthy animals. Therefore, most of these organisms are not considered primary pathogens.

P. aeruginosa infections in pet chinchillas and epizootic outbreaks in fur-ranching chinchillas are the most frequent bacterial diseases reported. Initially, the infection is usually localized to one organ and can be associated with conjunctivitis, enteritis, pneumonia, otitis media and interna, metritis, and abortion. As the infection progresses, systemic spread is common. An acute generalized form with septicemia and

sudden death can occur. *P. aeruginosa* can be part of the normal intestinal flora in healthy chinchillas and has been isolated from 40% of healthy chinchillas. Stress, concurrent disease, or contaminated drinking water predispose to infection and clinical disease. Conjunctivitis is a common initial sign of *Pseudomonas* infection in chinchillas. Anorexia, lethargy, and decreased fecal output often follow. Characteristic pathologic lesions are miliary glycosides in the internal parenchymal organs and a necrotizing typhocolitis. Strains of *P. aeruginosa* that are multidrug resistant have reduced antibiotic susceptibility and are highly virulent and widespread in chinchillas. Antimicrobial drug selection should be based on culture and susceptibility testing. Generally, *P. aeruginosa* is susceptible to fluoroquinolones, third-generation cephalosporins, or aminoglycosides. Topical polymyxin B and gentamicin-containing formulations can be used for empiric treatment because of the low prevalence of isolates resistant to these drugs. Multicomponent *P. aeruginosa* vaccines (formalin-killed bacteria, endotoxin-associated protein and/or toxoids) have been used in fur-ranch chinchillas with some success. However, they are not suitable for pet chinchillas because of their variable immunity against different *Pseudomonas* strains, limited immune response of 6–8 mo, and adverse reactions at the local injection site.

The causative agents of yersiniosis, *Yersinia pseudotuberculosis* and *Y. enterocolitica* occur worldwide in areas of moderate and subtropical climate, and outbreaks in fur-ranch chinchillas are described. *Y. enterocolitica* is the species most frequently isolated from chinchillas. Yersiniosis is an enteric disease that damages epithelium of the ileum, cecum, and colon, resulting in mucosal hemorrhage and ulceration. Lymphoid infiltration results in hypertrophy of Peyer's patches and mesenteric lymph nodes and necrotizing granulomas. Systemic spread results in granulomatous lesions in the lungs, spleen, and liver and death. A chinchilla-type strain of *Y. enterocolitica* (biovar 3, antigen or serovar 1, 2a, 3) persists enzootically among chinchilla stock worldwide.

Listeriosis is common in fur-ranch chinchillas but has not been reported in pet chinchillas. The original scientists who described listeriosis in chinchillas claimed that chinchillas are highly susceptible to infection with *Listeria monocytogenes*. It has not been proved, but unfortunately,

this claim is often repeated. *L. monocytogenes* is an environmental bacterium capable of existing both as an animal pathogen and plant saprophyte. Most cases of listeriosis in animals arise from ingestion of contaminated food, and the disease is common in animals, including chinchillas, fed on silage. Listeriosis is a cecal disease in chinchillas with bloodborne dissemination. The main target organ is the liver, where the bacteria multiply inside hepatocytes. Early recruitment of polymorphonuclear cells lead to lysis of hepatocytes, bacterial release, septicemia, and, in surviving hosts, development of lung, brain, spleen, lymph node, and liver abscesses.

Other recorded infections in chinchillas include clostridial enterotoxemia, salmonellosis, and *Klebsiella* infection. Affected animals display nonspecific septicemic signs such as loss of appetite, respiratory distress, and diarrhea and die within a few days after onset of clinical signs. *Salmonella* epizootics characterized by gastroenteritis and abortion are reported in fur-ranch chinchillas. Case reports of *Salmonella* infection in pet chinchillas have been linked to the presence of pet reptiles or wild birds.

Viral Infections: There are no species-specific viral diseases described for chinchillas. Chinchillas are susceptible to human herpesvirus 1 (HSV-1) and may play a role as a temporary reservoir for human infections. Two case reports exist that describe spontaneous, herpeslike viral infection in chinchillas. Affected animals displayed conjunctivitis and subsequently showed neurologic signs of seizures, disorientation, recumbency, and apathy. Nonsuppurative meningitis and polioencephalitis with neuronal necrosis and intranuclear inclusion bodies were found on histologic examination. In addition, the eyes displayed ulcerative keratitis, uveitis, retinitis and retinal degeneration, and optic neuritis. The clinical signs, distribution of lesions, and the viral antigen suggest HSV-1 is a primary ocular infection with subsequent spread to the CNS in chinchillas.

Parasitic Infections: Protozoa:

Historically, group-housed chinchillas in fur ranches and research colonies had a high prevalence of giardiasis. However, the role of *Giardia duodenalis* (synonym *G. lamblia*) in causing disease in chinchillas is difficult to establish. *Giardia* is rarely found in fecal samples from wild chinchillas, and

healthy chinchillas can harbor *G duodenalis* organisms in low numbers in the small intestine. Experimental infection of healthy chinchillas with *Giardia* cysts failed to induce clinical disease. Predisposing factors, such as stress and poor husbandry, are believed to cause an increase in parasite numbers, resulting in diarrhea and potentially death. Recently weaned animals seem prone to developing clinical signs. Signs of giardiasis in pet chinchillas can include a cyclic sequence of appetite loss and diarrhea, associated with declining body and fur condition. Chinchillas with giardiasis can be treated with metronidazole, albendazole, or fenbendazole. Whether these compounds eradicate *Giardia* cysts completely or only inhibit cyst production is unknown; therefore, treated animals may remain a source of chronic cyst shedding. To prevent reinfection, all animals in contact with infected individuals should be treated, and the environment should be thoroughly disinfected. Wooden cage interior parts such as resting boards should be discarded. *Giardia* cysts remain infectious for up to several weeks in a cool, humid environment.

Toxoplasmosis was commonly found in fur-ranched chinchillas but is now rarely seen. Necropsy lesions include hemorrhagic lungs, an enlarged spleen, and enlarged mesenteric lymph nodes. Chinchillas may also develop focal necrotic meningoencephalitis due to *Toxoplasma gondii*.

Other protozoan infections include *Eimeria chinchilla*, which is seen in fur-ranched chinchillas. Single case reports described in pet chinchillas include hepatic sarcocystosis, *Cryptosporidium* spp gastroenteritis, and *Frenkelia* spp meningitis.

Cestodes and Nematodes: Pet chinchillas have a low prevalence of nematode and cestode infections. Outbreaks of cerebral nematodiasis caused by the raccoon ascarid *Baylisascaris procyonis* are reported in chinchillas housed outside in high northern American climates. An orbital cyst due to *Taenia coenurus* has been reported in a pet chinchilla with exophthalmos.

Fungal Infections: There are two reports of *Histoplasma capsulatum* infection in chinchillas. At necropsy, there was pulmonary hemorrhage, bronchopneumonia, and pyogranulomatous splenitis and hepatitis, with the organism seen in numerous giant cells. *H capsulatum* was cultured from timothy hay used for food.

Dermatophytosis is uncommon in chinchillas. *Trichophyton mentagrophytes* is the dermatophyte most commonly isolated, although *Microsporum canis* and *M gypsum* have been incriminated in outbreaks of spontaneously occurring dermatophytosis. Infected chinchillas show small, scaly patches of alopecia on the nose, behind the ears, or on the forefoot. Lesions may appear on any part of the body, and in advanced cases a large circumscribed area of inflammation with scab formation occurs. Although most mycologic studies of chinchillas are based on animals with clinical signs, fungal cultures of fur-ranched chinchillas show a 5% incidence of *T mentagrophytes* in animals with normal skin and a 30% incidence in animals with fur damage.

Diagnosis of dermatophytosis is based on appearance of lesions and isolation of the causative agent by using dermatophyte test medium (DTM). Wood's lamp examination is rarely helpful, because most cases are caused by *T mentagrophytes*, which does not fluoresce under ultraviolet light. Treatment consists of either itraconazole (10 mg/kg/day, PO) or terbinafine (30–40 mg/kg/day, PO) for 4–8 wk. Dermatophytosis is contagious to people and other animals.

Metabolic and Nutritional Disorders

Systemic disease or painful conditions may result in secondary GI problems with nonspecific clinical signs such as anorexia, decreased fecal production, and lethargy. Identifying the underlying cause is critical to improve the outcome and reduce chance of recurrence. The initial diagnostic evaluation should consist of whole body radiographs, fecal parasite examination, fecal cytology, and fecal culture for enteric opportunistic pathogens (eg, *E coli*, *P aeruginosa*). Urinalysis, plasma biochemical analysis, and a CBC help to diagnose non-GI and coexisting metabolic disorders (eg, hepatic lipidosis, ketosis, renal disease) to determine prognosis and therapy. In addition to specific treatment for the primary underlying GI disorder, general treatment guidelines include replacing fluid deficits and maintaining normovolemia by parenteral and enteral fluid therapy, nutritional and caloric support, and analgesia (buprenorphine 0.03–0.05 mg/kg, SC, tid) if a painful condition is suspected.

Cheek tooth crown and root abnormalities are common in chinchillas. Abnormalities related to subclinical dental disease have been reported in one-third of apparently healthy chinchillas presented for routine physical examination. Nutritional

(eg, less abrasive diet in captivity) and genetic causes have been proposed as predisposing factors for development of dental disease. Tooth elongation and its secondary complications, affecting the reserve or the clinical crown or both, are the underlying cause of most clinical signs. Chinchillas are often able to eat and maintain good body condition until severe complications such as soft-tissue trauma from sharp dental spikes or periodontal abscessation have developed. A history of reduced food intake, changed food preferences toward more easily chewed feed items, weight loss, reduced fecal output, saliva-stained skin and fur with crusting and alopecia of the perioral area, wetting and crusting of the chin ("slobbers") and forefeet, epiphora, poor fur condition, and fur chewing are indicative of dental disease. On clinical examination, palpable irregularities of the ventral borders of the mandible and overgrown or irregular occlusal surfaces of the incisor teeth may be found.

A thorough examination of the oral cavity under general anesthesia is required, because 50% of intraoral lesions can be missed when examining the mouth in a conscious chinchilla. Endoscopic-guided intraoral examination is the preferred method. Cheek teeth often show coronal elongation, formation of sharp spikes buccally on the edges of the occlusal surfaces, and widened interproximal coronal spaces containing feed and fur. Loss of tooth substance or brown discoloration of occlusal and interproximal tooth surfaces is often seen. Erosions of the buccal mucosa, gingival hyperplasia, and gingival pocketing are common secondary findings. Radiography is a helpful tool to check tooth position and overgrowth of the roots. CT scans of the skull are useful in early diagnosis of malocclusion.

The prognosis for chinchillas with dental disease depends on the severity of disease, the animal's general condition, and owner compliance. Repeated intraoral examinations and treatments under general anesthesia are necessary to control complications and to maintain an acceptable quality of life for the animal. Treatment consists of removing spikes, reducing elongated crowns, and removing impacted debris in gingival pockets. Instilling doxycycline gel in deep gingival and periodontal pockets reduces periodontal inflammation. Animals with significant periodontal infection can be treated with penicillin G benzathine (50,000 IU, SC, every 5 days). Extraction of cheek teeth

should be limited to severely diseased and mobile cheek teeth. Analgesia is essential after any dental procedure (buprenorphine 0.03–0.05 mg/kg, SC, tid; meloxicam 0.3–0.5 mg/kg, PO or SC, once or twice daily). Chinchillas in advanced stages of dental disease should be fed soft, leafy grass hay, vegetables, moistened pellets, and "critical-care" formulas offered on a dish.

Chinchilla anatomy precludes the ability to vomit. Choking may be observed when the entrance to the trachea is occluded by a large piece of food or bedding or in postpartum females that eat their placentas. Aspiration of tiny particles from the foreign body can irritate the lower respiratory tract and precipitate a suffocating, edematous response leading to drooling, retching, coughing, and dyspnea as the chinchilla attempts to dislodge the foreign body. If untreated, choking may lead to asphyxiation and death. Megaesophagus, which leads to regurgitation and aspiration pneumonia, is described. Affected chinchillas show recurring pneumonia despite treatment. Contrast radiographs are used for diagnosis.

Gastric ulcers are common in young chinchillas and are frequently caused by feeding coarse, fibrous roughage or moldy feeds. Clinically affected animals may be anorectic or asymptomatic. Lesions may only be noted at necropsy, with gastric mucosal ulcers and erosions covered by thick, black fluid. Prevention includes decreasing dietary roughage and feeding a commercial pelleted diet.

Bloat, or tympany, can result from sudden dietary changes, especially overeating. Bloat has been reported in lactating females 2–3 wk postpartum and may be related to hypocalcemia. Gas production from the bacterial flora in static bowel loops rapidly accumulates within 2–4 hr. Affected animals are lethargic and dyspneic, with a painful, distended abdomen. They may roll or stretch while attempting to relieve their discomfort. Treatment may require passage of a stomach tube or paracentesis to relieve gas build-up. Lactating females may respond favorably to calcium gluconate administered IV slowly to effect.

Diarrhea and soft feces are common. Besides infectious causes (eg, parasites, bacteria), inappropriate feeding of fresh green feed high in simple carbohydrates or sudden changes in diet will result in dysbacteriosis and cause soft feces. Owners may describe feces smeared on the cage resting board and the presence of fecal-stained perianal fur. On clinical examina-

tion, the chinchilla may show no signs or, in severe cases, be anorectic, dehydrated, and depressed. Infectious causes are excluded based on the history and by appropriate diagnostic testing. Systemic parenteral antimicrobial therapy (enrofloxacin 10 mg/kg, SC, diluted bid) should be used to treat predominantly gram-negative opportunistic pathogens in chinchillas with severe dysbacteriosis, when an infectious cause is suspected but unconfirmed, or when the animal is in a compromised general condition. Oral drug administration should be avoided, because absorption and effectiveness of oral drugs are decreased when GI function is abnormal. Once an animal is eating and GI function is improved, the oral route can be used. Intestinal secondary yeast overgrowth, caused by *Cyniclomyces guttulatus* (previously *Saccharomycopsis guttulata*) that lines the stomach, is often seen in chinchillas with soft feces. However, increased numbers of this yeast in chinchillas is considered secondary, rather than a cause, promoted by an underlying gastroenteric disease process.

Constipation is more common than diarrhea. Chinchillas may strain to defecate and produce no fecal pellets or have a reduced output of smaller, thin, hard fecal pellets that may be stained with blood. Abdominal palpation reveals firm cecal ingesta and a tense abdomen. Intestinal intussusception is a critical differential diagnosis for absence of fecal pellets. A sudden change in diet, an inappropriate diet of insufficient dietary fiber and roughage, or infectious causes can result in dysbacteriosis, gastroenteritis, ileus, and consequently constipation. Dehydration, anorexia, dental disease, and uterine compression in gravid females may also result in constipation. Chronic cases may lead to rectal prolapse, intestinal torsion, cecal impaction, or colonic flexure. To provide relief, the GI tract should be rehydrated. Enteral fluid therapy (100 mL/kg/day, PO, divided into 4–5 doses) will stimulate the gastrocecal reflex and rehydrate dehydrated ingesta. Chinchillas with abdominal pain may resist enteral fluid therapy, and buprenorphine (0.03–0.05 mg/kg, SC, tid) and parenteral fluid therapy will be required.

Pathologists often see fatty liver without clinical signs or other histologic lesions in routine necropsies of chinchillas. This is most likely due to prolonged anorexia before death.

A few cases of apparent type II diabetes mellitus have been described in overweight chinchillas. Clinical signs may include poor appetite, lethargy, and weight loss.

Diagnosis is based on a history of polydipsia and polyuria, hyperglycemia (≥ 200 mg/dL), and glucosuria. Chinchillas and other hystricognath rodents (eg, guinea pigs, degus, tucos) are unusual in that their insulins exhibit a very low biologic potency relative to pig insulin, yet the receptor-binding affinity is significantly higher, indicating that the efficacy of their insulin on receptors is ~2-fold lower than that of pig insulin.

Hypoglycemia is always a great risk when treating diabetes with recombinant human insulin or porcine insulin. Treatment involves reducing obesity and feeding a diet high in protein, low in fat, and high in complex carbohydrates.

Traumatic Injuries

The predator avoidance mechanism known as fur slip, in which a chinchilla releases a large patch of fur, thus enabling it to escape, should not be confused with the vice of fur chewing. Chinchillas may chew each other's fur, resulting in a moth-eaten coat. Clinically, hair loss is seen along the shoulders, flanks, sides, and paws. The affected areas appear darker because the underfur is exposed. Mothers often transmit the vice to offspring. The higher incidence of fur chewing in commercial herds may be evidence of maladapted displacement behavior. Some clinicians claim affected chinchillas suffer from malnutrition and chew their fur for dietary requirements. Multiple food factors are probably involved in this type of malnutrition, and the exact cause requires further dietary studies.

During breeding, bite wounds that abscess are often seen in group-housed animals. Culture of the abscesses often yields *Staphylococcus* spp. Female chinchillas are larger than males and more aggressive. They are highly selective in their choice of males for mating and will keep "unsuitable" males at bay by urination, kicking, and biting. Bite wounds often result in the loss of pieces of ears and toes. Older females commonly kill a young male housed in the same cage.

The chinchilla's large, delicate ear pinnae are easily traumatized, most often from bite wounds. Therapy includes cleaning the traumatized area and applying topical antibiotics. Suturing large ear lacerations is usually not effective and not recommended. If damage is severe, ear tissue may require significant debridement or partial surgical removal. Trauma can result in rapid hematoma development, with blood and serum filling the space between skin and cartilage. Hematomas should be lanced, and

contents gently removed to avoid further damage to the ear. The skin over the hematoma must remain in contact with the underlying cartilage and should be immobilized by sutures if necessary.

Traumatic fractures of the tibia are commonly seen and associated with the animal catching its hindlimb in a cage bar. The tibia is a straight bone longer than the femur, with little soft-tissue covering; the fibula is virtually nonexistent. Tibial fractures are either transverse or short spiral and generally are associated with bony fragments. Tibias of chinchillas are thin and fragile, and surgical repair can be difficult; complications are common. Soft, padded bandages and lateral splints usually do not provide adequate stability for tibial fractures to heal. External fixation and intramedullary pins, alone or in combination, have been recommended for surgical stabilization of tibial fractures in chinchillas. Restricted exercise in a single-level enclosure, ideally without cage bars, is necessary. The prognosis for tibial fractures is guarded, and complications after surgical fixation are common and include bone-pin loosening and infection, nonunion, necrosis of the distal limb, and self-mutilation. Hindlimb amputation should be considered if surgical fracture stabilization fails or is not indicated. Chinchillas usually adapt very well after amputation.

Reproductive and Iatrogenic Disorders

In chinchillas, the fine structure of the interhemal membrane of the placental labyrinth is hemomonochorial, consisting of a single layer of syncytial trophoblasts. In this respect, the placental labyrinth is similar to that of the guinea pig, another hystricognath rodent. Female chinchillas may experience an unusual puerperal disorder of trophoblastic emboli, resulting in pulmonary embolism.

Chinchillas usually give birth early in the morning and only rarely after midnight. Dystocia is usually associated with the presentation of a single, oversized fetus or malpresentation of one or more kits. Uterine inertia has also been reported as a cause of dystocia. Chinchillas respond well to cesarean section.

Male chinchillas that groom excessively frequently produce small amounts of urine or strain to urinate; repeated cleaning of the penis may mean the animal has a fur ring. This is a ring of hair around the penis and under the prepuce that eventually stops the penis from going back into the prepuce. In

severe cases, an engorged penis is seen protruding 4–5 cm from the prepuce, resulting in paraphimosis. This painful condition may cause urethral constriction and acute urinary retention. Chronic paraphimosis may culminate in infection and severe damage to the penis, affecting breeding ability. Getting fur from a female during copulation is the most common cause of fur ring. However, the fur may come from other males or the same animal, because the condition is also seen in group-housed and single-housed males not exposed to females. Males should be examined for fur rings at least four times a year; active stud males should be examined every few days. In some male chinchillas, the penis will hang out of the prepuce all the time and is not engorged. In these cases, the condition is not caused by fur-ring but by excitement brought on by separation from a mate or exhaustion because of too many females in the same cage. Fur rings can be cut or gently rolled off the penis after applying a sterile lubricant. Occasionally, sedation or anesthesia may be required to remove the fur ring.

Neoplastic Disorders

Despite a life span reported up to 20 years, references on neoplasia in chinchillas are rare. Postmortem examinations of 1,005 fur-ranched chinchillas before 1949 and another 1,000 fur-ranched chinchillas ranging in age from <6 mo to 11 yr between 1949 and 1952 did not list neoplasia as a cause of death. Between 1994 and 2003, 325 chinchillas were presented for clinical investigation at a major university veterinary hospital. Tumors were diagnosed in only three animals (1%). During the same period, the incidence of neoplasia was higher in rabbits and rodents than in chinchillas (guinea pigs, 7%; rats, 34%; and rabbits, 6%). Single reports of tumors in chinchillas include neuroblastoma, carcinoma, lipoma, hemangioma, malignant lymphoma, hepatic carcinoma, and lumbar osteosarcoma.

Miscellaneous Disorders

Age-related Disorders: Aged chinchillas may develop posterior cortical cataracts and asteroid hyalosis.

Cardiac Disease: Heart murmurs ranging from mild to moderate are often heard in young chinchillas. Reports of cardiac disease in chinchillas are scarce, and the significance of heart murmurs in young,

clinically healthy chinchillas remains unknown. There have been anecdotal reports of cardiomyopathy, ventricular septal defect, and mitral and tricuspid valve insufficiencies. Echocardiography is used to differentiate innocent from pathologic murmurs.

Foot Disorders: Foot disorders predominantly affect the hind feet. Lesions can include hyperkeratosis and erythema; less commonly, deep infections or open lesions of the plantar aspect of the feet can develop. In mild cases, environmental improvements and application of glycerin or petroleum-based ointment often resolve the hyperkeratosis and erythema. In severe cases, lesions are surgically debrided, followed by open-wound management and bandaging until healing is complete.

Zoonotic Risk

The major zoonotic risk from chinchillas is potential transmission of *Giardia*. Studies have indicated the existence of seven genetic groups (or assemblages) within *Giardia*, two of which (A and B) are found in both people and animals, whereas the remaining five (C-G) are host-specific. Most chinchilla infections occur with assemblage B. However, genotyping within assemblages A and B of animal species *Giardia* to determine zoonotic potential has not been done. Therefore, *Giardia*-infected chinchillas could be a potential reservoir of zoonotic transmission.

GERBILS

Gerbils are also known as jirds or sand rats. The pet and laboratory gerbil is *Meriones unguiculatus*, commonly known as the Mongolian gerbil. There are 14 species in the genus *Meriones*.

Externally, gerbils are quite ratlike. The head and body length is 95–180 mm, and tail length is 100–193 mm. The average weight is 50–55 g for females and 60 g for males. The covering of fur on the tail is short near the base and progressively longer toward the tip so that it is slightly bushy. Coloration of upper parts varies from pale, clear yellowish through sandy and gray. The sides of the body are generally lighter than the back.

Wild Mongolian gerbils are found in Mongolia, adjacent parts of southern Siberia and northern China, and Manchuria. Gerbils inhabit clay and sandy deserts, bush country, and arid steppes. They have a high degree of resistance to heat stress and dehydration. They are terrestrial, and wild

Mongolian gerbils construct simple burrows (2–3 ft long) in soft soil where they spend most of their time.

Biology

Mongolian gerbils have several coat colors. The wild coat color is agouti and is controlled by an autosomal dominant gene. Sandy gerbils have a recessive color gene and show a yellow to ginger color on the dorsum and the typical creamy white belly of a wild-type Mongolian gerbil. The dorsal yellow hairs have short black tips and a light olive green base. A clear demarcation line between dorsal and ventral color is present. Black gerbils have an autosomal recessive gene; white albino gerbils with red eyes also have an autosomal recessive gene.

Gerbils have a large, ventral abdominal marking gland that is androgen dependent. It attains greater size in males and develops at an earlier age. The gland is used for territorial marking. Females mark their territory after parturition and become more aggressive.

The adrenal cortex produces nearly equal amounts of corticosterone and 19-hydroxycorticosterone. When the gland weight is compared with body weight, the adrenal gland is ~3 times larger in gerbils than in rats. Gerbils have a high proportion of RBCs with polychromasia, basophilic stippling, and reticulocytosis.

Male gerbils attain sexual maturity by 70–84 days. Vaginal opening in females occurs between 40–60 days, followed by 30 days before sexual maturity occurs. Gerbils tend to pair bond, and when older females lose their mate, getting them to accept another is often impossible. Early-maturing females are more likely to breed successfully on first pairing, and the lifetime fecundity of early-maturing females is more than twice that of their late-maturing littermates. Two-thirds of the early-maturing females that do not reproduce after a first pairing will become pregnant after a second pairing, but only 10% of late-maturing females do so.

The gestation period of nonlactating gerbils is 24–26 days, but lactating females always have a prolonged gestation of 27 days. If females are bred in the postpartum period, implantation is delayed, and gestation can be as long as 48 days. Mean litter size ranges from 3 to 7 animals. Young gerbils suckle for ~21 days and begin to eat solid foods at 16 days. In general, day 25 is considered suitable for weaning. The normal life span of a gerbil is 2–3 yr.

Husbandry

The diet of wild Mongolian gerbils consists of green vegetation, roots, bulb seeds, cereals, fruits, and insects. They hoard food and are not normally coprophagic, unless diets lack adequate nutrient value. Gerbils thrive on commercially available pelleted rodent diets with 18%–20% protein but may have deficiency problems when fed primarily homemade diets, sunflower seeds, or table scraps, which lack specific nutrients. Sunflower seeds are high in fat and low in calcium. Pelleted chow (5 g/day) has been recommended to avoid obesity. Gerbils will develop high blood cholesterol concentrations on diets containing >4% fat. This is manifest as lipemia and is more pronounced in males.

Gerbils excrete little urine, and fecal pellets are hard and dry. Their cages require less frequent cleaning than other pet and laboratory rodents. Gerbils adapt to a wide range of ambient temperatures. Because they have a propensity to develop nasal dermatitis at relative humidities >50%, a low humidity is advisable.

Gerbils require sandbathing to keep their coats from becoming oily. The lipids have two sources: Harderian gland nasal excretions spread by autogrooming and sebaceous exudates from the skin. The consequences of lipid removal by sandbathing are multiple; it not only cleans and grooms the pelage but also deposits lipids on the substrate that act as olfactory signals. Sandbathing is usually completed within 5 min. Additionally, it has homeostatic consequences. Hair color lightens in Mongolian gerbils allowed to sandbathe. When sandbathing is prevented, accumulating hair lipids mat the pelage, and behavior changes. Sandbath-deprived gerbils increase their frequency of "sand rolls" (rolling onto their side or back and returning to their feet within 1 second), decrease grooming, and increase territorial marking (especially males).

Gerbils often stand erect on their hindlimbs, so it is important that cages have a solid bottom and that the floor-to-lid height is tall enough to allow for this behavior.

Pet gerbils kept in inferior cages painted with lead paint or that use alloys containing lead have a high potential to develop chronic lead toxicosis because of their gnawing behavior and the urine-concentrating ability of their kidneys. Chronically, gerbils become emaciated, livers are small and pigmented, and kidneys are small and pitted. Microscopically, acid-fast inclusions

are noted in the proximal collecting tubules and hepatocytes.

Physical Examination

The gerbil's overall appearance and behavior, particularly in relation to its cagemates, should be noted. Sick animals are often isolated from others and may demonstrate weight loss, hunched posture, lethargy, rough fur, labored breathing, and a loss of exploratory behavior. Early signs of illness involve changes in the color, consistency, odor, and amount of urine and feces. The perineal area should be checked for fecal or urine stains or discharges from the vulva in females. Fecal samples may be taken for parasite detection and bacterial culture. The fur and skin should be examined for alopecia, fight wounds or other trauma, ectoparasites, and elasticity for evidence of dehydration. The oral cavity should be checked for overgrown teeth. Ears and eyes should be examined for discharges or inflammation. Feet should be examined for sores and overgrown or broken nails. The abdomen should be palpated for masses. Normal body temperature is 98°–102°F (37°–39°C). Respiratory rate or signs of labored breathing should be noted. The thorax can be auscultated with a pediatric stethoscope.

Gerbil tails are fragile, and only the base of the tail should be grasped during handling to avoid injury.

Infectious Diseases

Bacterial, Mycoplasmal, and Rickettsial Infections: "Facial eczema," "sore nose," and nasal dermatitis all describe a common skin condition seen in gerbils. Clinical lesions next to the external nares appear erythematous initially, progress to localized alopecia, and develop into an extensive moist dermatitis. The cause is believed to be increased Harderian gland secretion of porphyrins (similar to chromodacryorrhea in rats), which act as a primary skin irritant. Experimental Harderian gland–adenectomized gerbils do not develop nasal or facial lesions. Various staphylococcal species (*Staphylococcus aureus* and *S. xylosus*) may act synergistically to produce the dermatitis. Stress factors such as environmental humidity >50% or overcrowding cause excessive Harderian gland secretion. Nasal dermatitis infection may extend to the maxillary sinuses. Affected gerbils develop anorexia, stop drinking water, lose weight, and die. The distribution and nature of the lesions

are useful in diagnosis. Accumulated porphyrins will fluoresce under ultraviolet light (Wood's lamp). Routine bacteriology yields isolation of pathogenic staphylococci. Treatment includes carefully cleaning the skin lesions and use of topical (chloramphenicol 1% ophthalmic ointment, tid) or parenteral antibiotics (except streptomycin, which is fatal in gerbils). Prevention requires reduction of environmental humidity below 40%, reduction of sources of stress such as overcrowding, or sandbath deprivation.

Naturally occurring Tyzzer disease, an enterohepatic disease caused by the obligately intracellular bacterium *Clostridium piliforme*, is the most frequently described fatal infectious disease of gerbils. Common clinical and pathologic findings are sudden death or death after a short period of disease, and the presence of multiple foci of hepatic necrosis. Diarrhea and necrotic lesions in the intestinal tracts are variably present. The probable route of infection in naturally occurring infection is by mouth, because gerbils exposed to infected bedding will contract Tyzzer disease. Supportive fluids and prophylactic treatment with doxycycline (5 mg/kg, PO, bid for 7–10 days) or metronidazole (20 mg/kg, PO, bid for 7–10 days) are recommended to reduce mortality in cagemates. Because the bacteria form spores, the housing environment should be thoroughly sanitized and disinfected.

The Mongolian gerbil is susceptible to infection by *Helicobacter pylori*, which causes severe gastritis, gastric ulceration, and intestinal metaplasia. Gastric adenocarcinoma develops in approximately one-third of infected gerbils >15 mo old. *Clostridium difficile*-associated fatal enterotoxemia has been associated with treatment using nutritionally balanced triple-antibiotic wafers (containing amoxicillin, metronidazole, and bismuth) to eliminate naturally occurring *Helicobacter* infections. Affected animals are reported to die within 7 days of antibiotic treatment.

Viral Infections: Naturally occurring viral infections of gerbils are not reported.

Parasitic Infections: *Syphacia obvelata*, the mouse pinworm, and *Dentostomella translucida*, an oxyurid, are found in Mongolian gerbils. Pet store gerbils often are infected with mouse pinworms. *D. translucida* is commonly found in the small intestine of both research and pet gerbils. There is an average of four parasites per animal, but no clinical manifestations of disease are associated with the infection.

Infections with dwarf tapeworms, *Hymenolepis diminuta* and *Rodentolepis* (formerly *Hymenolepis*) *nana*, are reported in pet gerbils. Dehydration and mucoid diarrhea are often presenting signs. *R. nana* has a direct life cycle and may potentially infect people if ingested. Recommended treatment is niclosamide fed at 10 mg feed/100 g body wt for two 7-day periods separated by 1 wk. Also effective are thiabendazole (0.33% mixed in the feed for 7–14 days) or praziquantel (5–10 mg/kg, IM, SC, or PO, repeated in 10 days).

Historically, reports exist of pet gerbils infected with the tropical rat mite *Ornithonyssus bacoti* (see p 2030).

Fungal Infections: There have been no reports of naturally occurring or experimental dermatophyte infections in the Mongolian gerbil. Other fungal infections in *Meriones* spp are exceedingly rare.

Metabolic and Nutritional Disorders

Gerbils develop spontaneous, insidious periodontal disease after 6 mo on standard laboratory rodent diets. On the same diets, ~10% of the animals will become obese, and some will show decreased glucose tolerance, increased serum immunoreactive insulin, and diabetic changes in the pancreas and other organs.

Traumatic Injuries

Thin skin covers the tail of the gerbil. Unlike rats or mice, if a gerbil is picked up by the tip of its tail, the skin will often slip off, leaving a raw, exposed tail that eventually becomes necrotic and will shed. If the tail skin is lost, the bare tail must be surgically amputated where the skin ends.

Iatrogenic Conditions

A fatal syndrome of acute toxicity is produced in Mongolian gerbils after injection of penicillin-dihydrostreptomycin-procaine combination. The toxicity is due to the dihydrostreptomycin, and 50 mg will produce almost 100% mortality in adult gerbils. Approximately 20%–40% of gerbils develop reflex, stereotypic, epileptiform (clonic-tonic) seizures from ~2 mo of age. Animals seize in response to sensory stimulation and forced exploratory behavior, but the incidence and severity of their seizures are variable; the seizures generally pass in a few minutes, may be mild or severe, and have no lasting effects. Although the incidence and severity of seizures often decrease with age, certain

subsets of adult gerbils do not improve with age but progressively become more severe. The susceptibility is seen in selectively bred lines but may occur in pet gerbils. Seizures can be suppressed in genetically predisposed gerbils if they are frequently stimulated by handling during the first 3 wk of life. Anticonvulsant therapy is unnecessary.

Cystic ovaries occur frequently in Mongolian gerbils. Cysts range in size from 1–50 mm in diameter. Removal of affected ovaries does not significantly affect reproductive performance.

Females with one ovary are slightly inferior in fertility compared with normal females; a general decline in fertility may be evident in older females.

Neoplasia

Major surveys of spontaneous neoplasia in laboratory colonies of Mongolian gerbils have been reported. A 25%–40% incidence of neoplasia in gerbils usually occurs after 2–3 yr of age. Squamous cell carcinoma of the sebaceous ventral marking gland in males and ovarian granulosa cell tumor in females account for 80% of tumors seen in animals >3 yr old. The ventral marking gland tumors invade locally and can metastasize to lymph nodes and lung. Adrenocortical tumors, cutaneous squamous cell carcinoma, malignant melanoma, and renal and splenic hemangiomas were the next most commonly reported tumors. Numerous other tumors, including duodenal and cecal adenocarcinoma, hepatic lymphangioma, hemangioma and cholangiocarcinoma, splenic and renal hemangioma, uterine leiomyoma and hemangiopericytoma, ovarian teratoma, testicular teratoma, and malignant melanoma, were also reported. However, the total incidence of these tumors was <5%.

Case reports of spontaneously occurring tumors in pet gerbils include infiltrative craniopharyngioma, histiocytic sarcoma, systemic mastocytosis, malignant melanoma, and astrocytoma.

Miscellaneous Disorders

Congenital Disorders: Ventricular septal heart disease is seen occasionally in newborn gerbils.

Age-related Disorders: In two separate reviews, the pathologic findings in aging Mongolian gerbil colonies have been reported. Besides neoplasia, there was a high incidence of chronic glomerulone-

phropathy and focal myocardial degeneration and fibrosis, especially in older male gerbils.

Mongolian gerbils have a remarkable propensity for development of aural cholesteatoma. They occur in 50% of gerbils > 2 yr old. Cholesteatomas in the ear canal displace the tympanum into the middle ear. Compression and secondary infection result in bone necrosis and inner ear destruction. Clinical signs include head tilt.

Zoonotic Risk

There are no specific reports of zoonotic disease transmitted by pet Mongolian gerbils, although pet gerbils infested with *Ornithonyssus sylviarum* (the northern fowl mite) and *Dermanyssus gallinae* (the chicken mite) have been the source of avian mite dermatitis in children. Avian mite infestation is a rare cause of pruritic dermatoses in people. The mites spend most of their life cycle on the avian host but may be transmitted to people by direct or indirect contact. The scarcity of reports may be a true reflection of the absence of zoonotic disease in gerbils or may reflect their low popularity as a pet rodent.

GUINEA PIGS

Guinea pigs, like chinchillas, are hystricognath rodents. They belong to the family Caviidae, which contains 14 species of animals commonly known as cavies and Patagonian hares (or maras). Four digits on the forepaw and three on the hindfoot characterize Caviidae.

A stocky build, large head, short legs, and unfurred, short ears characterize guinea pigs. Head and body length is 200–400 mm, there is no external tail, and weight is 500–1,500 g.

In South America, wild cavies inhabit rocky areas, savannas, forest edges, and swamps from Columbia and Venezuela southward to Brazil and northern Argentina. They live in groups of up to 10 individuals and inhabit burrows that they or other animals dig. They are most active at night, when they forage for a variety of plant materials. Domestication of the guinea pig began at least by 900 BCE and may have begun as early as 5,000 BCE.

Biology

The American Cavy Breeders Association recognizes 13 breeds that it divides into groups or varieties. The most common breed is the American cavy and was known originally as the English cavy. Self cavies are

a group of solid-colored animals (eg, black, cream, red, lilac, beige, saffron, and chocolate). Nonsels are a group made up of the coated breeds, the marked breeds, and the ticked or agouti breeds. The coated cavies include the Abyssinian, Rex, Longhaired varieties (Peruvians, Silkie, Shelties, Coronets, and Texels), Crested, Teddy, and Satins. The short, wire-haired Abyssinian may look unhealthy because its coat is arranged in whorls or rosettes, giving it a ruffled, untidy appearance. An undercoat and projecting guardhairs make up the normal fur coat of a cavy. The Rex has short guard hairs that do not appear above the level of the undercoat, the Satin breeds have an abnormal hair fiber that produces a sheen, and the Teddy breeds have a kinked or bent hair shaft that causes the coat to stand erect over the entire body. The marked group contains Dalmatian, tortoiseshell, and Himalayan varieties. The term "variety" describes a color (eg, steel grey, tortoiseshell) that is not yet a recognized breed.

Several researchers have analyzed guinea pig calls and distinguish between 7 and 11 distinct sound patterns. Although different authors have given different names to each unique sound, there is general agreement on at least 5 sounds.

Lymphocytes are the predominant WBC in guinea pigs and range from 45%–80% of the WBC count. Many small lymphocytes are similar in size to erythrocytes. Large lymphocytes contain Kurloff bodies, large intracytoplasmic mucopolysaccharide inclusion bodies. Kurloff bodies are seen under normal conditions in guinea pigs and are estrogen dependent. Pregnant females may have 2%–5% lymphocytes with Kurloff bodies in their peripheral blood; they are present in large numbers in adult females, and numbers fluctuate with the stage of estrous cycle. There are few Kurloff bodies in adult males, and they are rarely seen in newborns.

Like chinchillas, guinea pigs share unusual reproductive physiologic characteristics of hystricomorph rodents. Female guinea pigs (or sows) have a pregnancy of 68 days (range 59–72 days) and an average estrous cycle length of 17 days (range 13–25 days). They have a vaginal closure membrane that is open at estrus and parturition but sealed during anestrus and pregnancy. Guinea pigs have an average of 4 young per litter, with a range of 1–13. The young (of both species) are born fully furred and well developed. Young guinea pigs usually nurse for 21 days, although they can survive on solid food alone after 5

days. Guinea pigs have only a single pair of inguinal nipples.

Male guinea pigs have pronounced penile styles or spicules on the glans penis. Young male guinea pigs reach puberty at ~3 mo of age and females at 2 mo. Guinea pigs live 6–8 yr.

Husbandry

As a species, guinea pigs are extremely adaptable to a great range of climates, although as individuals they are highly susceptible to variations in local temperature and humidity. Guinea pigs are nervous animals and may refuse to drink or eat for a period after any significant change in their location, feed, or husbandry. The effect of environmental changes on guinea pigs is minimal or nonexistent when two animals are kept together. If a sick guinea pig must be kept in hospital, housing a cagemate with the sick animal reduces stress.

Guinea pigs live in family units centered on an alpha male. Mature males, and especially strangers, will fight. However, two males raised together from a young age or a group of nonbreeding females will not encounter dominance problems. Social problems are diminished with castration and ovariectomy, but learned behavior in adult males after castration may still make them antisocial.

Guinea pigs require a constant source of water that must be changed daily. They dirty their water bowls or sipper tubes with food when they drink. They do not lick sipper tubes without training, defecate indiscriminately, and are prone to sit in and soil their food bowls and sleeping areas. However, they are generally good eaters and not as fussy as rabbits.

Guinea pigs produce two types of fecal pellets: one nitrogen-rich intended for cecotrophy, and one nitrogen-poor delivered as fecal pellets. When food is continually available, ~40% of the feces are reingested, and 90% of this coprophagy occurs at night. However, when food is limited, guinea pigs ingest feces during parts of the day when food is unavailable.

Physical Examination

Guinea pigs are easy to hold and restrain. Although they do not bite, very young guinea pigs may nip. Healthy guinea pigs feel "dense" and are alert. Fatigue, lack of interest in surroundings, and light body weight are often general signs of illness. Sick guinea pigs may show evidence of weight loss, hunched posture, abnormal gait, drawn in abdomen, scruffy fur, or

labored breathing. They may be lethargic or unresponsive to stimulation. Respiratory and GI conditions are most commonly encountered; thus, ocular or nasal discharges or diarrhea may be present. Feet should be examined for sores or broken nails. Teeth may sometimes overgrow and should be checked. However, the mouth is small, and examination of the oral cavity is difficult. Ears and eyes should be examined for discharges or inflammation, and the submandibular area should be examined for swellings.

Venipuncture can be difficult in guinea pigs because of the lack of obviously accessible peripheral veins. The lateral saphenous vein and the cephalic vein are useful to draw small amounts of blood. For large amounts of blood, the anterior vena cava can be used, with the guinea pig under anesthesia. This technique requires practice. If performed incorrectly, there is a risk of death associated with intrathoracic, pericardial, or pulmonary hemorrhage.

Infectious Diseases

Bacterial Infections: *Streptococcus equi* subsp *zooepidemicus* (previously *S. zooepidemicus*) may be carried in the nasopharynx as a latent infection. Abrasions of the oral cavity (eg, molar malocclusion) allow bacteria to be transported to draining lymph nodes of the head and neck, causing suppurative lymphadenitis. Clinically, guinea pigs present with large, unilateral swellings in the neck. The affected animal is often in good flesh and shows no other signs of disease. The differential diagnosis should always include cavian leukemia. Treatment is surgical excision of the affected lymph nodes and systemic antibiotic treatment. Bacterial culture and antibiotic sensitivity should always be recommended. Streptococci are generally sensitive to chloramphenicol (50 mg/kg, PO, bid), and this antibiotic is "safe" to give systemically to guinea pigs. Alternative "safe" antibiotics are azithromycin (15–30 mg/kg/day, PO; discontinue if soft feces) and fluoroquinolones; however, bacterial resistance to these antibiotics is now frequently seen.

Streptococcus pneumoniae may be carried in nares as an inapparent infection. Predisposing factors for development of bacterial pneumonia are changes in environmental temperature, humidity, or ventilation. This always occurs in winter in guinea pigs kept outside. The young, old, and pregnant are the most susceptible. Clinical signs of pneumonia are dyspnea,

wheezy breathing, sneezing, nasal discharge, and coughing. The affected guinea pig becomes depressed and anorectic. *S. pneumoniae* infections are nearly always associated with middle ear infection and head tilt. Increased radiodensity of the affected tympanic bulla may be seen on radiographs. Because of limited antimicrobial sensitivity, chloramphenicol (50 mg/kg, PO, bid) is the recommended treatment. A major differential diagnosis for pneumonia is *Bordetella bronchiseptica* infection.

Rabbits may harbor *B. bronchiseptica* in their respiratory tracts without developing disease. However, this organism is an aggressive pathogen in guinea pigs, causing pneumonia, conjunctivitis, otitis media, abortions, and stillbirths. The clinical signs include anorexia, inappetence, nasal and ocular discharge, dyspnea, and often sudden death (this could also include *S. pneumoniae* and *S. equi zooepidemicus*). Rabbits and guinea pigs should not be housed together as pets. Treatment is ciprofloxacin (10–20 mg/kg, PO, bid). *B. bronchiseptica* possesses a β -lactamase and is resistant to many penicillins and cephalosporins and mostly resistant to trimethoprim-sulfamethoxazole. Most isolates are sensitive to doxycycline (2.5–5 mg/kg, PO, bid) and fluoroquinolones (marbofloxacin, 4 mg/kg/day, PO; ciprofloxacin, 10–20 mg/kg, PO, bid; enrofloxacin, 5–10 mg/kg, PO, bid for 14 days).

Salmonella infections were historically common in guinea pigs in research colonies. With present standards of husbandry, rodent control, and good quality feed, the disease rarely occurs. It is most likely seen when guinea pigs are kept outside and wild rodents have access to their feed. Disease is more often seen in young or stressed animals. Infection may be subclinical, and diarrhea is rarely present. Clinical signs include conjunctivitis, fever, lethargy, anorexia, rough fur, palpable hepatosplenomegaly, cervical lymphadenitis, and abortion in pregnant sows. Mortality is often high in epizootic outbreaks. If animals recover, organisms may be shed intermittently. Diagnosis is accomplished by isolating the organism from blood, ocular secretions, lymph nodes, or spleen. Because of zoonotic considerations and the potential for a carrier state, treatment is not recommended.

Chronic dermatitis (especially of the forepaws) is a common condition usually seen in obese guinea pigs housed on wire or abrasive floors. Poor sanitation is also a predisposing factor. The feet are swollen

and hairless with ulcers and scabs 1–3 cm in diameter on the plantar surface. *Staphylococcus aureus* is the usual causative agent and probably enters the foot through a cutaneous wound. Awns and straw in the bedding can also cause foot punctures. The inflammation can progress to osteoarthritis and systemic amyloidosis secondary to chronic staphylococcal infection. Surgical treatment is often unsuccessful, because there is rarely an abscess to be excised or drained but rather a diffuse cellulitis that infiltrates surrounding tissue. Treatment involves housing the affected guinea pig on clean, dry, soft bedding, topical or parenteral administration of antibiotics, and foot bandages as needed. Unfortunately, the condition may not respond to therapy.

Chlamydial conjunctivitis is one of the most common causes of infectious conjunctivitis in guinea pigs. It is caused by *Chlamydia caviae*, an obligate intracellular bacterium. Clinical disease usually is found in young animals 4–8 wk old. Rhinitis, lower respiratory tract disease, and abortion can also occur. Concurrent bacterial infections can contribute to the respiratory symptoms. *C. caviae* can rapidly spread through a breeding or research colony. The organism infects primarily the mucosal epithelium of the conjunctiva and, less frequently, the genital tract of guinea pigs. Asymptomatic infection can occur, but clinical disease most often results in mild inflammatory conjunctivitis with a slight, yellow-white discharge, conjunctival hyperemia, chemosis, and even severe conjunctivitis with profuse, purulent ocular exudate. Demonstration of intracytoplasmic inclusion bodies in Giemsa-stained conjunctival epithelial cells often confirms the diagnosis. The most sensitive and reliable method of diagnosis of chlamydiosis is PCR testing. Antichlamydial therapy with doxycycline (5 mg/kg, PO, bid for 10 days) is the treatment of choice and usually results in complete recovery. Guinea pigs develop short-lived immunity to *C. caviae* and, after a short period, may be susceptible to reinfection.

Viral Infections: Adenovirus is species-specific for guinea pigs and may cause a primary respiratory pneumonia. The asymptomatic carrier state is thought to be common, but prevalence is unknown. Clinical disease, while rare, can be initiated by stress or inhalation anesthesia and occurs more often in immunocompromised, young, or aged animals. Morbidity is low, but animals usually die suddenly without clinical signs.

Other naturally occurring viral infections of guinea pigs such as cytomegalovirus and parainfluenza rarely cause detectable clinical disease. Serologic surveys indicate that guinea pigs will develop antibodies to rat and mouse pathogenic viruses but do not develop disease.

Parasitic Infestations: Mange, caused by the sarcoptid mite *Trixacarus caviae*, is a common disease. The clinical signs are dramatic: intense pruritus, widespread alopecia, and hyperkeratosis. *T. caviae* is transmitted through direct animal-to-animal contact from sow to weanlings during feeding, and through contact with infested cage material such as bedding. The mites may be capable of existing subclinically, becoming active with stressors (such as shipping or pregnancy), immunosuppression, or other underlying diseases. In affected animals that exhibit hematologic changes such as heterophilia, monocytosis, eosinophilia, and basophilia, vigorous scratching may trigger convulsive seizures. The seizures are controlled by diazepam (1–2 mg/kg, IM, as needed). The clinical presumptive diagnosis should be confirmed with several skin scrapings, usually revealing a massive *T. caviae* infestation. Treatment involves ivermectin (0.4–0.5 mg/kg, SC, repeated 2–3 times at intervals of 7–10 days), or spot-on dermal treatment with either selamectin (15 mg/kg for <800 g body wt; 30 mg/kg for >800 g body wt). The guinea pig should also have a whole body washing with fipronil repeated twice at intervals of 7–10 days. Fipronil should not be used when open skin wounds are present.

Other ectoparasitic diseases are infrequent in guinea pigs. Infestation with the fur mite *Chirodiscoides caviae* may result in pruritus and alopecia along the posterior trunk of the body, while underlying skin is relatively unaffected. Subclinical cases may be asymptomatic. Treatment is with selamectin (15 mg/kg for <800 g body wt, 30 mg/kg for >800 g body wt) administered twice at 2-wk intervals.

Lice infestation with either *Gyropus ovalis* or *Gliricola porcelli* is usually asymptomatic but in severe cases may lead to pruritus, alopecia, and flaky skin surfaces around the neck and ears. Lice may be observed directly on hair shafts with a magnifying glass. A single application of 0.05 mL of a topical solution containing 10% imidacloprid and 1% moxidectin is an effective treatment for lice infestations in guinea pigs. Prevention is aimed at improving sanitary conditions in the animal's environment.

Fungal Infections: Dermatophytosis is common in guinea pigs, and natural infection is always associated with *Trichophyton mentagrophytes* var *mentagrophytes*. Lesions typically begin as broken hairs and circular, scaly alopecia initially occurring at the tip of the nose, which spreads to the periocular, forehead, and pinna areas. In severe cases, the dorsal sacrolumbar area is also affected, but the limbs and ventrum are usually spared. Pruritus is usually minimal or absent. Some animals have more inflammatory lesions characterized by erythema, follicular papules, pustules, crusts, pruritus, and occasional scarring. High temperature and humidity may contribute to a more severe infection.

T. mentagrophytes can be isolated from the skin and fur in up to 15% of clinically normal guinea pigs. Guinea pigs can be tested for dermatophytes by using a new toothbrush to comb all parts of the hair coat and impress the bristles onto dermatophyte test medium (DTM) in several sites. In a healthy animal, dermatophytosis is generally a self-limiting disease, with full resolution after development of an appropriate cell-mediated immune response. In immunocompetent animals, this usually takes 100 days. Nevertheless, treatment is recommended because it will accelerate resolution of lesions caused by dermatophytes, thereby minimizing the time course of the infection and minimizing the potential for spread to other animals or people. Whenever possible, curing the infection in the pet, while simultaneously decontaminating the environment, is desirable. Environmental control should be performed every 14 days with enilconazole (0.2%) or concentrated chlorine laundry bleach (1:10) solutions.

Ringworm (*Trichophyton*) in a guinea pig. Dermatophyte infections on guinea pigs are often located on the face, back, or front feet. Courtesy of Dr. Louise Bauck.

Treatment is systemic therapy with or without topical treatment. Spot-on treatment products should not be used alone, because they may predispose individuals to chronic subclinical infection. Rather, whole-body shampooing, dipping, or rinsing with topical antifungal agents in conjunction with systemic therapy is preferred. For topical therapy, either enilconazole (0.2% at a dilution of 1:70) or miconazole shampoo (with or without chlorhexidine), once or twice weekly, can be used. Enilconazole is licensed for use as an environmental disinfectant and is used off-label in treatment of dermatophytosis. Systemic therapy is either itraconazole (10 mg/kg/day, PO) or terbinafine (30–40 mg/kg/day, PO) for 4–8 wk. Lesions may resolve in 2–3 wk, but antifungal therapy should be continued until two DTM cultures are negative, with a 2-wk interval between cultures. Often, dermatophyte infections of the skin require 2–3 mo of therapy.

Metabolic and Nutritional Disorders

Guinea pigs of all ages require a dietary source of vitamin C. The stability of vitamin C in diets varies with composition of the diet, storage temperature, and humidity. The feed content of vitamin C is reduced by dampness, heat, and light. In fortified diets, approximately half of the initial vitamin C may be oxidized and lost 90 days after the diet has been mixed and stored at temperatures >22°C (71.6°F). Water in an open container may lose up to 50% of its vitamin C content in 24 hr. Aqueous solutions of vitamin C will more rapidly deteriorate in metal, hard water, or heat and are more stable in neutral to alkaline solutions.

Clinical signs of hypovitaminosis C include diarrhea, alopecia, and pain (from joints); animals are thin and unkempt. Petechiae on mucous membranes are not always seen, although hematuria may be present. Guinea pigs will show signs of vitamin C deficiency within 2 wk if it is not provided. Serum hypercholesterolemia (>60 mg/dL) and hypertriglyceridemia (>30 mg/dL) is seen in vitamin C–deficient guinea pigs after an overnight fast. Guinea pigs need ~10 mg vitamin C/kg body wt daily for maintenance and 30 mg vitamin C/kg body wt daily for pregnancy. Vegetables high in vitamin C include red or green capsicums, tomatoes, spinach, and asparagus.

Metastatic calcification occurs most often in guinea pigs >1 yr old. Clinically, animals present with muscle stiffness and failure to thrive. Mineralization may be confined to soft tissues around elbows and ribs. Mineral

deposition may also be more widespread, involving lungs, heart, aorta, liver, kidneys, uterus, and sclera. Dietary factors such as a low-magnesium and high phosphorus diet, and high calcium and/or high vitamin D intake have been implicated. Feeding commercial, high-quality guinea pig diets has reduced the incidence seen in laboratory colonies.

There are two other, similar syndromes in guinea pigs that affect either the skeletal muscles (muscular dystrophy) or the myocardium and skeletal muscles (muscular degeneration and mineralization). These two conditions are associated with a vitamin E/selenium deficiency. A separate, incidental finding of multifocal mineralization of individual muscle fibers may be seen in major muscles of hindlimbs. Affected animals are often asymptomatic.

Spontaneous diabetes mellitus is common in guinea pigs. The clinical manifestations are mild or variable. Guinea pigs show polydipsia and weight loss while maintaining a good appetite. Hematology and urinalysis show glycosuria, hyperglycemia, and high serum triglyceride levels; ketonemia and ketonuria are not seen. Exogenous insulin is not required for survival.

Reproductive and Iatrogenic Disorders

Multiple cysts are often present on ovaries of females >1 yr old. The cysts contain clear, serous fluid and may reach 2–4 cm in diameter. Cysts may be unilateral or bilateral. Clinically, ovarian cysts are associated with reduced reproductive performance, cystic endometrial hyperplasia, mucometra, endometritis, and alopecia. Radiography and ultrasonography should be performed, especially if an abdominal mass is palpable. Diagnosis of the disease by plain radiography is difficult because of the similar opacity of ovarian cysts and abdominal neoplasms. Abdominal ultrasound allows differentiation by imaging the inner structure of the ovarian cyst. Treatment is laparotomy and surgical removal of the ovary and cyst. Differential diagnoses include splenic, uterine, and ovarian tumors.

Although the clinical signs are similar, there are two recognized forms of pregnancy toxemia: the fasting/metabolic form and the toxic form. Both occur in late pregnancy. Affected sows show depression, acidosis, ketosis, proteinuria, ketonuria, and a lowered urinary pH (from ~9 to 5–6).

Metabolic pregnancy toxemia occurs in obese sows, especially females in their

first or second pregnancy. The disease is caused by a reduced carbohydrate intake and mobilization of fat as a source of energy. Changes in feeding routine and stress may precipitate the crisis. Clinically, the sow stops eating and is initially depressed, then becomes comatose and usually dies within 5–6 days. Treatment is rarely successful in advanced cases. Aggressive treatment is necessary and involves administration of 5% glucose solution either IV or SC and/or propylene glycol orally, nutritional supplementation, and cesarean section. Sows in late pregnancy can be given water within which a small amount of glucose has been dissolved as a preventive measure.

The circulatory or preeclampsia form of pregnancy toxemia is due to uteroplacental ischemia. The gravid uterus compresses the aorta, resulting in significant reduction of blood flow to the uterine vessels. Placental necrosis, hemorrhage, ketosis, and death follow. If suspected, emergency cesarean section and/or ovariohysterectomy are required to save the sow's life.

Guinea pigs have a high perinatal mortality. Dystocia and stillbirths are related to large fetuses, subclinical ketosis, and fusion of the symphysis pubis. If females are first bred after 6 mo of age, the symphysis pubis often fuses and does not separate during parturition. Many stillbirths are often seen in primiparous females. Pregnancy lasts 59–72 days (average 63 days). If a female strains continually for >20 min or fails to produce young after 2 hr of intermittent straining, dystocia may be occurring. Careful examination of the cervix is necessary to assess how much separation of the symphysis pubis is present. There should be at least the width of the index finger to permit passage of the fetus. If adequate separation has occurred, oxytocin (1–2 units, IM) can be given. If the fetus is stuck, or parturition does not begin within 15 min of giving oxytocin, performing a cesarean section is necessary. The uterus should be opened close to the bifurcation of the horns. The guinea pig has a bicornuate uterus with one cervix.

Neoplasia

Spontaneous tumors are relatively uncommon in guinea pigs and are usually seen in animals >3 yr old. Trichofolliculoma, a benign tumor of the hair follicle epithelium, is the most common skin tumor of guinea pigs. The tumor presents as a slow-growing, oval mass varying in diameter from 0.5–7 cm and located predominantly in the subcutis of the dorsal

lumbar or sacral region, or in the lateral femoral and lateral thoracic area. Males are affected twice as frequently as females. The average age of affected animals is 3 yr. Epidermoid cysts arising from hair follicles are often associated with these tumors or may arise independently. Ulcerating tumors and ruptured cysts discharge caseous material. Treatment of trichofolliculomas and epidermoid cysts is surgical excision.

Tumors of the reproductive tract represent 25% of spontaneous tumors in guinea pigs. Most are ovarian and uterine tumors, although mammary adenocarcinoma is seen in both male and female guinea pigs. The prevalence of mammary tumors in males is higher than in other species.

Miscellaneous Disorders

Antibiotic Toxicity: The lethal sensitivity of guinea pigs to antibiotic therapy cannot be overemphasized. Antibiotics reported to cause enterotoxemia are penicillin, ampicillin (amoxicillin), bacitracin, erythromycin, spiramycin, streptomycin, lincomycin, clindamycin, vancomycin, and tetracycline. Topical antibiotics have also caused fatal enterotoxemia. The following therapeutic dosages of antibiotics have been used clinically in guinea pigs (see TABLE 31).

Trimethoprim-sulfamethoxazole, chloramphenicol, and enrofloxacin are safe to use in guinea pigs. Narrow-spectrum antibiotics with antibacterial activity against gram-positive bacteria should be avoided; the cause of death is a decreased gram-positive bacterial flora and increased gram-negative flora, with related bacteremia/septicemia.

Paradoxically, clostridial overgrowth (*Clostridium difficile*) has also been identified. *C. difficile* is a pathogenic organism, not normally recoverable from intestinal contents.

Treatment for antibiotic toxicity is primarily supportive. The antibiotics should be stopped immediately, fluid therapy (IV or intraosseous) should be administered, and analgesics should be provided to prevent abdominal discomfort. High-fiber diets should be syringe fed to prevent ileus. Cholestyramine (1 g in 10 mL water, tid, for 5–10 days), an ion exchange resin, has been used experimentally to bind clostridial toxins in clindamycin-induced enterotoxemia. If the enterotoxemia is severe, the condition is life-threatening and the prognosis guarded.

Age-related Disorders: Urolithiasis is a common problem in older guinea pigs, especially females, because of the proximity of the urethral orifice to the anus and the high risk of infection with fecal contaminants like *E. coli*. However, it may be seen in guinea pigs of both sexes and all ages. Clinical signs include dysuria, crying when attempting to urinate, and occasionally hematuria. Diagnosis is by abdominal radiology. The calculi are radiopaque and usually composed of calcium carbonate or calcium phosphate; calculi can also be composed of calcium oxalate. Obstructive urolithiasis, hydronephrosis, and possible concurrent septicemia can develop if the problem is not treated.

In addition to sex and age, diet may be related to urolithiasis. Foods high in calcium, eg, alfalfa hay, may result in a high

TABLE 31 ANTIBIOTIC DOSAGES FOR USE IN GUINEA PIGS

Antibiotic	Dosage
Azithromycin	15–30 mg/kg/day, PO (discontinue if soft feces occur)
Ceftiofur	1 mg/kg/day, IM (for pneumonia)
Cephaloridine	12.5 mg/kg, IM, once to three times daily for 5–14 days
Chloramphenicol	30–50 mg/kg, PO, SC, or IM, bid
Ciprofloxacin	10–20 mg/kg, PO, bid
Doxycycline	2.5–5 mg/kg, PO, bid
Enrofloxacin	5–10 mg/kg, PO or IM, bid
Gentamicin	6 mg/kg/day, SC (use cautiously)
Metronidazole	10–40 mg/kg/day, PO
Trimethoprim-sulfamethoxazole	30–50 mg/kg, PO, bid

dietary calcium:phosphorus ratio. Urinary ascorbate, if present at a high concentration, increases stone formation in guinea pigs given high-calcium or high-oxalate diets. This may be both beneficial and deleterious, ie, needing to give enough vitamin C to prevent scurvy but not increase stone formation.

Surgical removal is standard treatment. However, it is often complicated by exuberant inflammatory reactions to suture material. Prophylactically, potassium citrate/citric acid can be given as an inhibitor of crystal formation in urine. Citrate is not administered for its urine-acidifying effect as it is in dogs and cats, but because of its ability to bind calcium into water-soluble calcium citrate.

Dental Disease: The clinical signs and treatment of malocclusion in guinea pigs are almost identical to those in rabbits, except premolar teeth are more commonly affected (see p 1955).

Alopecia: Alopecia develops to a degree in all guinea pigs in late pregnancy (60–70 days) and during nursing. It results from reduced anabolism of maternal skin associated with fetal growth. Hair loss usually begins on the back and progresses bilaterally on the flanks and ventral abdomen. Nursing guinea pigs may worsen the condition by pulling hair from their mothers. The alopecia resolves slowly either after parturition or when the sow stops nursing.

Thinning hair is common in young animals at weaning. It is associated with a period of transition in which coarse guard hairs of the adult coat are developing and neonatal fur is being lost. Ear chewing and barbering are seen in group-housed guinea pigs that develop a social hierarchy. Often younger animals of lower rank develop hair loss from fur chewing by dominant older members. The hair loss is characterized by an irregular, almost stepwise pattern. Treatment involves separation of the aggressive animal(s).

Single-housed guinea pigs that become bored may inflict self-barbering. In these cases, areas the animal cannot reach such as the head, neck, and anterior shoulders are not affected. Changing the guinea pig's environment and providing large amounts of fresh hay often prevent boredom and stop this vice.

Bilateral, symmetric alopecia may be seen in older females with ovarian cysts. Other differential diagnoses for alopecia are mite infections and dermatophytosis.

Sebaceous glands are abundant along the dorsal surface of guinea pigs and around the anal orifice. The circumanal region contains

a large accumulation of sebaceous glands. The sebaceous glands are testosterone dependent, and in adult males, excessive accumulation of sebaceous secretions occurs in the skin around the base of the spine and the folds of the circumanal and genital region. In areas covered by fur, the hair becomes thick, matted, and greasy. These folds can be periodically cleaned with surgical alcohol or a gel hand cleanser to preclude infection and unpleasant smell.

Zoonotic Risk

Pet guinea pigs carrying dermatophytes are a zoonotic risk for their owners, especially children, who are often the only affected members of a household. Risk factors for human dermatophytosis are young guinea pigs and recent acquisition of a new guinea pig. When treating ringworm in guinea pigs, environmental treatment should also be recommended to the owners, with special attention given to the bedding and clothing of people in contact with infected or carrier animals. Contagious material may persist in the owner's clothing and bedding and is a common reason for a pet's relapse after an initial response.

HAMSTERS

The most common pet and research hamster is the golden or Syrian hamster (*Mesocricetus auratus*). All Syrian hamsters in captivity appear to have originated from a litter of eight hamsters collected near Aleppo in Syria in 1930. Four of the animals escaped, a male killed one female, and only one male and two females remained. From these three animals, litters were raised that were distributed to Europe and the USA for research and subsequently as pets. In 1971, an additional 12 Syrian hamsters were captured in the field by farmers and imported to the USA.

Syrian hamsters have a head and body length of 170–180 mm and tail length of 12 mm. They range in weight from 110–140 g, and females are larger than males. Wild Syrian hamsters have a light, reddish brown dorsal coat, and the underparts are white. The skin of Syrian hamsters is very loose.

Other species now common as pets are the dwarf hamsters such as the Djungarian (*Phodopus sungorus*) and Roborovsky (*P. roborovskii*) hamsters. They are small (<100 g body wt), have a docile disposition, do not attempt to bite or run away, thrive in captivity, and make good pets. This discussion primarily deals with diseases of the Syrian hamster.

Biology

At least 20 mutations affecting coat color in Syrian hamsters are known. Most are simple recessive traits, four are dominant, and two are sex-linked. Five mutations affect the fur, giving rise to long hair (also known as “teddy bear” hamsters), rex, and satin coats. Length of hair in the longhaired Syrian hamster is influenced by testosterone. Longhaired males from the age of sexual maturity have significantly longer hair than females or castrated males, which display fluffy, shorter hair.

Syrian hamsters possess paired, flank organs in the costovertebral area that are androgen dependent and consist of sebaceous glands, pigmented cells, and terminal hairs. They are larger and heavily pigmented in males and used for territorial marking. All hamsters possess enormous cheek pouches that open inside the lips, extend well back of the shoulders, and when filled with food more than double the width of the animal's head and shoulders.

Adult male Syrian hamsters develop large adrenal glands due to enlargement of the zona reticularis, which is three times the size of that in female hamsters. Like gerbils, Syrian hamsters have a high proportion of erythrocytes with polychromasia.

Female Syrian hamsters are heavier than males and generally are aggressive toward other hamsters. Nonestrous females can behave especially aggressively toward young males and may kill them. The 4-day estrous cycle is characterized by a copious postovulatory discharge on the last day. The discharge is creamy white and has a distinctive odor; it fills the vagina and usually extrudes through the vaginal orifice. Its stringy nature is distinctive, and if touched it can be drawn out as a thread of about 4–6 in. length. Estrus lasts ~1 day, and the gestation period is 16–19 days. The litter size ranges from 2 to 16, with an average of 9. Cannibalism of young accounts for nearly all pre-weaning mortality. Cold ambient temperatures ($<10^{\circ}\text{C}$ [50°F]), lean diets, and low body weight during pregnancy increase cannibalism. Disturbing the mother by handling the young or nest, and not providing adequate nesting material, warmth, food, or water, often results in cannibalism. Syrian hamsters are prolific breeders, and there may be 3–5 litters/yr. The young are weaned at 20 days and capable of reproducing at 7–8 wk. The life span of Syrian hamsters is 2–3 yr.

Husbandry

In the wild, Syrian hamsters live on dry rocky steppes or brushy slopes. They construct

shallow burrows. Deep bedding that is appropriate for burrowing is recommended. Cages with at least 40–80 cm of bedding enhance the welfare of Syrian hamsters.

Wild Syrian hamsters are omnivorous eating many kinds of green vegetation, seeds, fruit, and meat. Exposure to cold stimulates hamsters to gather food, and they will often hibernate at temperatures $<5^{\circ}\text{C}$ (41°F). Syrian hamsters do not fatten before hibernation and will starve unless they waken periodically to eat. Hibernating animals remain sensitive to external stimuli and are usually aroused if handled. Syrian hamsters have prominent depositions of brown fat beneath and between the shoulder blades, in the axilla, and in the neck and perirenal areas.

Syrian hamsters are active chewers and skillful at escaping from their cages. Glass water tubes are contraindicated for Syrian hamsters, because they will readily bite through glass. Stainless steel sipper tubes close to the floor are recommended. Because Syrian hamsters have broad muzzles that often prevent them eating from feed hoppers, feed pellets are placed on the floor of their cage. Hamsters are naturally coprophagic.

Physical Examination

The animal's overall appearance and behavior, particularly in relation to its cagemates, should be noted. Sick animals are often isolated from others and may show weight loss, hunched posture, lethargy, rough fur, labored breathing, and a loss of exploratory behavior. Early signs of disease involve changes in the color, consistency, odor, and volume of urine and feces. The perineal area should be checked for fecal or urine stains or discharges from the vulva in females. Fecal samples may be taken for parasite detection and bacterial culture. The fur and skin should be examined for alopecia, fight wounds or other trauma, and ectoparasites. The oral cavity should be checked for overgrown teeth or impacted cheek pouches. Ears should be examined for discharges or inflammation and eyes for discharges or conjunctivitis. Feet should be examined for sores and overgrown or broken nails. The abdomen should be palpated for masses.

Syrian hamsters are not normally aggressive but can be provoked if suddenly startled, awakened, or roughly handled. It may be easier to scoop Syrian hamsters up in a small container rather than pick them up directly. Their highly elastic skin should be grasped sufficiently to prevent the animal from biting.

Infectious Diseases

Bacterial Infections: Diarrhea may occur in Syrian hamsters of any age and is known as “wet tail,” although this euphemism is frequently used to describe the disease in young hamsters. Proliferative ileitis is the most significant intestinal disease of 3- to 10-wk old Syrian hamsters and results in high mortality. It is caused by the intracellular bacterium *Lawsonia intracellularis*. Treatment involves correcting life-threatening electrolyte imbalance and dehydration, administering antibiotics, and force feeding. Several antibiotic treatments are recommended, including doxycycline (5–10 mg/kg, PO, bid for 5–7 days), enrofloxacin (10 mg/kg, PO or IM, bid for 5–7 days), and trimethoprim-sulfamethoxazole (30 mg/kg, PO, bid for 5–7 days). Symptomatic treatment with bismuth subsalicylate may be given if diarrhea persists. Replacement electrolyte and glucose solutions should be given orally, and electrolyte fluid replacement such as saline or lactated Ringer's solution should be given at a dosage of 20 mL/100 g body wt once daily. Sequelae of proliferative ileitis in surviving Syrian hamsters may include eventual obstruction, intussusception, or rectal prolapse.

Diarrhea in adult Syrian hamsters is associated with *Clostridium difficile* enterotoxemia and, as in guinea pigs, may occur 3–5 days after administration of antibiotics such as penicillin, lincomycin, or bacitracin.

Tyzzler disease due to *Clostridium piliforme* is seen in Syrian hamsters and is usually precipitated by stress such as overcrowding, high environmental temperature and humidity, heavy internal and external parasite load, and nutritionally inadequate diets. *C piliforme* is opportunistic in immunosuppressed animals and not seen in immunocompetent animals.

Bacterial pseudomycetoma has been described in several dwarf hamsters. The treatment is excision.

Viral Infections: Hamster polyoma virus (HaPV) is the cause of epizootic lymphoma in young Syrian hamsters and epitheliomas in older enzootically infected hamsters. When first introduced into a naive population of breeding Syrian hamsters, HaPV results in an epizootic of lymphoma, with an incidence as high as 80%. Lymphomas often arise in the mesentery but can arise in the axillary and cervical lymph nodes. Once enzootic in a hamster population, the occurrence of lymphoma

Gross lesions of *Demodex* infection in a hamster. Note the characteristic hair loss on the head and neck. Courtesy of Dr. Louise Bauck.

declines to a much lower level. Enzootically infected Syrian hamsters develop HaPV skin tumors rather than lymphoma. HaPV lymphoma-affected Syrian hamsters appear thin, often with palpable masses in the abdomen. Often, they have demodectic mange due to either *Demodex criceti* or *D aurati*.

Parasitic Infections: Fecal smears of Syrian hamsters are abundant in protozoan organisms. However, their role in enteric disease is speculative, because similar protozoa are found in comparable numbers in both healthy and diseased animals.

Demodex criceti and *D aurati* are occasionally found on hamsters. Clinical signs consist of mild to moderate alopecia, pruritus, and erythema generally on the dorsal region of the body, the hindlimbs, and face. Additionally, crusts and scaling may be found on physical examination. Skin scrapings confirm the presence of a large number of *Demodex* spp in various stages of development. Treatment consists of a combination of 1% selenium sulfide shampoo and topical application of selamectin (15 mg/kg, applied once). Hamsters that do not respond to treatment or relapse often have serious underlying disease and typically die within 3 mo. Historically, reports exist of pet hamsters infected with the tropical rat mite *Ornithonyssus bacoti* (see p 2030).

Fungal Infections: Spontaneously occurring dermatophytosis is extremely rare in Syrian hamsters.

Neoplasia

In older Syrian hamsters, lymphoma is the most frequently observed neoplasm of the hematopoietic system. It is multicentric and

commonly affects lymphatic organs. Cutaneous lymphoma, resembling mycosis fungoides (an epidermotropic T-cell lymphoma in people), is seen occasionally in adult Syrian hamsters. Affected animals show anorexia, weight loss, and patchy alopecia. Cutaneous lymphoma can be misdiagnosed as hyperadrenocorticism (Cushing disease), because affected hamsters initially show patchy alopecia and dermal hyperpigmentation. However, cutaneous lymphoma shows rapid progression of the disease, with mean time from presentation to euthanasia ~10 wk. Adenomas of the adrenal gland are common in Syrian hamsters, but few reports exist of confirmed clinical Cushing disease in hamsters.

Melanomas, not only of the flank organ but also of the skin, are frequently reported in Syrian hamsters. There is a striking 10:1 male:female melanoma ratio.

Djungarian hamsters showed a high prevalence of neoplastic disease (5 times greater than Syrian hamsters), and most tumors are integumental (eg, mammary tumors, atypical fibromas, and papillomas).

Miscellaneous Disorders

Age-related Disorders: Atrial thrombosis occurs in aging Syrian hamsters with an incidence of up to 70%. Most thromboses develop in the left atrium secondary to heart failure and lead to a consumptive coagulopathy. Although the incidence does not differ between the sexes near the end of their respective life spans, atrial thrombosis occurs on average at a younger age in females (13.5 mo) than in males (21.5 mo). Aged Syrian hamsters present with clinical signs of cardiomyopathy such as hyperpnea, tachycardia, and cyanosis. In untreated Syrian hamsters, death usually follows within a week after these signs are evident. The incidence of atrial thrombosis is influenced by the endocrine status of the animal, especially by the amount of circulating androgens. Thus, the castration of male Syrian hamsters is linked to an increase in the prevalence of atrial thrombosis.

Weight loss is seen in older Syrian hamsters and often associated with hepatic and renal amyloidosis. It is the principal cause of death in longterm research studies. Females have a higher incidence (80% among hamsters >18 mo old), increased severity, and earlier age of onset of amyloidosis than males. There is a correlation between social stress induced by crowding and amyloidosis in laboratory Syrian

hamsters. Not surprisingly, it is infrequently reported in pet Syrian hamsters, in which overcrowding is not a problem.

Degenerative renal disease also occurs more frequently in older female Syrian hamsters. Affected kidneys are pale and granular. Microscopically, glomerular changes vary from thickening of the basement membrane to glomerular obliteration. Amyloid deposition occurs frequently as a concurrent event.

Polycystic liver disease is seen in Syrian hamsters >1 yr old. The lesions are due to developmental defects of the bile duct and are not associated with clinical signs. At necropsy, numerous thin-walled cysts may be seen.

Zoonotic Risk

Syrian hamsters have a reputation as carriers of lymphocytic choriomeningitis virus (LCMV), a rodent-borne virus that can cause substantial neurologic disease, particularly among prenatal and immunocompromised people. The common house mouse, *Mus musculus*, is the natural host and principal reservoir of LCMV. People are typically infected through close proximity to wild mice and their droppings. However, three of the largest outbreaks of LCMV infection in the USA were attributable to hamsters obtained from a single supplier in the late 1970s. More recently, individual cases of LCMV infection have been epidemiologically linked to hamsters among organ transplant recipients. Although the risk of hamsters transmitting LCMV to the general population may be overstated, a German survey of persons in contact with pet hamsters confirmed an increased risk of LCMV infection, especially in city dwellers, younger age groups, and females. Transplacental infection occurs in the fetus of women who develop viremia during the first and second trimesters. The virus acts as a neuroteratogen, causing chorioretinopathy, hydrocephalus, microcephalus, lissencephaly, and potentially fetal death. The relative risk posed by hamsters should be considered among transplant recipients and pregnant women, because infected animals may remain clinically unaffected by LCMV and can transmit the virus for at least 8 mo. When apparent, LCMV infection in hamsters is characterized by wasting. Early signs are decreased activity and appetite and unkempt coat. Later signs include weight loss, hunched posture, blepharitis, convulsions, and eventually death.

MICE AND RATS AS PETS

Mice and rats are not as common as pets as other rodents. They are used extensively in research and, consequently, a separate section on mice and rats as laboratory animals follows below (*see* p 2032). Although a great deal of information has been accumulated on wild and laboratory rodents, very little of this information pertains to pet rodents.

The prevalence and type of mouse and rat diseases seen in clinical practice are quite different from those seen in a research setting. The diagnosis and treatment of pet mice and rats involves evaluation and care of an individual animal from a household, not the health management of rodents from a research colony. Most problems in mice and rats are dermatopathies, respiratory infections, and neoplasia.

Biology

Male rats are sexually mature by 6–10 wk; female rats are sexually mature by 8–12 wk. The breeding life of both male and female rats is 9–12 mo. Estrous cycle length in female rats is 4–5 days, and estrus lasts 10–20 hr. Female rats ovulate ~10–20 eggs. Gestation lasts 21–23 days; pseudopregnancy from sterile matings lasts 12 days. Rats have an average litter size of 8–18 pups. Weaning takes place at ~21 days.

Both male and female mice are sexually mature by 6–8 wk and have a breeding life of 9 mo. Estrous cycle length in female mice is 4–5 days, and estrus lasts 10–20 hr. Female mice ovulate ~6–10 eggs. Gestation lasts 19–21 days; pseudopregnancy from sterile matings lasts 12 days. Mice have an average litter size of 5–12 pups. Weaning takes place at ~21 days.

Male mice and rats produce a small amount of sperm daily at puberty (eg, 40–50 days in a rat). It is not until 75–100 days (10–14 wk) in rats that optimal sperm production and reserve occur. Male rodents show a constant libido after sexual maturity; in contrast, females are receptive to copulation only during estrus. Males cannot fertilize females until 6–8 wk after reaching puberty.

The average life span of mice is 18–24 mo and of rats 18–36 mo. Restricting dietary calories without compromising overall nutrition results in increased life span. Obesity in pet rats and mice is common, and calorie-restricted pets live significantly longer lives.

Husbandry

The best cages are made of a material that is easy to clean and deodorize and is indestructible to rodent chewing or digging in the corners. The cage floor can be solid but should be waterproof and easy to clean. Wire mesh floors should be avoided, because rats and mice can trap their feet and especially hindlimbs in the openings, resulting in fractures and injuries.

Animal cage bedding is described based on its use (eg, contact, noncontact, and enrichment bedding) or the material from which it is made (eg, wood-based [chips, shavings, peelings, wood-wool and sawdust], paper-based [cotton and pulp fiber, recycled paper], corn [husks and cobs], cellulose, and vermiculite). The purpose of bedding is to keep animals dry and clean. Pet owners generally choose bedding based on cost and availability, whereas laboratory veterinarians choose bedding based on cost and water-holding capacity. Some pet bedding contains lemon and chlorophyll to give it a pleasant scent. This type of bedding irritates pet rodents, and the coloring agents can stain the coat of white rats or mice. Traditionally, owners prefer paper and softwood chips, such as pine or aspen, to straw because it requires fewer bedding changes. Cedar and other wood chip shavings reduce ectoparasite problems and have a pleasant scent. However, such bedding is not recommended, because it emits toxic aromatic hydrocarbons that increase the incidence of cancer in animals and cause mouse and rat pup mortality.

Owners must combine frequent bedding changes with good husbandry such as regular cage cleaning, low animal density, and low environmental temperature and humidity. This will reduce toxic or odor-causing gases such as ammonia from building up, because urease-positive bacteria in the feces act to break down urea in the urine. Aquariums are not suitable cages for rats and mice because of inadequate air circulation and subsequent buildup of ammonia. Environmental temperature and relative humidity can depend on husbandry and housing design and can differ considerably between the cage and room. Factors that contribute to variation in temperature and humidity include cage material and construction, number of animals per cage, frequency of bedding changes, and bedding type.

Size and manipulability of bedding material are the main determinants of mice and rats' choices. Mice and rats avoid bedding consisting of small particles,

whereas they prefer bedding consisting of large, fibrous particles. When exposed to different types of nesting materials such as paper strips, cornhusks, sawdust, and wood materials (shavings, peelings, and chips), rats choose long strips of soft paper. Rats also select opaque or semiopaque nest boxes to transparent nest boxes. Mice show no preference between paper and wood-derived materials but show a clear preference for materials that they can manipulate such as paper tissues, string, and wood materials (shavings, peelings, and chips). Many mice will combine two preferred nesting materials to make complex nests. Mice typically dislike wire-bottomed cages; however, both male and female mice will spend more time in a wire-bottomed cage with nesting material, despite the grid floor that they usually avoid.

In environmentally enriched cages with hollow tubes, mice have no overwhelming group preference for shape, opacity, or openness of tubes and prefer to sleep in sawdust when it is available. Mice will sleep in hollow tubes only after the sawdust is removed; they use short, wide tubes more frequently than long or short narrow tubes.

Mice and rats are optimally maintained at temperatures of 64°–79°F (18°–26°C). Relative humidity should also be controlled but not nearly as narrowly as temperature. An acceptable range of relative humidity is 30%–70%. Both temperature and humidity regulation are important to prevent ringtail and exacerbation of respiratory disease. Avascular necrosis of the tail, or ringtail, occurs primarily in young rats in low-humidity environments. Excess heat and humidity cause heat stroke and indirectly cause decompensation of chronic respiratory disease, resulting in death.

Mouse and rat owners should check water bottles daily. If mice are deprived of water for only a short time and experience dramatic fluctuations in the surrounding temperature, especially >99°F (37°C), they die. In contrast, healthy rats tolerate water deprivation and temperature fluctuations better. They can live for 7 days without water, in temperatures between 64°–79°F (18°–26°C), although they may lose up to 65% of their body weight.

Minimal space allocations of 23 sq in. (58 sq cm) are recommended for individual rats weighing ≤200 g, and 60 sq in. (152 sq cm) for rats weighing ≥500 g. For mice, minimal space allocations of 15 sq in. (38 sq cm) for individual mice weighing >25 g are recommended. These are small surface areas, and veterinarians should advocate that owners provide larger space for their pets.

Most rodent enrichment studies focus on modifying the area inside the enclosure rather than the size of an enclosure. However, rats prefer larger cages, and experimental studies suggest rats should have a larger space that allows sharing of the environment with up to four other rats.

The minimum recommended height of cages should take into account typical postures of rats and mice. This includes the animal standing fully erect on its hindlegs, and vertical movements such as stretching upward and possibly climbing. Consequently, minimal cage heights of 12–15 in. (30–38 cm) for rats and 7–8 in. (18–20 cm) for mice are recommended.

Environmental enrichment is important for both mice and rats. For example, suspended cloth hammocks are popular with rats, and suspended (plastic or stainless steel) shower hooks fitted into one another can make a swinging chain. Rats will use more enrichment devices than mice, but they usually stop using the devices after 3–4 days. Rotation of enrichment toys and introduction of novel devices excite their curiosity. Food treats are also valuable enrichment items. These can range from simple, inexpensive treats such as a daily piece of a breakfast cereal to formulated nutritious or calorie-free treats. Rats also love chocolate, and it is not toxic when fed in small amounts. Pet rodents accustomed to handling will eat food treats out of the owner's hand. This daily routine can allow owners to detect subtle changes in the pet's behavior. Sick rodents effectively hide signs of disease. Sick rats do not show the same interest in their daily treat, and this can alert the owner early to disease when it is still treatable and/or reversible.

Housing male and female rodents together will result in mating and subsequent litters. Mice and rats experience postparturient estrus, and fertilization can occur. However, implantation of the resulting blastocysts is delayed during lactation and occurs at weaning, ensuring that the next litter is not born until the earlier one has been weaned. Female mice become sexually mature at 6–8 wk of age, and female rats are sexually mature by 10 wk of age. Unless opposite-sex rodents housed together are separated or neutered, having a new litter every 3–5 wk is possible.

Rats and mice are omnivores and will eat food of both plant and animal origin. In the wild, rats and mice will eat a wide variety of seeds, grains, and other plant material as well as invertebrates, small vertebrates, and carrion. Their ability to scavenge partly

accounts for their successful colonization of diverse geographic regions.

Formulated pelleted diets for laboratory rodents are convenient and nutritionally balanced diets for early life and reproduction. However, laboratory rodent diets are relatively high in fat and low in fiber, and when provided ad libitum, they cause obesity. Consequently, the amount of pelleted diet owners provide daily should be limited. Diets formulated specifically for pet rodents are now commercially available. Owners should supplement their pet's diet with feeds high in fiber such as vegetables, limited amounts of fruit, and occasional treats.

Coprophagy is a normal behavior in rats and mice. It is an inherent behavior, because it is seen in germ free rodents purposely bred for research. Unlike rabbits, which eat cecal feces from their anus, mice and rats eat fecal pellets on the floor of their caging. The amount of feces eaten varies between rodents, their age and physiologic status (eg, coprophagy increases in pregnancy), and the diet fed. On a nutritionally complete diet, rats will eat ~10% of their feces. When rats are housed together, they ingest each other's feces. The unique odor of a colony is due in part to ingestion of feces, and the group scent enables distinction between members and nonmembers. Mice engage in coprophagy ~6 times/day. Growing mice show vigorous coprophagous activity, eating 13 pellets/day. However, it gradually decreases to 1½ pellets at 2 yr of age.

Owners should house different species of rodents separately to prevent interspecies disease transmission. For example, rats carry *Streptobacillus moniliformis* (see p 2418), a cause of fatal septicemia in mice, as part of the normal nasopharyngeal bacterial flora. Rodents of the same species should be housed in such a way to protect vulnerable animals from more aggressive members of their group. This includes separating young animals from older ones. Female rodents are generally compatible when housed in the same cage, unless one female has lived much of its life alone. Male rats are generally compatible, especially if raised together. However, owners should never house strange male rats in the same cage together because they will fight. Male mice generally fight if housed together, unless they are littermates raised together without females present. Male mice are best housed singly or with female mice.

Rats are social animals, and grooming is a socially affiliative behavior. Singly housed rats may develop isolated-rat stress syndrome if left alone without human

contact and environmental enrichment. Isolation-reared rats will experience fighting, physical injuries, and weight loss when placed into a colony of socially experienced rats. Young rats should be housed together to develop social affiliation. Singly housed rats should not be put together. Owners should be advised to encourage enrichment and human contact with pet rats.

Physical Examination

Observing the condition of the rodent's living quarters provides useful information. Information obtained from a physical examination is often limited because of the mouse or rat's size. Activity of the rat, condition of grooming, and the presence of a head tilt or discharges in the cage should be noted. If dyspnea or depression is seen, extreme care should be used when handling the animal, because it is probably very sick and could die from the stress of a physical examination.

Pet rodents that have been frequently and gently handled usually require only minimal restraint. Less cooperative animals need to be more firmly restrained, and use of a towel or even heavy gloves may be required. Weight measurement is essential to calculate appropriate dosages of medications and provides an opportunity to gauge the rodent's temperament before beginning the actual physical examination.

The head, ears, eyes, and nose should be examined for discharges, and the oral cavity for dentition. Lymph nodes and glands of the head can be observed for size and palpated for consistency. Assessment of the head is probably the most time-consuming part of the examination. The abdomen can be palpated for consistency and the presence of unusual masses. Animals should not be squeezed too vigorously, because overzealous palpation can result in visceral rupture. The anogenital region should be examined for discharges and staining of the fur or skin. When a rodent is picked up, it generally urinates and defecates. A dipstick should be ready to perform an immediate urinalysis; feces can be caught in a small tube and examined later. The limbs should be palpated for tenderness or fractures, with special attention given to the paws, noting the length of the nails and condition of the footpads.

Respirations and heart rate in mice and rats are rapid and, therefore, difficult to measure. Instead, signs of dyspnea should be noted. Some respiratory infections, such

as mycoplasmosis, are clinically silent. These diseases can be better heard than seen; abnormal sounds called “snuffling” in rats and “chattering” in mice are noticeable without a stethoscope.

Infectious Diseases

Bacterial Infections: Rats are the natural host of the bacterium *Streptobacillus moniliformis*. It is a commensal organism of the nasopharyngeal flora and does not cause disease in rats. However, individuals bitten by rats may become infected with *S moniliformis* and develop rat bite fever, a potentially fatal disease (see p 2418). Mice housed with rats will become infected with *S moniliformis* and develop fatal septicemia characterized by polyarthritis, cervical lymphadenitis, pneumonia, and splenomegaly.

Respiratory disease caused by infectious agents is the most common health problem in rats. Three major respiratory pathogens cause overt clinical disease: *Mycoplasma pulmonis*, *Streptococcus pneumoniae*, and *Corynebacterium kutscheri*. Other organisms such as Sendai virus (a paramyxovirus), pneumonia virus of mice (a paramyxovirus), rat respiratory virus (a hantavirus), cilia-associated respiratory (CAR) bacillus, and *Haemophilus* species are minor respiratory pathogens that rarely cause overt clinical disease by themselves. However, the minor respiratory pathogens interact synergistically as copathogens with the major respiratory pathogens to produce two major clinical syndromes: chronic respiratory disease (CRD) and bacterial pneumonia.

CRD is the best-understood multifactorial respiratory infection in rats. *M pulmonis* is the major component of CRD, and the disease is also known as murine respiratory mycoplasmosis. Rats with CRD rarely live >2 yr. Clinical signs are highly variable. Initial infection commonly occurs without any clinical signs; early signs involve both the upper and lower respiratory tracts and may include snuffling, nasal discharge, polypnea, weight loss, hunched posture, ruffled coat, head tilt, and red tears. Dyspnea, the primary presenting complaint, is caused by ciliostasis, subsequent buildup of lysozyme-rich inflammatory exudate in airways, bronchiectasis, and bronchiolectasis from inflammatory damage to broncholar membranes. Chronic disease often includes middle ear infection (via the eustachian tube). Antibiotic therapy may alleviate clinical signs but does not eliminate the infection. Enrofloxacin (10

mg/kg) and doxycycline (5–10 mg/kg) given orally bid for 14 days often alleviates severe clinical signs. Additional treatments such as daily nebulization therapy with 7% hypertonic saline to break down the mucus biofilm in respiratory passages, bronchodilators (theophylline 10 mg/kg, bid) to improve airway patency, and reducing ammonia levels in cages by daily removal of bedding and use of clean paper will ameliorate the disease. Chronic low dose doxycycline (5–10 mg/kg/day, PO) helps to prevent acute relapses. The doxycycline is both bactericidal for mycoplasma organisms and has a marked immunomodulatory effect on the chronic airway inflammation.

The most important aspect of CRD for clinicians is that respiratory mycoplasmosis varies greatly in disease expression because of environmental, host, and organism factors that influence the host-pathogen relationship. Examples of such factors include intracage ammonia levels; concurrent Sendai virus, coronavirus (sialodacryoadenitis virus), pneumonia virus of mice, rat respiratory virus, and/or CAR bacillus infection; the genetic susceptibility of the host; the virulence of the *Mycoplasma* strain; and vitamin A or E deficiency. Although CRD is rarely seen in laboratory rats, most pet rats have CRD to some degree. One survey of pet ratteries in the northwest USA showed virtually all (95%) were positive for CAR-bacillus and *M pulmonis*, and approximately half were positive for other viral respiratory agents.

Bacterial pneumonia is nearly always caused by *S pneumoniae*, but seldom in the absence of some combination involving *M pulmonis*, Sendai virus, or CAR bacillus. Infection with *C kutscheri* also results in pneumonia but only in conjunction with debilitation or immunosuppression. In pet rats, immunosuppression can result from diabetes, neoplasia, or dietary deficiencies. *C kutscheri* pneumonia is rare in pet rats. Pneumonia caused by *S pneumoniae* can be of sudden onset. Young rats are more severely affected than older ones, and often the only sign they exhibit is sudden death. Mature rats may demonstrate dyspnea, snuffling, and abdominal breathing. A purulent exudate may be seen around the nares and on the front paws from wiping of the nostrils. A tentative diagnosis is based on identification of numerous gram-positive diplococci on a Gram stain of the exudate or in a sample submitted for cytologic examination. Severe bacteremia is an important consequence of advanced disease and results in multiorgan abscesses and

infarction. Treatment is amoxicillin/clavulanic acid (13.75 mg/kg, PO, bid) or β -lactamase-resistant penicillins such as cloxacillin, oxacillin, and dicloxacillin, which can all be administered orally or parenterally.

Ulcerative dermatitis caused by *Staphylococcus aureus* infection results from self-trauma associated with fur mite infestation or, more commonly, from scratching of the skin over an inflamed salivary gland. Rats have a remarkable ability to resist infection with *S. aureus*. Treatment consists of clipping the toenails of the hindpaws, cleaning the ulcerated skin, and applying a topical antibiotic. Systemic treatment is rarely necessary.

The two most common causes of clinical respiratory disease in mice are Sendai virus and *M. pulmonis* infection. Sendai virus is associated with an acute respiratory infection in which mice display chattering and mild respiratory distress. Neonates and weanlings may die. Adults generally recover within 2 mo. When the disease expression exceeds this pattern, the cause is most likely concurrent mycoplasmal infection. *M. pulmonis* is the cause of chronic pneumonia, suppurative rhinitis, and occasionally otitis media. Chattering and dyspnea are caused by accumulations of purulent exudate in inflamed and thickened nasal passages. Survivors often develop chronic bronchopneumonia, bronchiectasis, and pulmonary abscesses. Antibiotic therapy may alleviate clinical signs but does not eliminate the infection.

Viral Infections: Viral diseases of mice and rats are common. However, most diseases are subclinical and important only in laboratory animals in which they have the potential to have a significant effect on research.

Sialodacryoadenitis virus, a coronavirus, causes inflammation and edema of the cervical salivary glands in rats. Owners of infected rats often describe their pets as having mumps. Sialodacryoadenitis virus infection is highly contagious. It initially causes rhinitis followed by epithelial necrosis and inflammatory swelling of the salivary and lacrimal glands. Cervical lymph nodes also become enlarged. There is no treatment for this disease. Glandular healing follows within 7–10 days, and clinical signs subside within 30 days, with minimal residual lesions remaining. During acute inflammation, affected rats are at high risk of anesthesia related mortality because of the decreased diameter of the upper respiratory tract lumen. Ocular

lesions such as conjunctivitis, keratitis, corneal ulcers, synechia, and hyphema can develop secondary to lacrimal dysfunction. The eye lesions usually resolve but occasionally progress to chronic keratitis and megaglobus.

Parasitic Infections:

Protozoa: Endoparasites are relatively common in mice. However, only two parasites regularly encountered in the digestive tract, the protozoan parasites *Spiroplasma muris* and *Giardia muris*, are considered pathogenic, even though they are not associated with clinical signs in immunocompetent hosts. Diagnosis is based on demonstration of characteristic trophozoites in wet mounts of fresh intestinal contents or feces. Treatment is metronidazole (10–40 mg/kg/day, PO, or 0.04%–0.1% drinking water solution for 14 days), but it does not completely eliminate the infection.

Nematodes: Pinworms are ubiquitous and considered nonpathogenic in mice. Two are commonly encountered: *Syphacia obvelata* and *Aspicularis tetraptera*. Often, the only indication of pinworm infestation is rectal prolapse due to straining. To establish a diagnosis of *S. obvelata* infestation, a clear cellophane tape impression of the perianal skin can be made. Adult *S. obvelata* females deposit ova around the anus. A *tetraptera* does not deposit its ova in this area, and fecal smear or flotation is required to confirm a diagnosis. Ivermectin (2 mg/kg, PO, given twice at a 10-day interval) eliminates pinworms from mice. The recommended label dosage for mice with ectoparasites (0.2 mg/kg, given twice at a 10-day interval) does not eliminate pinworms.

Mites: Most infectious causes of alopecia and dermatitis in mice are associated with fur mites. Generalized thinning of the hair, especially on difficult-to-groom areas such as the head and trunk, is seen. The coat often has a greasy appearance and, in cases of heavy infestation, noticeable pruritus and self-inflicted dermal ulceration may occur. Three mites are commonly seen: *Myobia musculi*, *Mycopetes musculus*, and *Radfordia affinis*. *M. musculi* is the most clinically significant mouse mite. Infestations are usually caused by more than one species. Mites are spread by direct contact with infected mice or infested bedding. Diagnosis is based on identification of adult mites, nymphs, or eggs on hair shafts with the use of a hand lens or stereoscopic microscope. Adults and nymphs appear

pearly white and elongate; eggs are oval and can be seen attached to the base of hairs or inside mature females. Mite infestations are treated with ivermectin (0.2 mg/kg, SC or PO, twice at 10-day intervals). Alternatively, a few drops of ivermectin solution (diluted to 1:100 in equal parts of water and propylene glycol for three treatments) can be placed on the mouse's head to allow spread by grooming and ingestion.

Ectoparasitic infestation is less common in rats than in mice. Occasionally, the fur mite *Radfordia ensifera* is seen. Although *R. ensifera* infestation produces few ill effects, heavy infestation may lead to self trauma and ulcerative dermatitis.

Ornithonyssus bacoti, the tropical rat mite or red mite, is a bloodsucking parasitic mite primarily found in wild rats such as the brown rat (*Rattus norvegicus*) or the black roof rat (*Rattus rattus*). It has a wide host range and occasionally infects pet hamsters, gerbils, rats, and mice living in very old buildings or when building construction or renovations disturb colonies of wild rodents that had been on the premises and acting as hosts. *O. bacoti* can survive for long periods in the environment and travel considerable distances in search of new hosts. If it does not find a suitable rodent host, it will feed on people. Its common name is a misnomer, because it is found worldwide in tropical and temperate climates. Mites appear white before feeding and become red-brown after engorgement. Heavy infestations on pet rodents resemble fine sawdust within the fur. *O. bacoti* typically does not cause clinical signs in pet rodents, but heavy infestations cause anemia, debility, weakness, pruritus, and death in small rodents. As well as causing discomfort, the mite is a vector for the rodent filarial nematode *Litomosoides carinii* and a potential vector of several human pathogens. Most infestations occur in late spring or early summer when fledglings are leaving the nest and the mites are searching for another food source. Infestation of *O. bacoti* is eliminated by a combination of bathing and treating the host animal with selamectin (15 mg/kg, one topical treatment), elimination of commensal rodent reservoirs, and insecticide treatment of the pet's cage (permethrin-impregnated cotton balls 7.4% placed inside the cage weekly for 6 wk) and environment (fipronil spray or synthetic pyrethroids).

Fungal Infections: Dermatophytosis is uncommon in pet mice and rats. It is caused by *Trichophyton mentagrophytes*. Lesions, when present, are most common on the face, head, neck, and tail. The lesions

have a scurfy appearance, with patchy areas of alopecia and variable degrees of erythema and crusting. Pruritus is usually minimal to absent, and the lesions do not fluoresce under a Wood's lamp. *T. mentagrophytes* can be isolated from the fur of clinically normal mice but is rare in rats.

Neoplasia

The most common subcutaneous tumor in rats is fibroadenoma of the mammary glands. The distribution of the mammary tissue is extensive, and the tumors can develop anywhere from the neck to inguinal region. Tumors can reach 8–10 cm in diameter and are seen in both males and females. The surgical technique for tumor removal is straightforward, and survival after mastectomy has been reported to be good if the tumor is benign. The prevalence of mammary tumors, as well as that of pituitary tumors, is significantly lower in ovariectomized rats than in sexually intact rats. However, the recurrence of fibroadenomas is common in uninvolved mammary tissue, and often several surgeries are needed.

In contrast, mammary tumors in mice are nearly always malignant and often are not amenable to surgical removal. The most common spontaneous tumors associated with the skin are mammary adenocarcinomas, followed by fibrosarcomas. The incidence of mammary tumors varies according to the mouse strain and the presence or absence of mouse mammary tumor viruses; the incidence is as high as 70% in some strains. In wild and outbred mice, the incidence of fibrosarcomas is 1%–6%.

Subcutaneous tumors are nearly always malignant and often have ulcerated by the time a diagnosis is made. Tumors can be treated by surgical excision, but the chance of recurrence is high and the prognosis is poor.

Miscellaneous and Iatrogenic Disorders

Dental Overgrowth: Dental problems are commonly seen in pet mice and rats because of their continually erupting teeth. Overgrown incisors are seen most frequently in rats and mice, in contrast with molar occlusion seen in guinea pigs and chinchillas. Overgrowth is easily treated with a high-speed drill that cuts through the overgrown incisors without splitting or splintering them, leaving a clean, smooth surface. Cutting the teeth with rongeurs

does not produce good longterm results, and problems may arise. The incisor may fracture longitudinally; the fracture may reach the apex and cause the animal discomfort. Bacteria can enter the fractured tooth, track down to the apex, and cause an apical abscess. Extraction of the incisors is an alternative to trimming; however, this procedure is difficult because of the incisors' long roots.

Age-related Disorders: Chronic progressive nephrosis is a common age-related disease in rats. The kidneys are enlarged, pale, and have a pitted, mottled surface that often contains pinpoint cysts. Lesions consist of a progressive glomerulosclerosis and widespread tubulointerstitial disease, primarily involving the proximal convoluted tubule. Proteinuria often is >10 mg/day. The disease occurs earlier and is of greater severity in males than in females. Dietary factors appear to have an important role in the progression of renal disease. Caloric restriction, the feeding of low-protein diets (4%–7%), and limiting the source of dietary protein reduce the incidence and severity of the disease. Treatment is supportive and involves feeding a low-protein diet.

Avascular necrosis of the tail, or ringtail, is seen primarily in young rats, and occasionally in young mice, kept in low-humidity environments. If ringtail is diagnosed, treatment involves amputation of the tail below the necrotic annular constriction.

Skin Disease in Mice: Most of the diseases seen in pet mice are associated with the skin and represent >25% of all cases. Behavioral disorders, husbandry-related problems, microbiologic/parasitic infections, and idiopathic skin diseases are seen. Behavioral, husbandry-related, and infectious causes of skin disease are relatively straightforward to diagnose and treat. However, many skin diseases characterized by chronic or ulcerated skin (often secondarily colonized by bacteria) are diagnosed as idiopathic. This group is commonly unresponsive to treatment, topical or systemic, and affected mice are often euthanized.

Barbering and fighting are manifestations of social dominance, a form of behavior relating to the social rank and dominance status of an individual mouse in a group. Barbering is a unique condition seen in group-housed mice in which the dominant mouse nibbles off the whiskers and hair around the muzzle and eyes of cagemates.

There are no other lesions, and only one mouse, the dominant individual, retains all of its fur. Removal of the dominant mouse stops barbering; frequently, however, another mouse assumes the dominant role. Barbering is often seen in female mice caged together. Male mice, except littermates raised together from birth, are more likely to fight, often very savagely, and inflict severe bite wounds on one another, especially over the rump, tail, and shoulders.

Mechanical abrasion resulting from self-trauma on cage equipment is a form of husbandry-related alopecia. Small patches of alopecia appear on the lateral surfaces of the muzzle. They result from chafing on metal feeders, poorly constructed watering device openings, and metal cage tops. Unlike barbering, dermatitis may also be associated with alopecia. Treatment consists of replacing the poorly constructed equipment with nonabrading equipment. Individually housed mice can display aberrant stereotypic behavior such as polydipsia and bar chewing that results in mechanical abrasion and alopecia. In these cases with one mouse, replacing the cage equipment does not help. Instead, environmental enrichment toys such as running wheels or hollow tubes should be provided. Nursing mice often have ventral abdominal and thoracic alopecia; this is normal and is nearly always associated with the extensive distribution of mammary glands.

Sometimes a pet mouse presents with clinical signs of mite infestation but no evidence of mites or known history of recent exposure to other animals. Biopsy samples may be useful in these cases to distinguish active acariasis from dermal hypersensitivity to mites or other allergens such as timber chip bedding. Dermal hypersensitivity is well described in certain inbred strains of mice and is characterized by severe pruritus, the presence of fine dandruff all over the body, and occasionally ulcerative dermatitis.

Idiopathic skin disease is characterized by ulcerative dermatitis with pruritus in mice that are negative for primary ectoparasitic, bacterial, or mycotic infections. Histopathologic examination and immunofluorescent microscopy of selected inbred strains of mice have revealed an underlying vasculitis attributed to immune complex deposition on dermal vessels. Dietary factors and dysregulated fatty acid metabolism have been implicated in the development of the ulcerative dermatitis in these mice. This common

disease of mice of a C57BL/6 background is caused by an underlying immune-mediated vasculitis, and the severity appears to be modulated by dietary fat and vitamin E content. Topical treatment twice daily with 0.2% cyclosporine in 2% lidocaine gel supplemented with gentamicin at 50 mcg/mL results in either complete healing or near-complete healing of the ulcerated skin, regardless of the size of the skin ulceration.

Skin swellings in mice are usually tumors or abscesses. Needle biopsy often reveals the nature of the contents and allows diagnosis. Three opportunistic pathogens, *Staphylococcus aureus*, *Pasteurella pneumotropica*, and *Streptococcus pyogenes*, are isolated frequently and can cause abscesses in other organs. Antibiotic therapy with penicillins or cephalosporins, concurrent with drainage and debridement of the abscess, is effective.

Chromodacryorrhea in Rats: The Harderian glands of rats are located behind the eyes and secrete porphyrins that are increased in response to stress and disease, coloring the tears red. When porphyrin-enriched tear fluid dries around the eyes and external nares, it resembles crusts of blood. Owners often describe their rats as hemorrhaging from the eyes and nose. The porphyrins can be readily differentiated from blood with a Wood's lamp, because they fluoresce under ultraviolet light. Although chromodacryorrhea is not pathologic, it is a consequence of acute-onset stress such as that caused by pain, illness, or restraint. It usually indicates a chronic underlying disease.

Zoonotic Risk

As rats have become popular as pets, children now account for >50% of the cases of rat bite fever (RBF) in the USA; 14% of RBF cases in children involved exposure to a rat at school. RBF manifests as a bacteremia and septicemia characterized by fever, chills, myalgia, arthralgia, headache, and vomiting. A petechial rash develops over the extremities, in particular the palms and soles, but sometimes is present all over the body. The incubation period is 3–10 days (average 5 days). Infants and children may experience severe diarrhea resulting in weight loss. Mortality occurs in 7%–13% of untreated patients. After infection, a polyarthritis develops in 50%–70% of patients. Prognosis is good with treatment with parenteral penicillin early in the disease. Fatalities are associated with late reporting or late recognition of the disease.

The nonspecific initial presentation combined with difficulties in culturing *Streptococcus moniliformis* produce a significant risk of delay or failure in diagnosis. Rats are not recommended as pets for children. Adults with pet rats should practice regular handwashing and avoid hand-to-mouth contact when handling rats or cleaning rat cages.

There are sporadic but persistent reports of cases of *Ornithonyssus bacoti* dermatitis from pet rodents that manifests as an erythematous papular rash. It often excoriates because of intense pruritus. Occasionally, vesicles, urticarial plaques, diffuse erythema, or hemorrhage are seen. Affected areas of the skin are those usually covered by clothing (such as arms and trunk), with the face and webs of fingers usually spared. There is considerable evidence that *O. bacoti* carry and have the potential to transmit several human pathogens. Experiments have shown that *O. bacoti* transmits *Rickettsia akari* (rickettsialpox), *Yersinia pestis* (plague), Coxsackie virus, *Francisella tularensis* (tularemia), and *Trypanosoma cruzi* (Chagas' disease). Researchers have also documented *O. bacoti* specimens with *Coxiella burnetii* (Q fever), hantavirus, *Borrelia* spp (Lyme disease), *Bartonella* spp, and *Rickettsia* spp.

Mice are inapparent carriers of dermatophytes, and pet mice are a zoonotic risk for their owners, especially children.

MICE AND RATS AS LABORATORY ANIMALS

Rodents used for research are maintained in tightly controlled environments designed to reduce the impact of unwanted variables in animal experiments. Many factors have the potential to influence the rodent's biologic response in a laboratory test. Besides a description of the experiment, research journals often require a description of the research rodent's source, microbiologic status, and environment (eg, feed, water, temperature, humidity, light exposure) in the materials and methods section. Environmental conditions, husbandry procedures, and animals must be similar if research data generated from one laboratory is to be judged based on reproducibility and thus validation. If variables such as feed, housing, rodent genetic background and disease-free or microbiologic status are not properly controlled, then experimental results can be of limited use or even worthless. Although

complete elimination of variables in animal experiments is not possible, many factors that contribute to variation can be significantly reduced or eliminated. One of the most important variables is the effect of infectious agents on research mice and rats.

Few infectious agents found in laboratory mice and rats today cause overt, clinical disease. Distinguishing between infection and disease is critical to interpreting the microbiologic status of laboratory animals. Infection indicates the presence of microorganisms, which may be pathogens, opportunists, or commensals, of which the last two are most numerous. Clinical disease does not need to be present for microorganisms to affect research. Animals that appear normal and healthy may be unsuitable as research subjects because of the unobservable but significant local or systemic effects of viruses, bacteria, and parasites with which they may be infected.

Knowledge of the varied and unwanted effects of natural pathogens in laboratory rodents has steadily increased over the past 130 years of conducting animal research. The historic struggle against pathogens of laboratory rodents is often divided into three periods. The first (1880–1950) was when mice and rats became common research animals. Many of these original stocks harbored a variety of natural, or indigenous, pathogens. During this period, improvements were made in sanitation, nutrition, environmental control, and other aspects of animal husbandry. The result was a great reduction in the range and prevalence of pathogens found in laboratory rodents. The second period (1950–1980) was one of gnotobiotic derivation, when cesarean rederivation was used to replace infected stock with uninfected offspring. Full-term fetuses were removed from an infected mother and transferred to a

germ-free environment and foster care. This procedure was successful in eliminating many pathogens not transmissible in utero, eg, endoparasites, most bacteria, and some viruses. The third period (1980–present) has been one of eradicating indigenous rodent viruses. The reduction in known viruses infecting rodents was accomplished through serologic testing of animals for antibodies to specific pathogens. Antibody-positive colonies were subsequently eliminated or cesarean-rederived.

Most modern research animal facilities incorporate some form of health monitoring into their animal care program (see TABLE 32). Since the 1980s, it has been based on serology, although molecular methods of detection (eg, PCR) are rapidly increasing in use. The laboratories that perform serologic assays primarily test groups of research rodents or their samples. The well-being of the animal colony is more important than the well-being of an individual animal, and laboratory animal medicine is effectively a type of “herd medicine.” Although health monitoring is costly, it results in significant longterm savings, because researchers can use fewer animals and the animals’ daily care is not as labor intensive. Health monitoring allows laboratory animal veterinarians to check the health status of a colony, inform researchers of their animals’ pathogen status, prevent entry of pathogens into the facility by screening animals received from unknown sources, and promptly deal with the presence of unexpected infectious agents in rodents. Undetected infection makes laboratory animals unfit for research and renders experimental data unreliable. It is more cost-effective to prevent entry of infectious agents into a facility or to detect and eliminate them early than to discard months of research data.

TABLE 32

INFECTIOUS AGENTS COMMONLY TESTED FOR IN LABORATORY RODENTS

Test	Agent	Description	Species
PROTOZOA			
E cun	<i>Encephalitozoon cuniculi</i>	A sporozoan parasite of rabbits and rodents	Mice, rats
BACTERIA			
C pil	<i>Clostridium piliforme</i>	Agent of Tyzzer disease	Mice, rats

TABLE 32

INFECTIOUS AGENTS COMMONLY TESTED FOR IN LABORATORY RODENTS *(continued)*

Test	Agent	Description	Species
CARB	Cilia associated–respiratory bacillus	A bacterial respiratory pathogen of rodents and rabbits	Mice, rats
M pul	<i>Mycoplasma pulmonis</i>	Agent of mouse and rat pulmonary mycoplasmosis	Mice, rats
VIRUSES			
ECT	Ectromelia	A mouse poxvirus	Mice
TH-1	Toolan's H-1 virus	A rat parvovirus	Rats
	Hantaan virus	A zoonotic hantavirus of rats; several types (HPS, NED) exist throughout world	Rats
K virus	Mouse pneumonitis virus	A mouse papovavirus	Mice
KRV	Kilham rat virus	A rat parvovirus	Rats
LCM	Lymphocytic choriomeningitis virus	A zoonotic arenavirus	Mice, rats
LDEV	Lactate dehydrogenase–elevating virus	A mouse arterivirus	Mice
MAD1 (FL)	Rodent adenovirus strain 1	Mouse adenovirus, rodent adenovirus strain 1 (FL)	Mice, rats
MAD2 (K87)	Rodent adenovirus strain 2	Mouse adenovirus, rodent adenovirus strain 2 (K87)	Mice
MCMV	Mouse cytomegalovirus	A mouse herpesvirus	Mice
MHV	Mouse hepatitis virus	A mouse coronavirus	Mice
MNV	Murine norovirus	A mouse calicivirus	Mice
MPV	Mouse parvovirus	A mouse parvovirus	Mice
MTV	Mouse thymic virus	A mouse herpesvirus	Mice
MVM (MMV)	Minute virus of mice	A mouse parvovirus	Mice
PolyVM	Polyoma virus of mice	A mouse papovavirus	Mice
PVM	Pneumonia virus of mice	A rodent pneumovirus	Mice, rats
SDAV	Sialodacryoadenitis virus	A rat coronavirus	Rats
Reo3	Reovirus type 3	A rodent reovirus	Mice, rats
SenV	Sendai virus	A type 1 paramyxovirus	Mice, rats
RTV	Rat theilovirus	A rat picornavirus	Rats
TMEV (GDVII)	Theiler murine encephalomyelitis virus	Mouse poliovirus, strain GDVII	Mice

SUGAR GLIDERS

Sugar gliders (*Petaurus breviceps*) are small, nocturnal marsupials native to Australia, Indonesia, and New Guinea that live in eucalyptus and acacia forests. They belong to the family Petauridae, which includes the wrist winged gliders. Gliders in this family possess a gliding membrane (patagium) that runs from the wrist of the forelimb to the ankle of the hindlimb and that allows them to glide as far as 50 m and forage for food using less energy. They use their tails as stabilizing rudders that enable them to change direction easily. The second and third toes on their hindfeet are fused to form a "grooming comb" that helps them clean their fur. Females are seasonally polyestrous and have a double vagina, two uteri, and a pouch containing four teats; they often have twin births. After 16 days of gestation, the young (joeys), each weighing only 0.2 g, migrate to the pouch to develop further and finally leave the pouch after 70–74 days. They remain in the nest until 110–120 days of age, when they are weaned. They stay with the colony until 7–10 mo old. Males have a forked penis (to match the female's double vagina) and a pendulous scrotum containing two testicles. Males do not urinate from the forked end of the penis but from the proximal end. Both males and females have paracloacal scent glands adjacent to the vent (the cloacal opening or common opening of urinary, reproductive, and GI tracts) with which they mark territory and each other, and males also have frontal scent glands on their foreheads and glands on their throats and chests. Sparse fur and an oily discharge are normal

on the frontal and sternal glands of post-pubescent males. These glands give both sexes a musky odor.

Sugar gliders have large, protruding, widely spaced eyes, giving them a wide field of vision, especially at night. Their ears move independently and are highly sensitive to sound. They also have a great sense of smell to locate food, sense predators, and recognize both their territory and their colony-mates. Wild gliders have gray fur and a central black stripe dorsally on their heads; domesticated gliders may look similar to the wild type but also come in several color variations. Sugar gliders are polygamous, territorial, and live in colonies of 5 to 12 individuals with a dominant male. They sleep in tree hollows by day and between foraging trips at night. They tolerate a wide range of environmental temperatures and go into torpor to conserve energy in very cold conditions. Sugar gliders are omnivorous and feed on sugar-rich plant and insect exudates (sap, gum, nectar, manna, pollen) and invertebrates as a source of protein. They are hindgut fermenters and possess a well-developed cecum that utilizes bacterial fermentation to break down complex polysaccharides contained in gum. *See also* TABLE 33, which summarizes important biologic and physiologic data for sugar gliders.

Physical Examination: For a full clinical examination, anesthesia with isoflurane via face mask may be required if gliders are very stressed or biting. More docile animals may be examined while wrapped in a small towel and cupped in the palm of the hand. Gliders inside fabric bags or pouches may be partially exposed, one body part at a time, for examination. Because gliders are nocturnal, it may be best to schedule clinical examinations earlier in the day when they are less active. If possible, the animal should be first observed moving in its cage to assess posture, coordination, and demeanor. If the glider is anesthetized, cloacal temperature, heart rate, and respiration rate can be recorded, and the heart and lungs assessed with a pediatric stethoscope. The fur and skin should be examined for ectoparasites, traumatic injury, fur loss, and degree of hydration; the oral cavity for broken teeth, dental abscesses, or tartar build up; and the eyes

Forked penis of a male sugar glider. Courtesy of Dr. Laurie Hess.

TABLE 33 SELECTED PHYSIOLOGIC DATA FOR SUGAR GLIDERS

Life span	9–12 yr
Adult male body wt	100–160 g
Adult female body wt	80–135 g
Respiratory rate	16–40/min
Heart rate	200–300 bpm
Body temperature	97.3°F (36.3°C)
Thermoneutral zone	80°–88°F (27°–31°C)
Food consumption	15%–20% body wt/day
Dentition	Diprotodont
Dental formula	2(I 3/1-2 C 1/0 P 3/3 M 4/4)
Puberty	8–12 mo in females, 12–15 mo in males
Estrous cycle	29 days
Gestation period	15–17 days
Litter size	2 (81%)
Birth weight	0.2 g
Pouch emergence	70–74 days
Weaning	110–120 days

and ears for any abnormalities. The cloacal area should be examined, and the penis of males extruded. The abdomen should be palpated, and the pouch in females examined. Major joints should also be palpated, and digits and toenails checked for evidence of trauma.

Diagnostic and Treatment Techniques:

If animals are dehydrated, isotonic fluids up to 10% of body wt can be administered SC over the shoulder region. Care should be taken not to induce edema to the patagium. Fluids also may be administered intraosseously in the proximal femur or tibia. SC injections may be given in the same area that SC fluids are administered. IM injections may be given in the epaxial muscles of the neck and dorsal thorax. IV injections are very difficult to perform but may be accomplished in cephalic or lateral saphenous veins in an anesthetized glider.

Radiographs generally require the glider be anesthetized for proper positioning. Pulmonary diseases are easiest to detect with radiographs. Feces may be easily sampled and checked annually with a fecal float and direct smear for parasites; animals with diarrhea should have their feces cultured and tested for appropriate antibiotic sensitivity.

Blood Collection, Hematology, and Biochemistry:

Reference ranges for sugar gliders are presented in TABLE 34. Chemical restraint, essential to allow blood collection, is most safely achieved with isoflurane/oxygen administered via mask and T piece. To assist in making clinical diagnoses, blood samples may be obtained from the cranial vena cava, jugular vein, medial tibial artery, or lateral tail vein. Blood volumes of up to 1% of body wt can be collected; typically 0.5–1 mL is obtained. To access the cranial vena cava, a 27- or 25-gauge needle on an insulin syringe may be inserted in the thoracic inlet just lateral to the manubrium, with the needle directed at a 30° angle from midline toward the opposite hindleg. The vena cava is not visualized directly during venipuncture but is accessed blindly using the manubrium as a palpable landmark. The jugular vein can be visualized if the hair is clipped and the vein is forced to fill by applying gentle digital pressure at the thoracic inlet; it sits midway between the point of the shoulder and the mandibular ramus. The needle can be bent at its base to facilitate venipuncture at this site. The medial tibial artery, which runs very superficially just distal and medial to the stifle joint, is easier to access and can be sampled with a 27- or 25-gauge needle and 0.5–1 mL syringe.

Pressure after sampling is required to prevent hematoma formation. The size of the lateral tail vein is most suited to skin prick and droplet collection into capillary tubes. Small blood samples (0.25 mL) may also be obtained from the cephalic, lateral saphenous, femoral, and ventral coccygeal veins with a 27-gauge needle on an insulin syringe.

Anesthesia and Surgery: Anesthesia in sugar gliders should be approached the same way it is in other small mammals.

Gliders ideally should be fasted for at least 4 hr preoperatively. Preoperative analgesics, sedatives to reduce preoperative stress, and local and gas anesthetics all may be used. Care must be taken to keep gliders warm during surgery to ensure rapid recovery. Gliders undergoing surgeries that last >1 hr or that require intra-abdominal access should be administered fluids intraosseously (in the femur or tibia) throughout the procedure if IV access is impossible because of small size. Shorter, simple

TABLE 34

SELECTED HEMATOLOGIC AND SERUM BIOCHEMICAL VALUES FOR SUGAR GLIDERS

	Conventional (USA) Units	SI Units
HEMATOLOGY		
Hemoglobin	13–15 g/dL	130–150 g/L
Hematocrit	45%–53%	0.45–0.53 L/L
RBCs	$5.1\text{--}7.2 \times 10^6/\mu\text{L}$	$5.1\text{--}7.2 \times 10^{12}/\text{L}$
Mean corpuscular Hgb concentration	30–33 g/dL	300–330 g/L
Mean corpuscular Hgb	18.2–20.6 pg	18.2–20.6 pg
WBCs	$5\text{--}12.2 \times 10^3/\mu\text{L}$	$5\text{--}12.2 \times 10^9/\text{L}$
Neutrophils	$1.5\text{--}3 \times 10^3/\mu\text{L}$	$1.5\text{--}3 \times 10^9/\text{L}$
Lymphocytes	$2.8\text{--}9.2 \times 10^3/\mu\text{L}$	$2.8\text{--}9.2 \times 10^9/\text{L}$
Monocytes	$0.06\text{--}0.2 \times 10^3/\mu\text{L}$	$0.06\text{--}0.2 \times 10^9/\text{L}$
Eosinophils	$0.02\text{--}0.14 \times 10^3/\mu\text{L}$	$0.02\text{--}0.14 \times 10^9/\text{L}$
Basophils	0	0
Plasma proteins	5.6–6.9 g/dL	56–69 g/L
Albumin	3–3.5 g/dL	30–35 g/L
Globulin	2.2–3.6 g/dL	22–36 g/L
BIOCHEMISTRY		
ALT	50–106 U/L	50–106 U/L
AST	46–179 U/L	46–179 U/L
Calcium	6.9–8.4 mg/dL	1.7–2.1 mmol/L
CK	210–589 U/L	210–589 U/L
Creatinine	0.2–0.5 mg/dL	17.7–44.2 $\mu\text{mol}/\text{L}$
Glucose	130–183 mg/dL	7.2–10 mmol/L
Phosphorus	3.8–4.4 mg/dL	1.2–1.4 mmol/L
Potassium	3.3–5.9 mEq/L	3.3–5.9 mmol/L
Sodium	135–145 mEq/L	135–145 mmol/L
Urea	18–24 mg/dL	6.4–8.6 mmol/L

procedures may necessitate only SC fluids. Commonly used preanesthetics include atropine or glycopyrrolate, midazolam, and either butorphanol or buprenorphine. Local anesthetic injections of a 50:50 mixture of 2% lidocaine with 5% bupivacaine may be used to infiltrate the incision site to help reduce the chance of postoperative self-mutilation. To facilitate castration, this mixture may be diluted with sterile water and infused into the base of the scrotal stalk nearest to the abdomen, while a low concentration of gas anesthetic is administered. Both isoflurane and sevoflurane may be administered via small face mask or via a large face mask used as an induction chamber. For surgery, gliders may be maintained on gas anesthesia with a face mask or intubated with a 1-mm Cook endotracheal tube threaded with a stylet.

During surgery, blood loss should be monitored carefully; use of radiosurgery may help minimize bleeding. Because sugar gliders tend to chew incisions after surgery, ideally subcuticular sutures and skin glue should be used to close skin incisions. Analgesics should be administered before surgery to minimize pain immediately after surgery. Gliders should recover from surgery in temperature-controlled incubators.

Orchiectomy and scrotal ablation are commonly performed on male sugar gliders to prevent breeding and decrease sexual frustration. Hair is clipped around the base of the scrotal sac and stalk, and the skin is cleaned without alcohol so as not to lower body temperature. A local anesthetic is administered at the base of the stalk, and with the glider under gas anesthesia, the incision is made over the scrotal stalk ~2–3 mm from the body wall. The spermatic cords are exposed by blunt dissection and are clamped and ligated with 5-0 polydioxanone suture or cut and cauterized with radiosurgery. The scrotal sac containing the testicles and distal spermatic cord is then removed, and the ligated stalk can be sutured to the abdominal wall fascia to prevent herniation. The skin is then closed with tissue glue. Standard ovariectomy is not routinely performed because of the internal position of the female reproductive organs, which are difficult to access beneath the pouch. With ovariectomy, the area around the pouch is clipped and scrubbed in a routine manner, and a 1–2 mm incision is made paramedian to the pouch. The linea alba is bluntly dissected and incised, and the bladder is exteriorized from the incision to reveal the ovaries beneath. The ovarian arteries are

ligated, as is the uterus proximally to the lateral vaginal canals. After resection of both ovaries and uteri, the linea is closed, and the skin is sutured subcuticularly and closed with skin glue. Distal penile amputation is another common surgery. Sexually frustrated males may self-mutilate the distal end of their penises or develop paraphimosis. Because males urinate only from the proximal end, the distal, forked segment may be safely amputated. Other surgeries performed in sugar gliders include cystotomy to remove uroliths, urethrostomy to alleviate urinary tract obstruction from uroliths in males, and surgical removal of impacted paracloacal glands. The skin over impacted glands is infiltrated with a small volume of local anesthetic and incised; the gland is bluntly dissected and removed without rupturing it. The blood vessel supplying the gland may be ligated with 5-0 or 6-0 polydioxanone or cut and cauterized with radiosurgery. The skin is closed with tissue glue.

Drug Dosages: Very few pharmacologic studies have been performed in sugar gliders, and most published drug dosages have been extrapolated from those determined for cats, ferrets, and hedgehogs. For drugs and dosages commonly used in sugar gliders, *see* TABLE 35.

Nutrition and Housing: Ideally, sugar gliders should be maintained as a group with one male and a number of females. If breeding occurs, the young should be removed soon after weaning, or violent attempts to disperse them may occur. Because sugar gliders are arboreal (tree-dwelling), a large cage (ideally of PVC-coated stainless steel) is best for nocturnal climbing. As large a cage as possible should be provided with a minimum size of 36 × 24 × 36 in. Bar spacing should not be more than 1 × 0.5 in. wide, or feet and heads may become entrapped. Caging containing vertical bars should be avoided, because vertical bars do not facilitate climbing. A wooden nest box (made for birds) or a fabric pouch positioned high up in the cage should be provided for hiding and sleeping. Cages should contain numerous branches (commercially available for bird cages) and horizontal shelves to promote climbing. Swings and chew toys made for birds are ideal for gliders to play with. Exercise wheels containing smooth interiors (so as not to entrap toes) should be provided for physical and mental stimulation. The cage bottom may be covered with newspaper or other

TABLE 35 COMMONLY USED DRUGS IN SUGAR GLIDERS

Drug	Dosage	Considerations
ANTIBIOTICS		
Amoxicillin	30 mg/kg, PO or IM, once daily or divided bid	For dermatitis
Amoxicillin-clavulanic acid	12.5 mg/kg/day, PO	Broad-spectrum against anaerobes and aerobes
Cephalexin	30 mg/kg/day, PO	
Enrofloxacin	2.5–5 mg/kg, PO or IM, once or twice daily	Potential tissue necrosis when injected
Gentamicin	1.5–2.5 mg/kg, SC, IM, IV, bid	Nephrotoxic
Metronidazole	25 mg/kg/day, PO	
Penicillin	22,000–25,000 IU/kg, once or twice daily	
Sulfadimethoxine	5–10 mg/kg, PO, once or twice daily	Ensure hydrated
Trimethoprim/sulfa	10–20 mg/kg, PO, once or twice daily	
ANTIPARASITICS		
Carbaryl 5% powder	Topically or in cage	Use small amounts to treat ectoparasites
Fenbendazole	20–50 mg/kg/day, PO, × 3 days	For roundworms, hookworms, whipworms, tapeworms
Ivermectin	0.2 mg/kg, PO, SC; repeat in 14 days	For roundworms, hookworms, whipworms, mites
Metronidazole	25 mg/kg/day × 3 days; repeat in 14 days	For intestinal protozoa
Piperazine	100 mg/kg, PO	
Pyrethrin powder	Topically	For ectoparasites
Selamectin	6–8 mg/kg, topically; repeat in 30 days	For ectoparasites
ANTIFUNGALS		
Itraconazole	5–10 mg/kg, PO, bid	
Nystatin	5,000 IU/kg, tid × 3 days	For <i>Candida</i>
ANALGESICS		
Acepromazine/butorphanol	1.7 mg/kg/1.7 mg/kg, PO	Postoperative analgesic and sedative to decrease self-mutilation of incision
Buprenorphine	0.01–0.03 mg/kg, PO or SC, bid	
Butorphanol	0.1–0.5 mg/kg, SC or IM, every 6–8 hr	
Meloxicam	0.1–0.2 mg/kg/day, PO or SC	Anti-inflammatory

TABLE 35 COMMONLY USED DRUGS IN SUGAR GLIDERS (continued)

Drug	Dosage	Considerations
PREANESTHETICS		
Atropine	0.02–0.04 mg/kg, IM, SC, IV	To lessen intraoperative secretions
Glycopyrrolate	0.01–0.02 mg/kg, IM, SC, IV	To lessen intraoperative secretions
ANESTHETICS		
Diazepam	0.5–2 mg/kg, PO, IM, IV	Sedative, anticonvulsant
Isoflurane	1%–5%	Via face mask or intubation
Ketamine	30–50 mg/kg, IM	
Ketamine/medetomidine	2–3 mg/kg/0.05–0.1 mg/kg, IM	Immobilization
Ketamine/midazolam	10–20 mg/kg/0.35–0.5 mg/kg, IM	Give ketamine 10 min after midazolam
Midazolam	0.25–0.5 mg/kg, IM or IV	Sedative, anxiolytic
Sevoflurane	1%–5%	Via face mask or intubation; possible toxicity, use cautiously
CARDIAC DRUGS		
Enalapril	0.22–0.44 mg/kg/day, PO	
Furosemide	1–4 mg/kg, SC or IM, every 6–12 hr	Diuretic
GI DRUGS		
Cisapride	0.25 mg/kg, PO, once to three times a day	GI motility enhancer
Metaclopramide	0.05–0.1 mg/kg, PO, bid–qid	GI motility enhancer
HORMONES		
Calcitonin	50–100 IU/kg, SC or IM	Helps mobilize calcium
Prednisolone	0.1–0.2 mg/kg/day, PO, SC, IM	Corticosteroid
VITAMINS		
Calcium gluconate	150 mg/kg/day, PO	Calcium supplement
Vitamin A	500–5,000 IU/kg, IM, once	For dermatitis
Vitamin E	25–100 IU/glider/day	
Vitamin K	2 mg/kg, SC, every 1–3 days	Intestinal and liver disease

recycled paper product that is nontoxic if ingested. Several food and water bowls should be provided throughout the cage, with designated areas for eating, drinking, exercising, and hiding.

The recommended diet for captive sugar gliders includes calcium-loaded insects (crickets, mealworms, waxworms,

cockroaches, moths) to promote dental health, as well as a daily nectar/sap substitute (eg, fructose/sucrose/glucose or honey diluted to 10% with water). Nectar should account for ~50% of the diet. Several nectar substitutes are commercially available, including Gliderade nectar supplement (Exotic Pet Nutrition Company, Newport

News, VA), acacia gum powder, and nectar diets meant for lory birds. Other protein sources in addition to insects include eggs, lean meat, newborn mice, and commercial pelleted diets meant for sugar gliders. Commercial diets or homemade insectivore or omnivore mixes should be provided in addition to live food, with insects and pelleted food accounting for nearly 50% of the total diet. Fruits, nuts, and vegetables should be offered only in moderation (<10% of total diet), because many fruits and vegetables lack essential vitamins, minerals, and protein and contain mostly water. Several commercial diets and recipes for homemade diets are available; no single diet studied has yet proved to be ideal for captive sugar gliders. Traditionally, before the availability of commercial pelleted diets, a homemade formula called Leadbeater's mixture was fed successfully in addition to insects, fruits, and vegetables. The mixture contains 150 mL of warm water mixed with 150 mL of honey, one hard-boiled shelled egg, one teaspoon of multivitamin/mineral supplement, and 25 g of high-protein dry human infant cereal. An alternative to the homemade Leadbeater's diet is commercially available High Protein Wombaroo Diet (Wombaroo Food Products, Glen Osmond, South Australia), a powdered gluten supplement that is mixed with water before feeding. In addition, if not provided in the diet, a multivitamin and mineral supplement with calcium should be sprinkled on food daily. Food should be offered in the evening, when sugar gliders are active, on an elevated platform, because gliders feel more secure eating up high, as they would in trees in the wild. Sugar gliders are generally robust in captivity when proper husbandry practices are followed; however, nutritional deficiencies, especially of calcium and protein, are commonly seen in captive gliders fed inappropriately. Obesity also is common in gliders fed excessive amounts of treats high in fat and protein and not provided with the opportunity to exercise. Iron storage disease, in which excessive dietary iron accumulates in the liver (hemochromatosis), spleen, and other tissues, has been reported in captive gliders and may be associated with wild gliders' evolutionary adaptation to extract limited iron available in natural diets. Hepatocellular toxic changes and cirrhosis from iron deposition may lead to death, unless the disease is caught and treated early with chelation and supportive care.

DISEASES AND SYNDROMES

Bacterial Diseases: Sugar gliders are susceptible to infection with common

bacteria, including *Pasteurella multocida* (commonly contracted from pet rabbits), staphylococci, streptococci, *Mycobacterium* sp (especially in skin), *Klebsiella* sp, and *Clostridium*. Clinical signs may be nonspecific, with depression, loss of appetite, and weight loss being the most readily detected. Bacterial infections in gliders may present as opportunistic skin infections associated with trauma or may result in sepsis from other underlying primary diseases. Although sugar gliders are hindgut fermenters, broad-spectrum antibiotic therapy is well tolerated, probably because diets fed in captivity are digestible without fermentation. Injectable, long-acting penicillin with clavulanic acid is an appropriate firstline antibiotic. If indicated by culture and sensitivity or by failure to respond to first-line treatment, chloramphenicol and enrofloxacin are also well tolerated in this species. Injections can be given IM into the epaxial muscles or SC over the shoulders. Palatable oral medications may also be administered.

Protozoal Disease: Toxoplasmosis is a common and serious disease of marsupials, typically presenting with neurologic signs. Gliders may be infected with toxoplasmosis oocysts found in cat feces. Care should be taken to avoid cat feces coming in contact with the bedding or food of sugar gliders. Prevention is more successful than treatment. Coccidia may also cause severe, sometimes fatal diarrhea in young gliders and may be contracted via fecal-oral transmission from other species.

Parasitic Diseases: Internal parasites rarely cause disease in captive gliders, but giardiasis and cryptosporidiosis have been seen in captive animals. Strongyle eggs also have been seen on fecal flotation. Internal parasites reported to infect sugar gliders include nematodes of the genus *Parastrongyloides* and *Paraastrostrongylus* and a liver trematode of the genus *Athesmia*. Wild sugar glider nests generally contain a range of host-specific mites and fleas, but ectoparasites are uncommon in captivity. Dusting with pyrethrin or carbaryl powder (50 g/kg) has controlled fleas and mites. Both the nest and the animal should be treated. Selamectin also has been used to treat ectoparasites on sugar gliders. Ivermectin and fenbendazole have been used to treat GI parasites.

Nutritional Osteodystrophy: Pet sugar gliders maintained on a mainly fruit diet with few gut-loaded insects or other protein

sources are very susceptible to nutritional osteodystrophy (nutritional secondary hyperparathyroidism). This condition results from an imbalance in dietary calcium, phosphorus, and vitamin D and manifests clinically as a posterior paresis progressing to hindlimb paralysis, muscle tremors, pathologic bone fractures, and sometimes, in advanced cases, seizures. Chronic malnutrition can lead to increased liver and kidney values, hypoproteinemia, and anemia. Radiography reveals osteoporosis of the vertebral column, pelvis, and long bones in particular. Measurement of ionized blood calcium typically demonstrates a low ionized calcium level. Treatment involves cage rest; administration of calcium, vitamin D₃, and fluids; assisted feeding; and correction of the diet. Seizing gliders should be given diazepam IV, ideally, or if not possible, IM, intraosseously, or intrarectally, to stop seizures. Severely affected gliders may be given calcitonin to decrease calcium resorption from bone once calcium supplementation has normalized plasma calcium levels. Severe skeletal (especially spinal) deformities may not be reversible.

Dental Disease: Sugar gliders consuming large amounts of soft, sugary foods are prone to tartar buildup and periodontal disease. Tartar may be scaled off under anesthesia. Advanced periodontal disease or traumatic tooth fracture may lead to tooth decay and exposed roots, necessitating extraction and treatment with antibiotics, analgesics, NSAIDs, and antiseptic mouthwash (either made for cats and dogs or fruit-flavored for children). Unlike rodent teeth, sugar glider teeth do not grow continuously or require trimming.

Diarrhea: Potential causes of diarrhea in sugar gliders include bacterial infection (from *Escherichia coli*, *Clostridium* sp, and other bacteria), GI parasites, malnutrition, stress, and metabolic disease (such as liver or kidney disorders). Sugar gliders with diarrhea should have a fecal analysis for parasites, fecal bacterial culture and Gram stain, blood testing (CBC and chemistry panel), and possibly radiographs. Gliders with diarrhea should be given supportive care with fluids, supplemental feeding, and drug therapy, as dictated by the cause of the GI signs. Rectal and cloacal prolapse can occur in gliders secondary to diarrhea and straining and is more common in malnourished animals. The prolapsed tissue must be cleaned, checked for necrotic areas (which must be removed

if present), and replaced once the glider is anesthetized. Vertical mattress sutures may be placed next to the vent to help prevent recurrence, and the glider should be given postoperative analgesics, antibiotics, and NSAIDs.

Urinary Tract Disorders: Sugar gliders can develop cystitis, crystalluria, and urolithiasis. They may show hematuria, stranguria, and dysuria. Affected gliders should have a urinalysis and urine culture and sensitivity testing and should be properly hydrated. Antibiotics should be administered based on results of culture and sensitivity testing. Cystostomy may be required to remove uroliths. Male gliders may develop urinary tract obstruction from uroliths and require urethrostomy if cystocentesis and flushing of the distal urethra do not relieve the obstruction. These gliders should receive analgesics, antibiotics, fluids, and NSAIDs. Sugar gliders with renal failure may show weakness, polyuria, and polydypsia and should be treated with standard treatment used in other mammals for renal disease.

Neurologic Disease: Causes of neurologic signs in pet sugar gliders include nutritional secondary hyperparathyroidism, bacterial meningitis, toxoplasmosis, traumatic brain injury, otitis media/interna, encephalitis from aberrant CNS migration of *Baylisascaris procyonis*, and encephalomalacia from hypovitaminosis E. Gliders exhibiting neurologic signs should undergo a full evaluation, including blood testing (CBC and chemistry), fecal testing for parasites, radiographs, and CT scanning plus CSF analysis, if indicated. Prognosis in many of these cases is poor.

Neoplasia: Gliders are prone to neoplastic disease in old age. Hepatocellular tumors and lymphoid neoplasia are common, as is mammary gland adenocarcinoma. Cutaneous melanoma, scent gland tumors, bronchogenic carcinoma, and chondrosarcoma of the jaw also have been reported. A soft-tissue carcinoma associated with a microchip implant was reported in a mahogany glider (*Petaurus gracilis*). A malignant testicular interstitial cell tumor in a mahogany glider was managed by hemicastration. Transitional cell carcinoma with squamous differentiation was noted pericloacally in a 10-yr-old male sugar glider.

Miscellaneous Disorders: Sugar gliders may develop cardiomyopathy/myocarditis, cataracts in juveniles (possibly associated

with nutritionally imbalanced handfeeding formula, hyperglycemia, and hypovitaminosis A), cloacitis/vaginitis (females), irregularity of ear margins/crusting of pinnae from ear mite infections, and retrobulbar abscesses associated with facial bite wounds in competing males. These syndromes are treated with medications and surgical procedures, when indicated, similarly to those used in other mammals with these conditions.

Behavior: Sugar gliders live in colonies in the wild and are very social. Thus, they should be kept in captivity in groups of two or more. Gliders love to crawl into pockets or pouches, where they feel safe and more relaxed. Behavioral disorders can develop in sugar gliders housed alone, with incompatible mates, or in inappropriate cages. When housed singly, not given enough social stimulation, or not provided with a nest box or pouch in which to hide or enough room to exercise, they may self-mutilate their fur and skin, develop stereotypic behaviors, or become aggressive. Anxious gliders will overgroom, causing fur loss, particularly at the tail base. Anorexia, polyphagia, polydipsia, coprophagia, cannibalism, and

pacing are also seen in stressed gliders. Sexually mature male sugar gliders without access to females may self-mutilate the tail base, limbs, scrotum, penis, or perineum and may develop paraphimosis, in which the penis remains extruded from the cloaca and becomes traumatized and devitalized, necessitating amputation. These gliders should receive pain relievers, antibiotics, and possibly antidepressants, plus an Elizabethan collar, to enable healing. At least 2 hr per day, preferentially at night, when they are awake, must be spent with pet gliders for proper socialization.

Zoonoses: Diseases that may infect sugar gliders, such as salmonellosis, giardiasis, leptospirosis, clostridiosis, and toxoplasmosis, are potentially zoonotic. Sugar gliders are best handled wrapped in a small towel, because they may bite and scratch, and although they are small, their lower incisors, which are designed to bite through tree bark, may inflict significant damage. Biting and scratching can be avoided by gentle handling and proper socialization. All ocular, nasal, GI, and genitourinary discharges should be treated as potentially infectious.

TASMANIAN DEVILS

The Tasmanian devil is the largest marsupial carnivore in existence, currently restricted to the island-state of Tasmania, Australia. Devils have black fur, and white flashes on the chest and rump may be present. They are sexually dimorphic, with males having a thicker neck and broader head than females. Males typically weigh 9–12 kg (up to 14 kg), and females 6–8 kg (up to 9 kg). Devils are mainly nocturnal and hide during the day in rock dens, log cavities, or underground burrows made by other animals. They live up to 6 yr in the wild and 9 yr in captivity. Devils are nonterritorial and generally live within an area of 10 km². They can occupy a wide range of habitats, from dry sclerophyll forest, open eucalypt environment, and coastal woodland, to pasture and agricultural areas where carrion (from domestic livestock and macropod populations) is abundant. Devils are specialist carrion feeders but will hunt prey, particularly those weakened by disease, injury, or old

age. Wallabies, wombats, and sheep are the usual source of carrion, but other dead domestic livestock, roadkill, and 1080-poisoned wildlife are also consumed. The proportion of hunting to scavenging is unknown. Female devils are facultative polyestrous with up to three estrous cycles within a breeding season, each cycle ~60 days apart. They are polyovular (up to 114 oocytes per ovulation) and may give birth to up to 40 embryos. Mating peaks over late February to the end of March and, as is typical for marsupials, females give birth to highly undeveloped young ~3 wk after mating. Females have a rear-facing pouch, with four teats in the pouch cavity, limiting the maximum total offspring raised per year to four. The young are carried in the pouch until they are 4–5 mo old, weaned at 5–8 mo, and become independent at 10–12 mo. Sexual maturity is reached at 2 yr of age for both females and males, although females have been confirmed to reproduce as young as 1 yr old.

Physical Examination and General Anesthesia:

Wild Tasmanian devils can be restrained and examined in a hessian sack by an experienced handler. Devils have an exceptionally strong bite for their body size, and handling conscious animals must only be done by or attempted in the presence of experienced personnel.

The handler sits on the ground and locates and holds the devil's muzzle closed from outside the sack. The devil is then positioned between the handler's legs, with the devil facing outward and head uppermost. The head and face are gently revealed with one side of the sack left covering the devil's eyes. The handler then moves the free hand directly onto the muzzle, continuing to hold it closed, and the teeth/mouth can be examined to estimate age of the devil by lifting the upper lip. The mouth can be opened for intraoral examination. It is important to visualize all aspects of the oral cavity, including under the tongue, for signs of tumors. Normal lymph nodes are not palpable in devils; therefore, subcutaneous masses should be considered suspicious. If a blood sample is required, the devil is positioned as described, ie, facing away from the handler. An assistant can collect up to 12 mL of blood from the jugular vein. The jugular vein is not visible or palpable; to locate it, the index finger of one hand palpates the groove immediately cranial to the clavicle and just lateral to the sternohyoideus muscle. The finger pulls the skin distally and, with the other hand, a 21-gauge needle is inserted 0.2–0.5 cm into the groove while applying negative pressure to the syringe. Gentle digital pressure is applied to the venipuncture site after blood collection is complete. The devil can then be placed back into the sack, with the head facing up and away from the handler, so the tail, cloaca, and pouch can be examined.

Devils bred in captivity or brought to captivity before 2 yr of age are generally not amenable to handling, so general anesthesia is required for examination. These animals can be trapped in their enclosure and transferred to a hessian sack or picked up by the tail base and transferred to the sack. Anesthesia can be induced by using a mask on the devil through the sack. Isoflurane has been used successfully. Ideally, the devil's muzzle is positioned in a corner of the sack to facilitate mask placement. The sack should be secured around the devil to prevent excessive movement and escape from the mask. Devils are induced in 2–3 min and then removed from the sack. A pulse oximeter can be attached to the ear to

monitor heart rate and peripheral oxygen saturation. For quick procedures such as physical examination and blood collection, a mask is sufficient to maintain anesthesia. For longer procedures, an endotracheal tube (5–5.5 Fr) is indicated. The devil's larynx is narrow, and a laryngoscope is essential. Local anesthetic must be applied to prevent laryngospasm before intubation. As the devil starts to recover from anesthesia, it is placed back in the sack and observed until it is fully awake and ready to be returned to its enclosure.

Proliferative Lesions: Tasmanian devils are prone to developing proliferative lesions, the most common being devil facial tumor disease (DFTD). Cell proliferations (benign and malignant) affecting skin and adnexa, and endocrine and lymphoreticular tissues (eg, squamous cell carcinomas, lymphosarcomas, adenocarcinomas) are commonly seen at necropsy in adult and senile captive devils. In older captive devils (≥5 yr old), mammary and anal gland tumors are the most common.

Devil Facial Tumor Disease: Devil facial tumor disease (DFTD) is a malignant infectious tumor first observed in 1996. As a result of >70% of the population having succumbed to DFTD, devils have been listed as an endangered species. The prevalent characteristic of DFTD, as the name suggests, is the presence of tumor(s) on the facial area. Tumors are also found inside the mouth (gingival mucosa, hard palate, lips) and on the head and neck. Rarely, DFTD tumors may be found on the rump or other areas of the body, but these are thought to be metastatic tumors rather than primary. More than one tumor is often

Tasmanian devil with extensive ulcerated tumors on the muzzle and nose. Devil facial tumor disease nodules can be seen also on the lower left gum and left cheek. Courtesy of Dr. Alexandre Kreiss.

seen, and tumors on the same devil often vary considerably in size and appearance. The tumors often ulcerate and display epithelium break up, necrosis, exudation, and bacterial contamination. Most devils affected with DFTD show signs of metastases (65% of cases in a study of 91 affected devils), principally to the regional lymph nodes but also to the lungs and spleen.

The most remarkable characteristic of DFTD is its transmissible nature, a concept supported by several independent lines of research. The tumor is of Schwann cell origin and is transmitted by biting. Devils with tumors in the oral cavity have free tumor cells "coating" the canine teeth. The tumor cells are transplanted when a bite wound penetrates the subcutaneous tissue or mucosa of the next devil. The most common bite site in devils is the head, which, therefore, is where almost all DFTD tumors are present. The incubation period is unknown but is estimated to be 3–15 mo. Most devils die within 6 mo of a tumor becoming grossly visible. Death results from starvation, depending on the size and location of the tumor, or from metastatic disease. No evidence of this disease in other species has been found.

No preclinical diagnostic test is available. The tumor cells have a characteristic and consistent karyotype, showing loss of three autosomes, loss of both sex chromosomes, and addition of four marker chromosomes. Histologically, DFTD tumors share the same morphologic features as a high-grade malignant tumor composed of diffuse sheets of small, rounded to polygonal shaped cells with ovoid hyperchromatic nuclei. Mitotic figures are frequent, and eccentrically located nuclei result in a plasmacytoid appearance. Tumor cells might appear cohesive and epithelioid in appearance and form elongated trabecular and solid alveolar structures. The gold standard diagnostic test for DFTD tumors is immune-staining with periaxin. It is common for devils to develop other cell proliferations, which must be differentiated from DFTD.

There is currently no known treatment for DFTD; vincristine and doxorubicin have been tried without tumor reduction, and to date surgery has not been successful. Radiation therapy has not been assessed. Research into a vaccine is underway.

The only other tumor transmitted by direct cell implantation is the canine transmissible venereal tumor (CTVT, see p 1408) of dogs. Although CTVT is generally a benign tumor, it shares the same immune-escape mechanism as

DFTD; the tumor cells "down regulate" major histocompatibility complex (MHC) molecules on the cell surface, so that antigen presenting cells do not recognize the tumor cells. In dogs, the immune system might overcome this by producing cytokines and "forcing" the tumor cells to express MHC and become targets for cytotoxic T cells.

Cutaneous Lymphoma: This lymphoid skin tumor has been recently seen in both captive and wild caught devils, affecting predominantly older females. No etiologic agent has been implicated. It can present as a localized erythematous lesion, mainly in the limbs and ventral part of the body, or as a generalized alopecic and exudative form. This condition progresses over several months. There is no known treatment.

Parasitic Diseases: Tasmanian devils are susceptible to both *Demodex* sp infection and the sarcoptiform *Diabloticoptes sarcophilus*. The latter is common and can be treated with ivermectin 200 mcg/kg, SC, every 4 wk for 3–4 mo. Wild Tasmanian devils often harbor the dasyurid-specific flea *Uropsylla tasmanica*. This unusual flea has all stages of its life cycle on the host. The larva is commonly found embedded in the subcutis of the tail, limbs, or ventral area. Adult fleas are less common.

The two most common GI parasites are the nematode *Baylisascaris tasmaniensis* and the cestode *Anoploetaenia dasyuri*. If the cestode burden appears excessive in captive devils (visible proglottids on feces), they can be treated with praziquantel (5 mg/kg, SC).

Spinal Cord Degeneration: A common condition in aged (≥5 yr old), captive Tasmanian devils has been described as a degenerative leukoencephalopathy and myelopathy. It manifests by a progressive swaying of the hindlegs, eventually worsening to paresis and paralysis in several months. Histologically, it is characterized by axonopathy and vacuolation of the spinal cord. Intervertebral disc disease is a common finding. There is no known treatment.

Zoonotic Concerns: *Trichinella pseudospiralis* appears to be endemic in the Tasmanian devil population, with no known human cases to date derived from devils. Devils also harbor *Salmonella* species in the feces.

ZOO ANIMALS

The physical health as well as the social and behavioral well-being of zoo animals depends on enclosure design, nutrition, husbandry, management, group social structure, behavioral enrichment, and good medical and surgical care. Naturalistic enclosures with soil and vegetation are appealing to the public and more stimulating for the animals, but they present challenges for both sanitation and parasite control programs and may complicate restraint procedures. Mixed species exhibits may increase risk of disease transmission between species and can result in interspecific aggression if appropriate choices are not made.

This chapter provides a general discussion of management practices, preventive medicine, clinical care programs, and some of the more commonly encountered disorders in zoo animals. For more specific information, refer to other chapters within this section (eg, *see* AMPHIBIANS, p 1734; MARINE MAMMALS, p 1856; LLAMAS AND ALPACAS, p 1844; RATTLES, p 1960; NONHUMAN PRIMATES, p 1876; REPTILES, p 1967; and VACCINATION OF EXOTIC MAMMALS, p 2054). For more information on nutrition, *see* NUTRITION: EXOTIC AND ZOO ANIMALS, p 2287.

MANAGEMENT

Husbandry: The animal's exhibit should approximate its natural environment and enhance the visual experience for zoo visitors. Many healthy mammals and birds can tolerate a fairly wide temperature range if given access to shade and water in hot weather and to a dry, draft-free shelter with a warm spot and ample food to meet increased energy requirements in cold weather. It is essential to ensure that each animal has access to the protected environment and that one dominant individual does not exclude others from shelter, food, or water; such exclusion can result in frostbite or even death due to exposure. Feed receptacles should be designed to avoid fecal contamination and be easy to clean.

With large numbers of birds or mammals, and especially in mixed species exhibits, several watering and feeding stations should be established at appropriate heights to reduce territorial conflicts that may result in injuries or deaths. The timing of feedings is important. In many species, it is best to feed small amounts throughout the day to stimulate activity; this is beneficial for the

animal and results in a better display. Food can also be used to attract an animal to an area where it can be more easily and safely examined or treated.

Reproduction: The biology and social behavior of animals must be understood to promote reproduction. Species should be maintained alone, in pairs, or in groups, depending on their established social systems. For example, in mixed species groups of Artiodactyla, it is possible to establish species estrous cycles through a variety of techniques, including monitoring hormone levels in the urine and feces. Monitoring reproductive cycles may be used to determine when to introduce and remove breeding males, with males of other species rotated to coincide with the estrous periods of the females of each species. This may also reduce injuries from interaction between breeding males. At parturition, the males of some species should be removed for several weeks to prevent attacks on the postpartum females or their offspring. In colder climates, males should be introduced at a time that will allow births to occur during warm weather.

Artificial reproductive technologies such as artificial insemination, in vitro fertilization, and embryo transfer have been successfully used in diverse zoo species. These efforts have made a significant difference in some endangered species breeding programs (eg, black-footed ferret). However, success requires substantial investment of resources (financial, personnel, etc) to determine basic parameters of reproductive cycles and responses to pharmacologic manipulation.

An emerging management priority in maintenance of zoologic collections is the need for selective reproduction. Indiscriminate reproduction is unethical and carries the potential for overproduction that exceeds the capacity of the exhibit, the zoo, or other zoos to appropriately house the progeny. Overly successful breeding programs carry a risk of limiting resources that could compromise other captive propagation programs. Regional cooperative breeding programs such as Species Survival Plans should be followed. Management is aimed at ensuring genetic diversity of the species into the future. Contraceptive efforts in zoos are multifaceted and include permanent techniques

(castration, vasectomy, ovariectomy, tubal ligation), as well as reversible ones such as separation of the sexes, administration of birth control pills, hormonal implants, gonadotropin-releasing hormone agonists, and oral or injectable progestins. Reversible contraception can also be used to control timing of reproductive cycles. There is ongoing work with immunocontraception through administration of porcine zona pellucida vaccines. The Association of Zoos and Aquariums Wildlife Contraception Center is a good source of up-to-date information on contraception techniques.

PREVENTIVE MEDICINE

The foundation of a medical program for zoo animals is preventive medicine. Preventive medical programs should be adaptive and include attention to individual specimens as well as the herd, troop, or flock. Components of the program include quarantine of new arrivals, periodic fecal examinations and treatments for parasites, booster vaccinations, health screening procedures, nutrition evaluation, necropsy examination of deceased specimens, and a comprehensive pest control program. Animals should be evaluated to ensure their health complies with local, state, and federal health requirements before shipment to other zoos or before release in managed reintroduction programs. Preshipment evaluations can also be used as an opportunity to assess the overall health status of the group in which the animal has been living.

Quarantine: Animals entering a collection must undergo quarantine. Quarantine facilities should be designed to allow handling of animals and proper cleaning and sanitizing of enclosures. Shipping crates should be cleaned and disinfected before they leave the quarantine area, and the crates' contents disposed of appropriately. Quarantine facilities require barriers against ingress of potential vectors and vermin. Separate keepers who are skilled at recognizing signs of stress and disease and who will carefully monitor feed intake and fecal characteristics should care for quarantined animals.

Quarantine entry should be strictly controlled. Only essential personnel should be allowed into the quarantine facility. Individuals leaving the quarantine facility should not return to other animal areas without showering and changing clothing. The duration of quarantine should be

appropriate to ensure that infectious diseases are not introduced into the permanent collection when the quarantined animals are released to exhibits. Quarantine facilities should follow the "all-in/all-out" principle, ie, if additional animals are added to an ongoing quarantine, the quarantine period should be restarted.

During quarantine, animals should receive appropriate vaccinations and diagnostic testing (eg, tuberculosis, heartworm). They should be examined and treated for ecto- and endoparasites and screened for enteric bacterial pathogens. Before release, animals should receive physical and laboratory examinations, which may include radiographs, serology, hematology, and clinical chemistries. Serum should be frozen for future reference and possible epidemiologic studies. All procedures and results should be recorded in each individual animal's medical record, which is an essential component of the medical program. Each animal should also be identified by some permanent method (eg, tattoo, tag, band, eartag, transponder) to ensure future identification.

When new animals are introduced to enclosures, caution and forethought are necessary to prevent self-induced trauma. Visual barriers, eg, suspending canvasses from fences or enclosure walls or obscuring glass with soap to provide a visual cue, are standard management steps to protect newly introduced specimens from accidents during acclimation to a new exhibit.

Parasite Control: Like domestic animals, zoo animals are vulnerable to a wide variety of ecto- and endoparasites, and similar drugs are used for treatment. Care must be exercised in the choice of medications because of species-specific sensitivities to some drugs. Young animals and those stressed by shipment, disease, or injury are the most likely to be adversely affected by parasites. At these times, commensal parasites (especially protozoa) can cause disease. Acute diarrhea can result from massive infections of coccidia, *Trichomonas*, *Giardia*, or *Balantidium* spp. Amebiasis, which is fairly common in primates and reptiles, can be fatal in a compromised animal. Intestinal parasites may be a major, continuous problem in species kept in naturalistic exhibits or on dirt substrate or pasture, especially in young, newly introduced, or stressed individuals. Of most concern are parasites with direct life cycles. Incorporating anthelmintics directly into the feed is helpful. As in domestic species, anthelmin-

tic resistance may develop and necessitate rotating medication. Parasites with indirect life cycles are less frequently a problem if the exhibit area is free of intermediate hosts.

Vaccination: Vaccination programs for carnivores, nonhuman primates, equids, artiodactylids, and birds should be developed. Vaccination of zoo carnivores is essential because of their susceptibility to various diseases such as feline panleukopenia, feline rhinotracheitis, feline calicivirus, rabies, canine distemper, and canine parvovirus. (See also VACCINATION OF EXOTIC MAMMALS, p 2054). Previously, only killed virus vaccines were recommended, but recent studies have shown that some modified-live vaccines are safe for use in select species. Further studies are required, because some modified-live vaccines (especially canine distemper) can result in fatal disease in certain species. A canarypox-vectored recombinant canine distemper vaccine has proved safe for use in those species susceptible to modified-live virus vaccine-induced disease. Appropriateness of rabies vaccination depends on the circumstances of each collection. If indicated in rabies-endemic areas for protection of individual animals, only a killed rabies vaccine should be used. The decision to vaccinate zoo animals for less common diseases for which a vaccine is available should be made on an individual basis. Recombinant and subunit vaccines are being developed for a variety of infectious diseases for domestic animals. Extra-label use of vaccines should be done with caution until safety and efficacy studies have been completed for zoologic species.

Necropsy: All dead animals should be necropsied. This should include gross and histopathologic evaluation of tissue and viral, bacterial, or fungal cultures when appropriate. Tissues should also be saved for potential future examinations. A thorough pathology examination allows evaluation of medical, management, and nutritional programs. It is also valuable in identifying problems requiring immediate action to safeguard the health of the collection. Variations in anatomy should be recorded, because such observations may aid in future diagnostic procedures or therapy in the species.

Pest Control: A successful control program is continual and requires a concerted effort by zoo staff to minimize harborage and food for pests, in addition to

the use of mechanical and chemical control methods. Choice of agent, method of use, and storage may minimize zoo animals' access to pesticides and the risk of secondary poisoning. Common zoo pests may serve as important disease vectors. For example, cockroaches are intermediate hosts for GI parasites of primates and birds; rodents can harbor and spread *Listeria*, *Salmonella*, and *Leptospira* spp and *Francisella tularensis*. Wild and feral carnivores such as foxes, raccoons, and domestic dogs and cats can devastate animal collections through predatory attacks and may be important vectors for viral diseases such as rabies, parvovirus, and canine distemper. Raccoons may also transmit *Baylisascaris* parasites, which can cause larval migration, resulting in fatal neuropathy in some species. Pigeons, geese, ducks, and starlings are potential reservoirs for avian diseases; they consume or contaminate animal food and deposit droppings everywhere. Arthropod vectors can transmit pathogens such as West Nile virus.

Nutrition: Some zoos have either a staff nutritionist or a nutritional consultant on contract. Zoos that do not should have some degree of veterinary oversight of diets and diet changes. This is especially true for addition of native or exotic plant species to the diet as browse for either enrichment or as an integral part of the diet. Protocols should be developed for diet formulation, diet changes, and addition of plant material to the diet.

CLINICAL CARE PROGRAMS

The mainstay of the zoo medical program is a qualified and dedicated keeper staff. The keepers know the individual animals under their care and observe them daily. They are the first to recognize abnormalities such as anorexia, inactivity, abnormal feces, or changes in behavior that may reflect early medical problems. Overzealous reporting of observations is preferable to indifference. Because many zoo animals, especially prey species, instinctively conceal overt signs of illness until the disease process is well advanced, it is necessary to make keepers aware of the significance of what may seem to be trivial changes. Past associations with the veterinarian may arouse some animals' responses to the veterinarian's presence, which will mask subtle changes noticeable to keepers.

Once a diagnosis is made, the treatment of zoo animals is similar to that of domestic

species except in the method of drug administration and restraint. A comparative medical approach is generally most successful and involves application of medical or surgical information about diseases affecting free-ranging animals, related domestic animals, or people. Frequently, other veterinary experts or human medical or dental specialists are consulted for advice or assistance with complicated medical or surgical cases. Knowledge of comparative anatomy, physiology, behavior, nutrition, pathology, and taxonomy is useful. Attention must be paid to both individual and population health.

Unless medical conditions dictate otherwise, it is often preferable to leave an animal under treatment at its home exhibit where it can maintain contact with its conspecifics and keepers. This can also prevent disruptions in social hierarchies, which may cause difficulties with reintroductions to an established group.

Behavioral Training: An active behavioral training program enables improved health care. Through positive reinforcement, amphibians, reptiles, birds, and mammals in zoo settings have been trained to perform behaviors on command that facilitate accomplishment of various management or medical procedures. Management behaviors include shifting on and off exhibit, onto scales, and into restraint devices or shipping containers. Medical procedures include urine collection, venipuncture, IM injection, tuberculin testing, ultrasonographic examination, and rectal or vaginal examination. Often, these behaviors are incorporated into behavioral and environmental enrichment programs. Enrichment programs are designed to encourage animals to display more of their normal behavioral repertoire, eg, increasing opportunities for foraging or social interaction, which allows animals to spend their time more as they would in nature.

Protected contact, a management system for elephants, uses positive reinforcement to encourage the elephant to present appropriate body parts through openings in a wall. Procedures such as venipuncture from the ear, foot trimming, reproductive evaluation, artificial insemination, and trunk washes are routinely performed using protected contact. This system provides safety for personnel working with elephants and gives the elephant a degree of choice.

Physical Restraint: Most zoo animals resent being handled and resist manual

restraint. Struggling with an animal to administer treatment may do more harm than can be offset by treatment. Physical restraint is indicated in some species for minor manipulation or close observation. Restraint devices (squeeze cages) or chute systems are frequently used for species that are large, dangerous, or difficult to handle. Many procedures can be performed on unanesthetized animals so confined, including limited physical examinations, tuberculin testing, administration of injections or anesthetics, collection of blood samples, trimming malformed claws or overgrown hooves, and application of topical medications.

Although the dimensions and construction of these devices vary, some operate by movement of one wall to restrain the animal against the other. Openings are provided to allow safe access to the animal. Many restraint devices for hoofstock are designed with a "V" shape; once the animal enters, the floor is lowered and the animal's body is restrained by the "V" with its feet suspended off the ground. Whenever possible, animals should be trained to enter or be enticed, rather than forced, into the restraint device. Ideally, these facilities should be designed as part of the animal's regular quarters and located in an area where the animal is normally shifted as part of the daily routine. Exhibits should contain nest boxes or restraint pens equipped with doors that operate remotely to confine the animal. From these areas, the animal can be transferred to a restraint device, anesthetic chamber, or shipping container. Weighing facilities are essential.

Small mammals and birds may be caught and restrained in long-handled hoop nets. These nets must be deep enough that the animal can be confined in the blind end, with the upper part of the net twisted to prevent escape.

Personnel participating in capture or restraint procedures must understand their role and be aware of the behavioral characteristics and physical abilities of animals. This is essential to ensure safety of both animals and personnel. Heavy gloves protect handlers from teeth and claws when animals are manually held after capture. Care must be used to avoid excessive pressure on animals, because gloves hinder both dexterity and the perception of the amount of pressure being exerted. Gloves are also difficult to clean and can be a fomite for transmitting infectious agents.

Diagnostic Techniques: The fundamental diagnostic technique is a good history

and thorough visual and physical examination (often requiring anesthesia). Ease of sample collection for laboratory testing (CBC, biochemical profile, serology, cytology); fecal examination for parasites; urine for urinalysis; and aerobic, anaerobic, fungal, and viral culture depends on species anatomic differences. Radiography and ultrasonography are commonly done. Endoscopy, laparoscopy, and minimally invasive surgery are used when indicated, with use of CT and MRI becoming more common. Virtually any technique used for other species can be modified for use in zoo species.

Drug Administration: Few drugs are approved for use in zoo species, but extra-label drug use laws allow drugs to be legally used in species for which they are not licensed. Providing quality medical care to zoo animals requires that medications be used without documented therapeutic benefit, dosage, treatment schedule, contraindication, and toxicity data in these species. Whenever possible, drug administration should be based on pharmacokinetic data. If appropriate data are not available, extrapolation from what is known about these parameters in other species using metabolic scaling is necessary. Appropriate dosage is necessary if therapy is to be beneficial, especially with drugs that have the potential for organ toxicity. Antibiotic, antifungal, and analgesic treatments, as well as anesthetic dosages, are becoming less empirical because of increasing species-specific knowledge resulting from pharmacokinetics studies in zoo species. When using a drug on a group of animals for the first time, it is often wise to initially administer it to just one or two individuals. If no adverse effects are seen, the rest of the group can then be treated.

Drug administration can be challenging. Oral medication has the advantage of minimal disturbance to the animal, but ensuring adequate individual intake may be a problem, especially when animals are housed in a group. Mixing the medication with favorite foods or treats is helpful. Oral antibiotics in hoofstock and other species can disrupt normal bacterial flora and lead to GI problems. Oral sedative or anesthetic administration can result in variable onset, duration, and depth of effect because of inadequate consumption or delayed absorption. IM injections with a hand syringe can be difficult unless a restraint device or other means of physical restraint is used. Remote IM injections may be made by firing a projectile syringe from a dart gun.

However, these injections may be painful and add the trauma of dart impact and injection, especially when delivering large volumes (eg, 10 mL) over long distances (50 m). Problems can be minimized through careful selection of the most appropriate drug and drug concentration, as well as the type of dart gun for the intended use. In addition, practice with projectile darts is mandatory before their use. Marksmanship and familiarity with the weapon are essential—such weapons in the hands of a novice can be fatal. Other less traumatic methods of IM injection, over shorter distance, include syringe poles or blow guns. Through behavioral training, it is also possible to administer IM injections through voluntary participation of the animal. IV therapy is generally restricted to anesthetized animals or those maintained in restraint devices or small enclosures for the duration of treatment.

Anesthesia: Safe anesthesia of zoo animals is of special concern. Many procedures routinely accomplished on domestic animals with minimal restraint require anesthesia of zoologic species for the welfare and safety of both zoo animals and personnel. Before anesthesia of a zoo animal, the veterinarian should be familiar with the species and choice of anesthetic agent. Anesthesia records for the individual, other specimens of the same species in the collection, or published references for the species should be reviewed. Consultation with someone knowledgeable in the field is advised, because there are large differences in effective drugs and dosages in the diversity of species in a zoologic practice. An anesthetic plan should be developed for each anesthetic episode; the plan should include the anesthetic drugs and doses to be used, other needed pharmaceuticals (eg, emergency drugs, analgesics, anthelmintics, vaccines), monitoring equipment, and any other special equipment to perform the procedure at hand.

Many factors influence an animal's response to anesthetic drugs, including age, sex, stage of reproductive cycle, general nutritional status, and most especially mental state before drug administration. Variations may be marked between species as well as individuals and between different collections of the same species. An excited animal usually requires more drug and, once anesthetized, has a greater tendency to develop capture myopathy secondary to hyperthermia, respiratory depression, and acidosis. Capture myopathy can also occur in manually restrained animals and is more

common in ungulates or long-legged birds (see p 2884). Monitoring of anesthetized animals may include heart and respiratory rates, temperature, ECG, oxygenation (measured by blood gas determination or pulse oximetry), ventilation (measured by blood gas determination or end-tidal CO_2), and blood pressure (measured directly or by oscillometric techniques). Attention must be paid at all times to appropriate positioning and padding of anesthetized animals and extremes of environmental conditions to prevent secondary complications.

The nature of an enclosure in which animals are to be anesthetized should be carefully considered before initiation of an anesthetic episode to minimize complications. For example, prey species that are darted may startle and hit fences or other barriers. In herd situations, the herd members may attack and injure or kill the darted animal as anesthetic induction begins (eg, ataxia).

Xylazine, detomidine, or medetomidine (α_2 -adrenoreceptor agonists) used alone produce adequate sedation in some ungulates, mainly bovids, to allow some manipulative procedures. The sedative effects can be antagonized by administration of yohimbine, tolazoline, or atipamezole. α_2 -Agonists should not be used as the sole anesthetic agent in dangerous carnivores, because the animals may appear sedated but can respond aggressively when stimulated. Peripheral vasoconstriction caused by these agents alone or in combination with other drugs can lead to significant hypertension, so blood pressure should be monitored. Peripheral vasoconstriction may also interfere with monitoring pulse oximetry and can make venipuncture more difficult.

The cyclohexamine ketamine (either alone or in combination with tranquilizers or sedatives such as xylazine or medetomidine) is a common anesthetic for small to medium-sized mammals, especially carnivores, primates, and some ungulates. A concentrated ketamine preparation (200 mg/mL) can be obtained from compounding pharmacies, with a resultant decrease in the required injection volume. Combining ketamine with a sedative or tranquilizer speeds induction, minimizes excitement, increases muscle relaxation, and provides a smoother anesthetic induction and recovery than using ketamine alone. The ability to reverse the sedative effects of xylazine or medetomidine with the antagonists yohimbine, tolazoline, or atipamezole enables the use of a lower ketamine dosage and a more complete and

rapid reversal after the procedure has been completed.

Tiletamine-zolazepam, a dissociative anesthetic-tranquilizer combination, is relatively safe in most species, has a rapid induction, and can be concentrated to 200 mg/mL to allow a small delivery volume. It is commonly used for anesthesia of carnivores and primates. However, a disadvantage of this drug combination is that no complete antagonist exists; therefore, recoveries can be longer than with other combinations that can be completely reversed.

The rapid onset and short duration of anesthesia induced by the sedative-hypnotic propofol renders it particularly attractive for use in zoo species. However, because of the necessity for IV administration, its use is limited to species such as reptiles, birds, and small mammals that can safely be manually restrained for drug administration. It is also useful as an adjunct anesthetic agent in large mammals first immobilized with another drug combination.

The potent opioids etorphine, carfentanil, and thiofentanil, alone or in combination with other agents (eg, azapropazone, acepromazine, xylazine, detomidine), have been used extensively for anesthesia of ungulates, elephants, and rhinoceros. The antagonist of choice for these opioids is naltrexone, a pure narcotic antagonist, which induces complete reversal when given at 100 mg of naltrexone per mg of opioid. The reversal dosage of naltrexone can be given IV or IM, and in species prone to renarcotization after reversal, additional naltrexone may be administered SC. It can also be given IM 6–8 hr later by remote delivery to prevent renarcotization when the animal is not being observed. Accidental exposure of people to ultrapotent narcotic analgesics is quite dangerous. Therefore, they should be used only by trained, experienced personnel, and only after development of accidental exposure protocols.

Various drug combinations (using ketamine, telazol, medetomidine, detomidine, butorphanol, midazolam, diazepam, or xylazine) have been developed for specific species and purposes. Administration to novel species should be undertaken with care.

Isoflurane has become the inhalation anesthetic of choice for small mammals, birds, and reptiles. It is also used as a supplement to an injectable anesthetic or as an anesthetic maintenance agent to prolong anesthesia in virtually all species. Isoflurane

is safe and potent and has minimal adverse effects, short induction, and quick recovery periods. Sevoflurane has the advantage of even shorter induction and recovery periods and may be preferred over isoflurane in some species. Small animals can be induced with a face mask or placed in an anesthetic chamber. Inhalation anesthesia can be maintained or supplemented using a face mask, nasal cannulae, or intratracheal intubation, depending on the species and anesthetic plane.

Regulatory Issues: Collection, transport, and exhibition of wild animals requires compliance with local, state, and federal laws. Permits may be necessary to maintain these species. Institutions in the USA must comply with appropriate rules and regulations such as those of the USDA, United States Fish and Wildlife Service, National Oceanographic and Atmospheric Administration, and National Marine Fisheries Service. Some specific health requirements in the USA include compliance with the USDA's Animal Welfare Act and CDC regulations governing importation of primates and maintenance of colonies of captive bats. The Drug Enforcement Agency governs the purchase and use of controlled substances in the USA. Specific regulatory rules and regulations may dictate management of certain species. As an example, in the USA, the USDA requires that elephants have three negative trunk wash cultures for tuberculosis during a 12-mo period, collected on separate days, preferably during a 7-day period.

Zoonoses: Many human infectious and parasitic diseases are of animal origin, ie, are zoonotic. Free-ranging and captive wild animals may harbor zoonotic diseases that pose a potential health risk for those who work with these animals. Reptiles are commonly asymptomatic carriers of *Salmonella* spp. Avian species may be infected with *Chlamydia* spp. Tuberculosis infections in manunals, especially primates, ungulates, and elephants, can be transmitted from people or harbored and shed by animals to infect zoo staff. Many enteric bacterial or parasitic pathogens of primates can be transmitted to people. Bats may be a source of *Histoplasma* spp or rabies. Carnivorous species of reptiles, birds, and mammals that consume uncooked meat-based commercial diets or whole prey may develop an asymptomatic *Salmonella* carrier state. Numerous zoo species, as well as feral domestic or native species on zoo grounds, may harbor *Leptospira* spp,

Baylisascaris, etc. Recognition of these zoonotic diseases and institution of procedures to minimize the disease risk to zoo staff and the visiting public are important components of a zoologic practice. An occupational health program should be developed for personnel coming in contact with collection animals. Personal protective equipment (eg, disposable gowns, gloves, face shields) should be used as required by zoo personnel. Frequent hand washing is also recommended. (See also ZOONOSES, p 2414.)

COMMON DISORDERS AND PROCEDURES

In general, the disease processes and treatments of zoo species are similar to those of domestic pets, agricultural species, laboratory animals, or people. Commonly encountered medical problems include acute or chronic gastroenteritis, traumatic injuries (bite or gore wounds, lacerations, fractures, luxations), localized (abscess or cellulitis) or generalized (septicemia) bacterial infections, parasitic infestations, obstetric problems, lameness, arthritis, and GI foreign bodies.

Avian Aspergillus infection generally results in chronic respiratory tract disease (see p 1901). Affected birds may exhibit weight loss, markedly increased WBC counts, and in later stages, dyspnea. Death can also occur peracutely if there is a localized aspergilloma that occludes the trachea or in cases of fungal septicemia. Necropsy generally demonstrates extensive fungal granulomas in the air sac and lungs. Species that are more sensitive to *Aspergillus* infections are penguins, pheasants, and waterfowl. Treatment is generally unrewarding because of the advanced state of infection when diagnosed but can include oral (flucytosine or itraconazole), IV (amphotericin B), or nebulized (enilconazole) antifungal medications.

Infectious pododermatitis (bumblefoot) is a common disorder of birds. It can be either unilateral or bilateral and is characterized by lameness, inflammation, and swelling of the footpad due to localized bacterial infection. Sequelae of infection can include chronic pododermatitis, septicemia, or amyloidosis. It can occur due to injury, infection, inappropriate substrate, obesity, or unilateral limb problems (trauma, arthritis) that result in excess and abnormal weight bearing on the contralateral foot. Treatment includes correction of the primary problem, local and systemic antibiotic and symptomatic treatment, and in more advanced cases, surgery.

Avian mycobacteriosis is a chronic problem in many bird collections, and control measures are difficult, because premortem tests are unreliable (see TUBERCULOSIS, p 2869). Aggressive sanitation of the infected enclosures and culling of infected and exposed birds may help limit disease dissemination but will not eliminate it. Marsupials and young primates may also develop infection when exposed to infected birds or contaminated environments (such as in a mixed species exhibit). The disease in marsupials can manifest by development of lung or bone lesions and is resistant to most therapies. The disease in primates is often benign but may result in nonspecific tuberculin test responses.

Prevention of flight in birds is accomplished by amputating one wing just distal to the radiocarpal joint (pinion) or less commonly by performing a tenectomy and fusing the radiocarpal joint. Pinioning of young birds soon after hatching is easier and more successful. The appropriateness of performing this procedure on birds is controversial. (See also ROUTINE GROOMING PROCEDURES, p 1888 et seq.)

Bone fractures are repaired with splints, casts, surgical fixation, or a combination of these methods. Because maintaining a splint on a zoo animal can be difficult, rigid internal fixation or an external fixator are preferable. For best results, fixation should be rigid, strong, and require minimal postoperative care. Because casts must be left in place for 6–8 wk, freedom of movement and a minimum of discomfort must be assured. Newer lightweight, strong, waterproof, fiberglass casting material is especially useful.

Mammalian tuberculosis still occasionally occurs in zoo collections, and routine screening of primates, hoofstock, elephants, and keeper staff is indicated (see p 687). Interpretation of intradermal tuberculin tests can be problematic in nondomestic species because of the occurrence of nonspecific responses. When a test is suspicious or positive, a complete health evaluation should be performed, including additional tests such as radiographs and gastric and bronchial lavage for mycobacterial cytology and culture. Diagnostic immunologic tests are available for zoo bovids and cervids and include lymphocyte stimulation tests and ELISA. Other tests under development include antigen 85 and γ -interferon testing. The incidence of elephant-to-human transmission of tuberculosis has increased in recent years. Most cases of tuberculosis in elephants is caused by *Mycobacterium*

tuberculosis; however other species, including *M bovis*, have caused clinical disease in elephants. Asian elephants are more frequently infected than African elephants. Clinical signs are nonspecific and usually present only in advanced cases; they include chronic weight loss, anorexia, weakness, exercise intolerance, discharge from the trunk, cough, and dyspnea. Definitive diagnosis is by culture. Screening by serologic testing, including immunochromatographic (lateral flow), multi-antigen print immunoassay, and dual path platform test, are not confirmatory and are not used as definitive regulatory tests. The USDA has established testing and treatment protocols for captive elephants in the USA.

Hoof and nail trims are necessary when overgrowth occurs and are most often required in ruminants, equids, elephants, rhinoceros, and larger carnivores. These procedures should be conducted on a regular basis to avoid excessive overgrowth. On occasion, the services of an equine farrier are used for more complicated cases such as when an equid has foundered. Elephant foot care is especially important to prevent chronic musculoskeletal problems and can usually be accomplished in an awake elephant through training. Many other species require chemical immobilization for foot care.

Mandibular osteomyelitis (lumpy jaw) is a common problem of small ruminants and macropods (wallabies and kangaroos). It can occur secondary to coarse feed, oral trauma, or dental disease. Animals generally present with localized facial swelling and a foul oral odor or discharge. Treatment consists of lancing the abscess, debriding infected bone, removing affected teeth if indicated by radiographs, and treating with systemic antibiotics.

Dentistry in zoo animals presents unique problems. The roots of canine teeth in primates and carnivores are more extensive than the exposed crown. Simple traction and rotation cannot remove such teeth intact; dislodging with a dental elevator is essential. A small electric drill or bone chisel is used to remove a section of alveolar bone around the root. Root canals are indicated when a large canine tooth is fractured and viable pulp exposure occurs. Specialized long dental instruments are required to remove the nerve tissue from these elongated canals. The incisor teeth of rodents, such as beavers, porcupines, and capybaras, grow continually; unless these animals are supplied with coarse feed or logs to gnaw on, their incisors grow excessively and interfere with their ability

to feed. Periodontal disease in zoo animals is treated by routine cleaning (under general anesthesia) and by providing adequate chewing substances to supplement the soft, prepared diets fed to many zoo animals.

Because of excellent management, husbandry, nutrition, and veterinary care, many zoo animals live to advanced ages. Care of **geriatric specimens** is becoming increasingly common, including such disorders as diabetes, heart failure, chronic arthritis, and neoplasia. The same diagnostic and therapeutic principles of management of these disorders in people or domestic animals may be successfully applied to the care of affected zoo animals.

Elephant endotheliotropic herpes-virus infection (EEHV) is one of the most significant disease threats to captive elephants. Several virus types that cause disease have been described, although viral latency is common. EEHV primarily causes acute hemorrhagic disease, mostly in young Asian elephants (*Elaphas maximus*) with a mortality rate of up to 85%. Clinical signs are predominately nonspecific and include lethargy, anorexia, mild colic, and tachycardia. There is often edema of the

head, neck, trunk, and thoracic limbs. Cyanosis of the tip of the tongue that progresses caudally and hemorrhage of the tongue and oral ulcers are also seen. Antemortem diagnosis is currently made by PCR analysis of whole blood. Early, aggressive treatment with antiviral agents (famciclovir or ganciclovir) with good supportive care has decreased the mortality rate since 2009.

Since the emergence of **West Nile virus** in the USA in 1999, it has been detected in 22 orders of birds, 8 orders of mammals, and 2 orders of reptiles. Mammals showing clinical infections in zoos include alpacas, sheep, reindeer, harbor seals, Indian rhinoceroses, a polar bear, a wolf and several domestic canids, a Barbary macaque, white-tailed deer, and a killer whale. Clinical signs have also been seen in alligators.

Highly pathogenic avian influenza (HPAI) is a threat to zoo bird collections. Zoos should develop HPAI response plans and establish a dialogue with state and national agricultural regulatory agencies to mitigate the impact of HPAI on zoo collections.

VACCINATION OF EXOTIC MAMMALS

Exotic mammals are susceptible to many of the same infectious diseases that affect domestic mammals. However, vaccination of these species is often extra-label, because vaccines are tested and approved for use only in domestic species. Vaccination protocols recommended for exotic mammals are therefore based on limited published information, anecdotal experience, and relative risk of disease to the species from the infectious agent or vaccination itself. Reports of lack of seroconversion, antibody production, sustained protection, and induction of the disease resulting in morbidity and mortality in a variety of species, particularly for rabies and distemper, are common after vaccination of exotic mammals. Regardless, vaccination should be considered in captive wildlife and conservation programs based on a number of factors. Many diseases preventable by vaccination such as canine distemper virus, canine parvovirus, feline calicivirus, feline panleukopenia virus, and rabies virus have caused population declines or reduced host

fitness in critically endangered mammals. Certainly, infectious disease outbreaks in small numbers of highly genetically valuable individuals can disastrously affect conservation projects. Unfortunately, the biology of many of these preventable diseases (incubation period, transmissibility, etc) in exotic mammals is often unknown. Captivity may enhance the risk of acquiring disease based on food sources, exposure to rodents and other disease hosts, and an unknown degree of exposure of other zoo animals, which is unlikely to occur in nature. Thus, due consideration of protection of captive nondomestic species, even those destined for release to the wild, is warranted. Core vaccines are designated as those that protect captive animals from life-threatening, globally distributed diseases. The determination of protection has largely been based on studies in domestic species; nonetheless, based on current knowledge, these vaccines deserve full consideration for inclusion into vaccination regimens for captive exotic mammals.

Individual animal safety dictates that inactivated or recombinant viral or bacterial vaccines are preferable to modified-live virus (MLV) vaccines, which have the potential to cause disease in exotic mammals and abortions in hoofstock. However, in select species, especially Old World apes, MLV vaccines have received sufficient use to warrant consideration based on the serious risk of morbidity and mortality. Use of MLV vaccines for rabies and distemper are generally contraindicated in exotic mammals. In particular, use of MLV distemper vaccines in exotic mammals may result in postvaccinal myelitis or distemper. Recently developed canary pox–vectored vaccines are the current vaccine of choice for distemper and appear both safe and efficacious. The following concepts should be considered before extra-label use of a vaccine in an exotic animal. Possession of the animal should be legal per state community and other applicable laws. Informed consent of the owner and discussion of the availability or lack of safety and efficacy trials associated with the use of this vaccine in the animal should be documented in the medical record. Use of product and vaccination procedures with record of previous success such as those used or recommended in zoo (Association of Zoos and Aquariums or American Association of Zoo Veterinarians) protocols, and those with publications supporting their safety and efficacy in the species, should be considered. Vaccination may be foregone in the face of lack of data to support that a certain disease occurs, despite antibody presence, in some species.

Vaccination protocols developed for exotic mammals should be determined with respect to number of animals, husbandry, relative value of animal and offspring, pregnancy, species susceptibility to a disease, likelihood of encountering disease, disease prevalence in the surrounding locality, ability to obtain useful products, information of reported or anecdotal benefits or disadvantages with usage of a vaccine in that species, housing and vector control programs, and zoonotic and infectious potential of the disease. As in domestic species, animals that are febrile or have other clinical signs of illness should not be vaccinated. Because a full vaccine dose is required to elicit a satisfactory immune response, remote vaccine administration should be weighed against anesthetic and disease risk. Some nondomestic mammals and their recommended vaccination protocols (e.g., cervids, rodents, lagomorphs, camelids) are reviewed

elsewhere in the Manual, and the reader should refer to the relevant chapters. In domestic mammals, young animals have differing vaccine schedules than those presented in TABLE 36 based on waning maternal antibodies. Consideration of the provided references and consultation with experts in zoo medicine and exotic mammal husbandry are recommended to develop vaccination protocols. Specific vaccine protocols should be developed for neonates. For apes, a youngster vaccination schedule, based on the human schedule, should include the killed polio series and *Haemophilus* vaccination (see www.cdc.gov/vaccines/schedules/index.html).

Although titer determinations may be useful for evaluation of vaccination in exotic mammals, the lack of antibodies does not equate to lack of immune response. This method quantifies only the humoral immune response, not the cell-mediated aspect, and protective titer levels for exotic mammals have not been evaluated or established. Examples of titers that may be assessed include rabies, distemper, parvovirus, and leptospires, as well as the encephalitic viruses and many viruses affecting nonhuman primates that also affect people. Yearly and preshipment viral titers, which vary based on species, are recommended for all primates. Titers change based on natural disease exposure, independent of vaccination, may or may not confer protection from disease, and may also wane quickly, despite repeated exposure.

Bovine Herpesvirus 1: Inactivated and attenuated-live vaccines for infectious bovine rhinotracheitis and infectious pustular vulvovaginitis are available. Vaccines may not prevent infection but reduce clinical signs and significantly reduce shedding of field virus. Use of the inactivated vaccine in exotic hoofstock may be preferred, because abortions and initiation of disease in vaccinated hoofstock have not been adequately studied.

Canine Distemper: Most, if not all of the Carnivora, including canids, procyonids, mustelids, and the viverrids, are considered susceptible to canine distemper virus (CDV); the susceptibility of most Ursidae and Hyenidae is unknown. Giant and red pandas are an important exception among the ursids and appear quite susceptible; canine distemper vaccination has been specifically evaluated in and is recommended for use in this species. Large felids, particularly tigers and lions, also appear

susceptible to disease, which in exotic mammals manifests primarily in the neurologic form. CDV is considered a core vaccination in captive canids and should also be considered in captive exotic felids with a history of disease in the collection. Many species of small carnivores have developed vaccine-induced distemper after receiving an MLV vaccine. The recombinant

canary pox–vectored subunit distemper vaccine, which causes appropriate serologic titers and appears safe and effective, is now recommended for use in susceptible exotic mammals. Generally recommended vaccination regimens for young animals incorporate an initial vaccination after weaning with a 1-mo booster followed by yearly revaccination. Vaccination of

TABLE 36 VACCINATIONS RECOMMENDED FOR EXOTIC MAMMALS

^a MLV = modified live virus; K = killed

^b DPT = diphtheria, pertussis, and tetanus

^c Canicola or Icterohaemorrhagiae

^d Not ferret origin; recombinant canarypox origin preferred

^e Controversial; some believe hyaenids are not susceptible

^f BVD = bovine viral diarrhea

^g EEE = Eastern equine encephalomyelitis

^h WEE = Western equine encephalomyelitis

free-living animals should be carefully considered, because vaccine efficacy is unknown for many nontarget species, and animals may have recovered from or be incubating disease, rendering vaccination a poor use of resources.

Canine Parvovirus and Feline

Panleukopenia: Canine parvovirus, raccoon parvovirus, and feline panleukopenia virus are closely related antigenically and pathogenetically. Canidae, Felidae, and most Mustelidae, Procyonidae, and Viverridae are considered susceptible to one or more of these parvoviruses. Binturongs are susceptible to feline panleukopenia, and vaccination is recommended. Vaccinations that protect from feline panleukopenia are considered core vaccines in exotic felids, while those that protect from canine parvovirus are core vaccine for canids. Based on insufficient attenuation of MLV vaccines for some species, only inactivated vaccines of tissue or tissue-culture origin are recommended for use in exotic mammals. Vaccine and dosage regimen have been empirically determined but should adhere to label directions, with boosters recommended at 2 wk, 6 mo, and then annually. Based on reports of vaccine reaction associated with MLV combinations of canine distemper, canine adenovirus 2, canine parainfluenza, and canine parvovirus, multivalent vaccination with killed feline panleukopenia, feline

rhinotracheitis, and feline calicivirus is preferred for use in exotic mammals.

Equine Encephalomyelitis: Because nondomestic equids are susceptible to equine encephalomyelitis, vaccination should follow guidelines for domestic equids in endemic areas. Inactivated trivalent (Eastern, Western, Venezuelan) or bivalent (Eastern, Western) vaccine, or a combination of these with tetanus toxoid, are administered according to manufacturer instructions. Initial immunization is two doses, 1–2 wk apart with annual revaccination. Although susceptibility of tapir species is unknown, a similar vaccination regimen has been recommended in this species. The susceptibility of exotic equids to West Nile virus is unclear, but zebra, tapir, and related species are often vaccinated for West Nile virus; efficacy and safety of the inactivated equine (more commonly used) or the DNA West Nile virus vaccination in these species is unknown.

Equine Herpesvirus 1 Infection:

Equine herpesvirus 1 (EHV-1) can cause abortion in exotic equids; killed virus vaccination is recommended, because adequacy of attenuation in MLV vaccines is unknown for nontarget species. Vaccination of foals should begin at 4 mo, with boosters at 4-mo intervals up to 1 yr. Mares must be vaccinated often to provide protection from

abortion, because EHV-1 natural protective immunity after infection lasts only 4 mo.

Erysipelas: The bacterium *Erysipelothrix rhusiopathiae* is pathogenic for the Tayassuidae, nondomestic Suidae, cetaceans, and pinnipeds. Erysipelas bacterin can be administered with the standard regimen to nondomestic swine and peccaries (see p 2817). Despite the importance of preventing erysipelas in marine mammals, there is no bacterin designed specifically for these animals. Vaccination of cetaceans and pinnipeds is controversial, but a subunit vaccine has been investigated in dolphins (see also BACTERIAL DISEASES OF MARINE MAMMALS, p 1861). In facilities where captive cetaceans are vaccinated, extra-label bacterins are used to prevent erysipelas outbreak. Based on vaccine breaks, the necessity of bacterin culture and sensitivity testing before revaccination, and the risks of fatal anaphylaxis, sterile abscessation, tissue reaction, and animal immobilization, some facilities have reduced vaccination to one-time administration, even though antibody titers fall below the presumed effective level. Booster at 6 mo and annual revaccination are recommended to maintain protective antibody titers. Because disease appears less common and vaccination is not without significant risk of morbidity and mortality while protective efficacy remains unknown, vaccination is not routinely recommended in pinnipeds.

Feline Caliciviruses: Exotic felids are susceptible to feline caliciviruses, and some strains may cause serious morbidity and mortality. This is considered a core vaccine in exotic felids. Vaccines are often combined into a multivalent formulation, and vaccine regimens are as for feline rhinotracheitis.

Feline Herpesvirus Rhinotracheitis: Feline viral rhinotracheitis is a serious disease threat in exotic Felidae and is considered a core vaccine. Available vaccines, inactivated, subunit, and MLV, are combined with feline calicivirus and are usually in multivalent formulations with other pathogens (eg, feline panleukopenia). A single dose should be administered at weaning, with monthly boosters until 4 mo of age and annually thereafter. In domestic cats, vaccination provides reasonable disease protection but does prevent infection or viral latency. Vaccinated cats can be infected; however, clinical signs and viral shedding are reduced.

Infectious Canine Hepatitis (Canine Adenovirus 1): All Canidae and binturong, a viverrid, are susceptible; Ursidae may also be susceptible. In foxes, the disease is called fox encephalitis due to a predominant neurotropism and neurologic signs. Canine adenovirus (CAV) is a core vaccination for captive canids. Because a killed vaccine is not commercially available, multivalent MLV vaccines containing canine distemper and CAV-1 or CAV-2 are often administered. Based on the close antigenic relationship of CAV-1 and CAV-2, vaccination with either virus provides cross-protection. CAV2 is thought less likely to cause postvaccinal reactions, such as corneal opacity and hemorrhagic and necrotizing hepatitis (vaccine-induced adenoviral hepatitis). However, administration of CAV-2 MLV vaccine to a maned wolf (*Chrysocyon brachyurus*) has resulted in vaccine-induced adenoviral hepatitis. Therefore, vaccination recommendations for this species are limited to canine distemper virus, canine parvovirus, and rabies; vaccination with MLV CAV-2 is contraindicated in this species. For other canids, recommended vaccine regimens are a single dose of the multivalent vaccine at weaning, with monthly boosters until 4 mo of age followed by annual revaccination.

Canine Influenza Virus: Canine influenza virus vaccination for domestic carnivores is considered noncore. However, if a collection has a history of canine influenza or is located in an endemic area, vaccination may be considered. Vaccination may also be considered for great apes, as well as for contact staff on a yearly basis before flu season. Equine influenza vaccine is administered to nondomestic equids in some zoos.

Leptospirosis: Leptospirosis occurs sporadically in exotic Canidae, Procyonidae, Viverridae, Ursidae, Mustelidae, Suidae, primates, Tayassuidae, and in Cervidae and other ruminants of the families Bovidae, Artiodactyla, Perisodactyla, Proboscidae, Camelidae, Giraffidae, etc. Vaccination of domestic carnivores with *Leptospira* bacterins is considered noncore. However, if a collection has a history of or is in an endemic area for leptospirosis, vaccination should be considered with bacterins that contain immunogens against *Leptospira interrogans* serovars Canicola and Icterohaemorrhagiae. Carnivores are vaccinated with a 1- or 2-mL dose, IM or SC, at 6-8 wk of age, repeated in 14 days. Boosters are given every 6 mo. Hoofed

animals are immunized with 5 mL of pentavalent bacterin IM; annual or preferably semiannual boosters are recommended. Vaccination does not necessarily prevent shedding of the causal organism(s).

Ruminants, pigs, and peccaries are immunized with pentavalent bacterins that contain the serovars Pomona, Hardjo, Icterohaemorrhagiae, Canicola, and Grippotyphosa. Hoofstock should have an initial vaccination with a booster 4–8 wk later (as per label instructions); booster vaccination is essential, because leptospirosis vaccines are killed vaccines. At a minimum, hoofstock should be revaccinated yearly approximately 6–8 wk before the breeding season. However, because protective titers can wane within a year, a semiannual vaccination schedule may be instituted if leptospirosis is an issue or occurs in valuable breeding stock. Vaccination does not necessarily prevent shedding of the causal organism(s).

Measles, Mumps, and Rubella: Pongidae are often immunized against measles, mumps, and rubella at 2–3 mo of age and annually thereafter with 0.5 mL of MLV human vaccine injected SC. This vaccination is also recommended for monkeys. New World monkeys are more resistant than Old World monkeys, but mortality is high when infected. Vaccine administration in other primates is optional, depending on colony-specific concerns. Vaccination of susceptible populations of nonhuman primates (>6 mo old) should be considered when contact with people cannot be adequately controlled (eg, nonhuman primates as pets). Annual booster doses are given.

Parainfluenza 3: Exotic sheep and goats are susceptible to pneumonia caused by parainfluenza 3 (PI-3) and *Mannheimia haemolytica*. Modified-live virus PI-3 vaccines, particularly those administered intranasally are useful to reduce the incidence of pneumonia in lambs. Vaccine is administered at 3–4 mo of age, 1 mL per nostril, and repeated 3–4 wk before anticipated shipment and annually thereafter.

Poliomyelitis: Primates, particularly the Pongidae (great apes) are susceptible to poliomyelitis. Oral trivalent MLV poliomyelitis vaccine is preferred to parenteral inactivated vaccine because of ease of administration. A single human dose (0.5 mL) is given PO on a sugar cube after 6 mo of age and annually thereafter. Vaccinated animals should be isolated from unvaccinated primates (including people) for 1 mo after inoculation.

Rabies: All exotic mammals are susceptible to rabies (see p 1302). Vaccination is considered core for felids and canids in endemic areas and recommended for mammals in zoos in areas where incidence of rabies in free-living wildlife is high. However, the efficacy of parenteral rabies vaccination of exotic mammals has not been established, and no commercially available vaccine is licensed for use in free-living animals. Use of rabies vaccines in these species is extra-label and is not considered protective in the event of a bite. Based on the potential for human rabies exposure, keeping wild-caught carnivores as pets should be discouraged and is illegal in many jurisdictions. Wild-caught animals such as foxes, raccoons, and skunks may have been exposed to the virus when quite young and may incubate disease for a prolonged period (>1 yr), rendering a short observation period inadequate. The National Association of State Public Health Veterinarians recommends that wild-caught animals with public contact (eg, in zoos) should be quarantined for at least 180 days.

When vaccination is considered necessary, only killed virus vaccine should be used, and it should be administered via deep IM injection. MLV rabies vaccine licensed for use in domestic species should never be used in exotic animals, because such vaccines are often insufficiently attenuated and may produce clinical rabies and death. Several inactivated vaccines prepared of nervous tissue (eg, murine, ovine, or caprine) or tissue culture have been found satisfactory in terms of safety and immunogenicity, the latter based on limited tests that demonstrated adequate antibody responses in some exotic carnivores. The human diploid cell-line origin killed-virus vaccines appear to have the best immunogenicity in domestic species. Young animals are vaccinated at 3–4 mo of age, and vaccinations must be repeated annually. Vaccination for rabies of bats in captivity is done at some institutions; MLV vaccination of bats incubating the rabies virus may hasten the disease course and result in death (as occurs in people). Use of oral bait vaccination for control of rabies in wildlife continues in several countries; this vaccination is not intended for use in captive, single animals.

Clostridial Diseases: Primates, exotic Equidae, Proboscidae (elephants), Pongidae, Cervidae (deer), camelids, and exotic sheep and goats should be immunized against tetanus. Although the susceptibility of tapirs to tetanus has not

been documented, vaccination is recommended. Exotic Equidae and elephants are vaccinated on the same schedule as domestic horses; primary immunization at 3–4 mo of age consists of two IM injections of tetanus toxoid, 1 mo apart. A single booster dose is given annually.

Pongidae are often vaccinated against tetanus using the diphtheria, tetanus toxoid, and phase 1 pertussis (DPT) vaccines intended for use in human children or monovalent human tetanus toxoid. Monovalent tetanus toxoid is preferred, because pertussis and diphtheria are not considered health risks for nonhuman primates. However, susceptibility of these diseases likely varies in primates, because olive baboons were recently found to develop clinical signs of pertussis and a strong anamnestic response. Primary immunization consists of 0.5 mL of vaccine injected IM on three occasions at 3-mo intervals, with a booster dose 1 yr after the third injection. Thereafter, booster immunizations of 0.5 mL of diphtheria-tetanus toxoid or tetanus toxoid alone are given every 3–5 yr or after potential exposure due to injury.

In exotic hoofstock, the need for clostridial vaccines depends on animal husbandry and density, environment, and local disease circumstances. If vaccination is warranted, vaccines should be given according to manufacturers' recommendations for hoofstock. Multivalent clostridial vaccines are available for prophylaxis; tetanus antitoxin can be used if tetanus is a concern. Pregnant animals should be vaccinated 4–8 wk before parturition to increase specific colostral immunoglobulins. Neonates can be vaccinated at 4 and 8 wk of age with *Clostridium perfringens* type C and D. Exotic sheep, goats, and cervids are sometimes vaccinated beginning at 10–12 wk of age with multivalent clostridial bacterin-toxoids containing immunogens for *Clostridium tetani*, *C. perfringens* (types B, C, D), *C. septicum*, *C. chauvoei*, *C. novyi*, *C. sordellii*, and *C. haemolyticum* in areas of high exposure risk. The initial dose is 5 mL followed in 6 wk by a 2-mL dose, administered SC. A 2-mL booster dose should be given annually.

Miscellaneous: A number of infectious diseases, including bovine viral diarrhea (BVD), bluetongue, malignant catarrhal fever, epizootic hemorrhagic disease of deer, anthrax, encephalomyocarditis virus, cowpox, and brucellosis, may appear as serious local problems but are not

widespread in zoos. Unfortunately, satisfactory vaccines for many infectious diseases are not available for exotic animals. Inactivated BVD vaccines are recommended in situations in which BVD has been a problem. Annual vaccination with one standard bovine dose IM should begin at 3 mo of age. Satisfactory vaccines for bluetongue, epizootic hemorrhagic disease, malignant catarrhal fever, and encephalomyocarditis virus are not currently available in the USA. In contrast, a number of vaccines are available for extra-label use in exotic mammals, which may not be efficacious or necessary. These noncore vaccines for domestic carnivores include feline leukemia virus, feline immunodeficiency virus, *Chlamydia felis*, feline infectious peritonitis, feline *Giardia* vaccine, coronavirus, and Lyme disease. If a collection has a history of these diseases or is in an area endemic for disease, vaccination may be considered. Anthrax vaccine has been administered to cheetah (*Acinonyx jubatus*) and black rhinoceros (*Diceros bicornis*) without apparent ill effect, and conference of protective immunity in some with a single booster was recommended. Vaccination of valuable animals could be considered in the event of an outbreak. Brucellosis affects both free-living and captive marine mammals, with minimal apparent zoonotic potential. No vaccination or other control methods for brucellosis are established for these or other exotic mammal species in captivity. Vaccination programs for free-living bison and cervids are controversial. Although the MLV vaccine effectively prevents future abortions and the transmission of brucellosis, it does not protect from infection or seroconversion, may induce abortions in pregnant animals, and is infectious to people. The reemergence of brucellosis worldwide and an increasing incidence of human disease underscore the need for new and improved brucellosis vaccines. The vaccinia, cowpox, and smallpox (variola) viruses are closely related pox viruses that may have all evolved from a single ancestral virus. Cowpox virus has caused morbidity and mortality in canids, felids, equids, elephant, rhino, camelids, viverrids, rodents, primates, and hoofstock; zoonotic disease has been reported. Vaccinia titers have been documented in free-living nonhuman primates in South America. The CDC currently limits distribution of vaccinia vaccine to health care and bioindustrial laboratory workers with exposure risk.

MANAGEMENT AND NUTRITION INTRODUCTION

Almost all domesticated animals rely on their caretakers to maintain their health and well-being, to provide appropriate nutrition, and to meet behavioral needs and any special physiologic requirements. The success of proper management and nutrition is especially important to agricultural species that must sustain growth and production.

Genetic advancement has led to continual increases in productivity that place similar continual pressure on animal husbandry management to ensure it does not limit animal health, well-being, or productivity.

Proper management and nutrition are also central to the prevention and control of infectious and noninfectious diseases.

Infectious diseases occur after colonization of an animal by microbes (eg, a bacterium, virus, rickettsia, parasite), but simple infection by a microorganism is not usually sufficient for disease to develop. Environmental and host factors influence whether the animal will develop clinical or subclinical disease or have impaired productivity. Management has a substantial impact on environmental and host conditions that contribute to disease susceptibility.

Eradication and exclusion of specific organism(s) that cause disease is the only certain way to prevent infectious disease. This is usually impractical or impossible for many common diseases of agricultural animals. As a result, it becomes necessary to control rather than to prevent infectious disease by reducing circumstances that favor the presence or the spread of the infectious agent, by mitigating environmental circumstances that contribute to development of disease once animals have become infected, and by minimizing circumstances that increase host susceptibility. Circumstances that contribute to the development of a disease are called risk factors, and they can be related to the microbe, the environment, or the host. Identifying and mitigating the impact of risk factors is the goal of a management strategy to prevent specific diseases and to maintain productivity.

A multifaceted approach to disease prevention and control through management practices is particularly important when dealing with many of the common infectious and noninfectious diseases seen in food animal production systems (eg, enzootic pneumonia in calves and piglets, neonatal diarrhea, bovine respiratory disease complex of feedlot cattle, infectious infertility in swine and cattle, metabolic disease in dairy cows) as well as in companion animals (eg, respiratory disease in catteries, kennel cough in canine boarding facilities, infertility and viral respiratory disease in horses). Many of these diseases are difficult to control without an integrated approach, because they either have a complex etiology involving the interaction of multiple microbes or are caused by pathogens for which there are no reliable treatments or effective specific preventive measures.

Prevention and control of these diseases is best achieved by implementing management practices to mitigate recognized risk factors for infection, disease development, and impaired productivity. Often, these are general management recommendations that are not targeted at specific infectious organisms. Effective control may also require implementation of management practices to

address risk factors unique to particular pathogens and diseases.

The need to identify and implement multifaceted management strategies that will maintain health and enhance productivity is likely to increase in animal agriculture. This need for new strategies is driven by competitive and economic forces within the industry and by pressure for change from interested parties outside agriculture. Identifying and implementing these management changes requires collaborative efforts of all groups working in livestock production, including veterinarians, animal scientists, and nutritionists, with consideration of economic and other forces acting on producers.

All of agriculture, but particularly animal agriculture, is under pressure from consumer and special interest groups to address concerns arising from some industry practices. These concerns include potential links between agricultural practices and antimicrobial resistance in human pathogens, relationships between environmental contamination and intensive animal production, the role of agricultural management practices in reducing the risks of foodborne illnesses and risks of exposure to zoonotic pathogens, and the impact of agricultural practices on animal welfare. Even though there may be no conclusive evidence linking livestock production to these public health and public interest issues, livestock production management will likely change in response to the perception of such links. Any changes in current practices will require development of new approaches to maintain animal health and production, which will require a substantial investment in research and education.

Increasingly, livestock production must ensure that management practices are implemented at the farm level as part of the industry-wide system to maintain the safety and wholesomeness of the food supply. Validated on-farm food safety programs are often based on Hazard Analysis and Critical Control Point (HACCP) principles. They emphasize that all stages of the food production chain have a role in ensuring food quality and safety. Developing, implementing, and auditing these management programs are essential to maintain consumer confidence. These programs require implementation and documentation of management practices that reduce the risk of physical, chemical, or microbial hazards entering the human food supply through production practices on farms.

Animal agriculture is also under pressure from within the industry to better protect the industry itself. Well-publicized outbreaks of

disease such as bluetongue, Schmallenberg virus, avian influenza, and transmissible spongiform encephalopathies in several species (eg, bovine spongiform encephalopathy, scrapie, chronic wasting disease) have focused the industry's attention on biosecurity as a disease prevention and control strategy. Biosecurity is a set of management practices that aims to prevent the introduction of infectious or other disease-causing agents and/or to prevent the further spread of agents that are introduced or are already present (*see also* below). Biosecurity programs can be implemented at a room, building, farm, regional, or national level. Similar to disease prevention programs, biosecurity programs often comprise a set of general practices and sets of management practices targeted at specific pathogens.

Nutritional management is a subcategory of animal management. Proper nutrition is essential to health and productivity. Nutrition also plays a role in susceptibility to disease (eg, feline lower urinary tract disease) as well as in medical management of certain diseases (eg, diabetes in dogs and cats, equine metabolic syndrome, ketosis and hypocalcemia in dairy cattle). Rations/diets must be formulated to provide for basic physiologic needs (eg, energy, protein, fats, carbohydrates, vitamins, minerals) and to ensure optimal growth and productivity. Proper ration formulation considers age, sex, breed, physical activity, and lactation and gestational status.

Nutritionally related diseases include diseases associated with a nutritional excess (eg, direct toxic effect, digestive upset), nutritional deficiency (either primary or secondary), or nutritional imbalance. In animal agriculture, health and production are also heavily influenced by feeding management in addition to ration formulation. Feed preparation and delivery are often as important in ensuring animal health and productivity as the actual nutritional value of the ration itself. Inadequacies in nutritional delivery can directly cause disease (eg, ruminal acidosis, laminitis) or increase susceptibility to disease (eg, *Clostridium perfringens* enterotoxemia).

Nutritionally related diseases in companion animals also include both conditions of excess (eg, developmental orthopedic disease in dogs related to excess calcium and energy) and of deficiency (eg, blindness in cats related to taurine deficiency).

Feeds and feeding management can also influence animal health if feeding results in exposure to physical hazards (eg, sharp objects), chemicals (eg, mycotoxins, toxic plants), allergens (eg, dust mites, mold spores), or microbes (eg, molds, *Salmonella* spp). Feeding and waste management practices are also important to prevent and control infectious disease spread through fecal-oral transmission (eg, salmonellosis, neosporosis, paratuberculosis, toxoplasmosis).

BIOSECURITY

The tenets of biosecurity have been long recognized by veterinarians. However, throughout the past decades, interest in biosecurity as a scientific discipline has surged because of 1) disease outbreaks that have threatened to devastate agricultural economies, and 2) bioterrorism. In fact, the meaning of the term biosecurity and the structure and focus of biosecurity programs have evolved throughout time to more accurately reflect the scientific community's evolving perception of disease as well as the needs of the consumer, the veterinary profession, and producers and owners.

In modern animal medicine, biosecurity is probably best defined as "all procedures implemented to reduce the risk and consequence of infection with a disease-causing

agent." This broad definition recognizes that disease is a complex interaction between the host, the disease-causing agent, and the environment. Biosecurity can be considered in terms of individual animals or populations of animals (flocks or herds), economic entities (production facilities or companies), or geographic regions (counties, states, countries, or continents), thus facilitating compartmentalization for trade purposes. Importantly, it addresses strategies for both disease prevention (eradication) and control (limiting the consequence of infection).

Benefits of an effective biosecurity program include optimized animal health and welfare and, in the case of food animal medicine, improved productivity and

end-product value, as well as safe regional/international trade. Although implementation of a comprehensive biosecurity plan or program has obvious benefits, allocation of resources must be economically (food animals) or emotionally (companion animals) justified. Unless a disease poses a specific risk to human health or animal welfare, its mere presence in an individual animal or population of animals is not significant. Intervention strategies are consequently chosen based on both their economic and biologic efficiency.

A dynamic and integrated epidemiologic and economic analysis is required to determine and quantify the negative effect of a disease challenge, and the anticipated positive response to the proposed intervention strategy. Such integrated analysis has become significantly more important in intensive production systems.

The economic impact of disease can be difficult to assess. This is particularly so in intensive production systems in which economic return is governed by not only animal productivity but also product quality. In addition, the consequential loss from disease challenge is, at best, only partially recoverable. Using the cost of disease to justify intervention overemphasizes the consequence of inaction, and it is useful only in justifying intervention strategies directed at preventing disease challenge.

PRINCIPLES OF BIOSECURITY

Disease control and prevention relies on the interrelated processes of bioexclusion, surveillance, and biocontainment. Prevention of disease is costly, difficult, and time consuming and is primarily directed at preventing epidemic or exotic diseases. It invariably involves eradication of disease-causing agents from a population of animals or geographic area. In contrast, control programs are less demanding and primarily focus on limiting endemic diseases to tolerable levels within a population of animals or geographic area. Although preventing exposure to disease-causing agents remains an objective of control strategies, strategies are primarily focused on limiting the consequence of disease.

Disease Prevention: Disease prevention depends on 1) stringent bioexclusion to avoid contact between the disease-causing agent and the host, 2) early detection of a breach in biosecurity through vigilant surveillance, and 3) rapid implementation of a ruthless biocontainment policy. This is feasible only if there is an effective means of detecting infection; containing the infection

through slaughter, clean-out, and disinfection; and preventing dissemination of the disease-causing agent. Eradication is reserved for those diseases that pose a dire public health threat, that have a devastating effect on animal performance, or that severely compromise end-product quality.

Disease Control: In disease control strategies, the emphasis shifts from preventing disease to reducing its consequence or economic impact. Prevalence data are now used primarily to assess the level of protection and challenge, not merely the presence or absence of disease. Although biosecurity still relies on principles of prevention, disease-control programs focus more on limiting the extent and consequence of exposure. Many biosecurity measures aimed at preventing or eradicating epidemic disease also produce beneficial by-products, such as establishment of a firm foundation for control of erosive/endemic diseases and enhancement of host resistance through immunization.

Disease Management and Disease Determinants

Disease-risk management must be an integral part of any animal management program. Economic analysis is a critical step in biosecurity plan design, because resource allocation must be aligned with risk. The success of a disease control program depends on the ability to identify and subsequently address risk of infection. Disease risk in a population is characterized by the probability of point infection and subsequent spread. Aggregate risk is the sum of each individual risk of adverse health effects in an exposed population. The spread and consequence of point infection is influenced by several factors referred to as disease determinants.

Because infectious disease is the result of a complex interaction between several factors, any factor that influences the risk and consequence of disease challenge is a disease determinant. Disease determinants have traditionally been classified as primary or secondary; intrinsic or extrinsic; and host-, agent-, or environment associated. In intensive production units, the housing environment, agent, and host determinants are largely under the control of the manager/caretaker, who thus has the greatest influence on disease determinants.

Risk Assessment: Risk assessment is used to estimate the probability of exposure to an agent, the probability that exposure will cause infection and disease, the probability that disease will spread, and the consequence of such spread. Statistical

techniques such as the chi-square test can be used to assess whether a specific factor/process is correlated with disease, but these provide no estimate of the degree of disease risk. The measure of association most frequently used to assess risk magnitude is the risk ratio (probability of disease given exposure divided by the probability of disease given no exposure).

Disease control begins with evaluating each part of the production process as a risk factor for infection. On a basic level, risk of infection equals the probability of each event causing infection multiplied by the number of times each event occurs. But estimating the degree of risk requires analysis of many other factors, including host resistance and the dose/virulence of the organism.

As a first step to limit health risk, a biosecurity program should critically assess the necessity of all events or processes that potentially carry risk, and only crucial ones should be allowed. Limiting the potential for infection within crucial events is focused on improving host resistance or reducing the challenge dose or virulence of the infecting organism.

Host Resistance: Immune efficiency is the key factor governing host resistance. A healthy animal produces an appropriate immune response sufficient to combat infection and its impact on productivity. Conversely, a response that is either excessive or insufficient will adversely affect well-being and performance. Resistance varies among individuals primarily due to genetic differences that typically follow a Poisson distribution.

Immunosuppression reduces both individual and herd/flock immunity. The weakest members of a population will be most negatively impacted by individual stressors (eg, disease or poor nutrition), which have a cumulative impact on immunity. Such highly susceptible animals tend to skew the resistance curve to the right, resulting in a dramatic decline in flock/herd immunity.

Host resistance, challenge dose, and organism virulence determine whether an infectious challenge results in disease. Dose is the number of organisms to which an individual animal is exposed, and virulence is the inherent capability of the agent to infect (infectivity) and cause disease (pathogenicity) within the host. The traditional measure of infectivity is the infective dose 50 (ID_{50}), which is defined as the dose required to infect 50% of the animals in a specific population.

When designing a health program, it is important to remember that the ID_{50}

represents more than a measure of disease virulence. It is more factually the dose required to infect the least resistant animal within the population. This is because the risk of a challenge exposure increases once one animal in a population becomes infected or diseased. Agent replication increases the risk of exposure by increasing the dose and (possibly) virulence of the agent, with each new infection escalating the risk further until even relatively resistant animals become at risk.

Epidemiology: See also BASIC PRINCIPLES OF EPIDEMIOLOGY, p 2397. Effective biosecurity requires an understanding of the causal relations between exposure and disease, because the prevalence and consequence of any infectious disease involves a complex interaction between several disease determinants. The epidemiology and relative risk for each disease should be assessed to determine the best way to allocate resources for effective control procedures. Furthermore, epidemiologic statistics can be used to determine the best way to limit current and future financial risk. Several important epidemiologic factors need to be considered (below).

Source of Infection: In addition to identifying those animals that have become infected, other variables, which are associated with the relative importance of a particular source, should be assessed, including the shedding pattern, host range, mode of transmission, and farming practices.

Transmission: Disease transmission within a population is influenced by direct contact with infected animals, as well as by indirect exposure from contaminated objects (fomites). These forms of horizontal transmission influence the rate and extent of transmission within and among groups. This is in contrast to vertical transmission between parent and offspring. Vertical transmission may result from direct contamination or (in some cases) from transovarial transmission of disease-causing agents within the embryo itself.

Spread: Disease spread is influenced by factors such as incubation period, replication rate, resilience, and virulence of the disease agent. These factors influence spread within the population as well as disease course (acute, subacute, chronic) within individuals. For example, disease spread is accelerated by a resilient organism with a short incubation period and high replication/shed rate.

Susceptibility and Predisposition: For an effective control program, it is important

to know the range (species, breed, type) of susceptible hosts. Furthermore, host, agent, and environmental factors can predispose animals to infection or disease. For example, environmental stress can compromise immune function.

Prevalence: Disease prevalence is directly proportional to the risk of challenge. Endemic diseases are difficult to prevent, whereas diseases that are exotic (ie, not normally present) or epidemic in nature are easier to track, contain, and eradicate.

Morbidity and Mortality: Morbidity refers to the animals in a population showing signs of disease at particular times. Diseases that spread rapidly typically have a high morbidity rate (percent). Mortality rate represents the percentage of animals in a population expected to die during a particular disease outbreak.

Recovery: Disease recovery is influenced by many factors (ie, disease determinants).

THE THREE LEVELS OF BIOSECURITY

A comprehensive biosecurity program should represent a hierarchy of conceptual, structural, and procedural components directed at preventing infectious disease transmission within and across farms, companies, facilities, regions, countries, and continents. Avoidance is the most effective way to prevent disease transmission involved with animal ownership or production. But given that all movement of animals within or across groups/borders involves risk of contact, biosecurity measures are needed to reduce unavoidable risk.

Conceptual Biosecurity: This primary level of biosecurity revolves around the location of animal facilities and their various components. The most effective way to limit risk is physical isolation, making this a primary consideration when siting new confinement facilities or farms. Facilities/farms should not be located next to public roads, especially when the area has a high density of animal facilities. Similar isolation methods include limiting the use of common vehicles and facilities, limiting access by personnel not directly involved with the operation, and controlling the spread of disease by vermin, wild animals, and wind.

Structural Biosecurity: This secondary level of biosecurity deals with physical factors such as farm layout, perimeter fencing, drainage, number/location of

changing rooms, and housing design. Long-range planning and programming is important and should consider on-site movement of vehicles, equipment, and animals; traffic patterns; and feed delivery/storage.

Procedural Biosecurity: This tertiary level deals with routine procedures to prevent introduction (bioexclusion) and spread (biocontainment) of infection within a facility. These activities should be constantly reviewed and quickly adjusted as needed in response to emergencies.

DEVELOPING A BIOSECURITY PROGRAM

Biosecurity programs consist of bioexclusion, surveillance, and biocontainment.

Bioexclusion

The primary focus of bioexclusion is to limit the level of exposure to disease-causing agents below the threshold for infection or colonization. This requires a systematic approach to preventing pathogen movement across physical or imaginary barriers (protection zones), so as to eliminate or decrease the number of disease-causing organisms within the animal's environment. Sound epidemiologic principles should be used to establish zone boundaries while making use of existing physical/geographic barriers.

Global Perspective: The global nature of the animal industry results in daily shipment of animals and animal products throughout the world. This trade is regulated by the World Organization for Animal Health (OIE), and such commerce must comply with OIE regulations, including those pertaining to farm-level control measures.

Country Perspective: To control spread of disease, the OIE aids in the establishment of international agreement on animal and plant sanitary (SPS) measures. Such an agreement within the World Trade Organization establishes common definition and describes OIE in-house procedures for dealing with international trade disputes. This treaty has also established guidelines and principles governing the transparent, objective, and defensible assessment of risk. More specifically, import risk analysis provides importing countries with an objective and defensible assessment of the disease risks associated with importation of such items as animals, animal products, biologic products, genetic material, feedstuffs, and pathologic material.

Region or State Perspective: To account for the difficulties in controlling the disease status and management practices of animal populations across the vast expanse of large countries (eg, the USA), the Terrestrial Code makes allowance for zoning and compartmentalization. The code defines subpopulations based on animal health status, allowing member countries to limit damaging trade effects associated with disease outbreaks, without exposing the importing country to risk from disease spread. There are also “compartments” based on biosecurity procedures and “zones” based on geography. The requirements to establish these subpopulations vary based on disease specifics and the requirements of the trading partners, and they are best decided before disease outbreak. Factors such as disease epidemiology, environmental influences, natural/artificial boundaries, surveillance and monitoring, and applicable biosecurity measures (eg, movement controls and husbandry) are of particular interest. To establish local zones/compartments, the veterinary services of an exporting country must clearly define subpopulations as stipulated in the Code. Relevant claims must be reported to the veterinary services of an importing country and supported by official, detailed documentation.

Zone borders are based on natural, artificial, or legal boundaries, making them relatively easy to establish and officially communicate. Compartments based on biosecurity procedures are more difficult to define. The requirements for a compartment include defining adequate biosecurity plans, operating procedures, and management practices that are well documented (including documentation of compliance). This process involves developing a partnership and clearly stipulated responsibilities between animal owners and the appropriate veterinary authority.

Requirements of biosecurity plans include adequate and robust disease surveillance, animal identification, and traceability. This necessitates detailed records for factors such as animal movement and production, feed sources, sources of replacement stock, disease surveillance (including morbidity and mortality), vaccination and medication history, personnel training, and visitor logs. Risk mitigation also requires that the plan be regularly audited, reviewed, and adjusted as needed.

Company Perspective: For purposes of biosecurity, companies operate as compartments within a country, state, or

region. Minimal requirements of international trade require that companies conform to international standards, thereby meeting OIE requirements. As compartments within the biosecurity rubric, each trading company, region, state, or country should classify prescribed OIE diseases according to expected prevalence; design, document, and implement a biosecurity plan to prevent/control these diseases; and provide proof of plan compliance. This biosecurity plan forms the basis for all disease prevention, diagnosis, and control strategies. The plan should identify potential pathways for disease introduction/spread within the company and describe the measures being (or that will be) taken to minimize risk as prescribed within the OIE Terrestrial Code.

Primary Control Zone—Animal Confinement Facility:

Bioexclusion begins at the animal confinement facility, which is the smallest epidemiologic unit within the company. The animals within this facility share a common environment, common management practices, and similar likelihood of pathogen exposure. The boundaries of these facilities represent well-defined barriers to entry and an ideal place for implementation of critical control procedures. Every crossing of the facility perimeter should be considered an “event” with potential for pathogen transfer or disease risk.

Reducing the risk from such events requires an “all-in, all-out” strategy. Thorough cleaning, decontamination, and chemical disinfection should be performed when the facility is empty. Once animals arrive, the focus shifts to limiting the number of events (in-house perimeter crossings), as well as the probability of pathogen transmission and infection during unavoidable events.

Secondary Control Zone—Farm or Site:

The next zone/compartment in the disease-control hierarchy is the farm or site. In this case, the epidemiologic unit is the farm rather than the containment facility. There is a defined boundary surrounding the farm, and the farm animals share a common environment with common management practices, thereby sharing a common likelihood of exposure to pathogens from nearby containment facilities.

The farm/site establishes real (eg, fence) or imaginary boundaries that serve as access points to the secondary control zone, which is a critical zone for disease control. From a biosecurity standpoint, the site is considered “closed” if the farmer/producer enforces full

biosecurity with no uncontrolled access after disinfection. The site is considered “open” if general biosecurity is enforced at the start of transfer/depletion, with access granted only to necessary vehicular traffic. The site is “fully open” if routine control is enforced from the point of last animal removal. Sites involved in an outbreak should remain closed until the responsible veterinarian declares them clean.

Tertiary Control Zone – Complex:

Groups of animals that share a communal animal handling facility (ie, a complex) constitute a tertiary control zone. The complex represents its own epidemiologic unit, because sites/farms within it share facilities such as feed mills and processing plants. Production processes within the complex (eg, rearing farms and grow-out farms) similarly constitute separate epidemiologic units. All the defined areas may represent tertiary control zones for biosecurity purposes. Tertiary zones are seldom fenced, so access boundaries are typically imaginary.

As a cost-effectiveness measure, tertiary zones are often established around high-value sectors of the operation, such as the valuable stock used in breeding operations. To reduce transmission risk, critical control points such as transit facilities can be established beyond the site perimeter. At these points, procedures such as showering, changing into protective clothing, and transfer to site/zone-dedicated transport significantly reduce the probability of disease transmission onto the site.

Surveillance

The terms monitoring and surveillance are both used to describe ongoing data collection to estimate disease prevalence and severity in a population. However, a monitoring program is typically geared toward collecting statistically reliable prevalence data that can be used to track trends in disease incidence and severity over time. A surveillance program is based on prevalence data from a readily available sample of the population, with the goal being timely action to correct perceived increases in disease incidence. The importance of these programs increases when remote management-control is needed to keep up with increases in herd/flock size and production.

When catastrophic outbreaks require eradication, the surveillance program should be focused toward detecting source cases, allowing implementation of biocontainment

through quarantine and slaughter. For situations in which eradication is not required, collection of prevalence data should be adjusted so as to differentiate background variation from effects of disease.

The data collection system should be designed so as to provide insightful and epidemiologically informative disease indicators. During design, it is good to keep in mind the need for important parameters (eg, sample size) that can be used to calculate other animal-health estimates, such as prevalence, incidence, morbidity, mortality, and herd/flock immunity (as indicated by antibody titers, farm production records, etc). In the absence of random sampling, such statistical estimates cannot be taken as absolutely accurate but may serve as adequate markers of the need for intervention.

For purposes of disease eradication and trade, it may be necessary to demonstrate freedom from infection in the country, zone, or compartment/company. Although there may be no obvious evidence of infection in the population, it is impossible to definitively prove freedom from infection unless a perfect (100% sensitive/specific) test is used to examine every member of the population. In this situation, the surveillance system should be able to statistically estimate to an acceptable level of confidence that infection is below a specified prevalence level.

As part of health tracking, individuals should be monitored for disease at regular intervals. Any change in prevalence suggests a change in incidence that may require corrective action to prevent disease spread. The frequency at which animals are monitored depends on disease epidemiology and the level of biocontainment (eg, need for quarantine or slaughter). Factors such as latent period, mode of transmission (eg, vertical or horizontal), potential for animal dispersion and tracking, and test sensitivity are important considerations.

Biocontainment

Biocontainment strategies reduce the consequence of disease challenge by limiting the opportunity for challenge (bioexclusion), enhancing resistance (immunization), and preventing spread (quarantine). When eradication is required, quarantine is usually followed by emergency slaughter. Control measures are routinely applied for endemic diseases but more sporadically for epidemic outbreaks.

The term quarantine refers to the practice of enforced isolation of animals exposed to infectious agents, as well as the place in

which these animals are isolated and the time period of isolation. Quarantine is routinely required when live animals or their products are imported. To avoid disease entry into a country, region, zone, compartment, or population, potentially infectious animals/material must be isolated until they have been shown to be disease free.

Enforced isolation is the first biocontainment step when potentially infected animals are brought to a production setting. Movement within or through the control area is restricted and monitored. The size/nature of the control zone depends on disease risk but usually involves a containment facility, farm, site, or complex within a particular company. The control zone may be expanded to a 2-mile radius for diseases of national/regional importance.

Disease monitoring is used to establish the extent of an outbreak, first within the quarantine zone and then in a well-defined surrounding contact zone. The relevant veterinary authority assumes control in cases of foreign/notifiable disease. All vested parties (eg, countries, states, regions, companies, owners) should prearrange an emergency response plan sufficient to address relevant details of containment and eradication.

Chemoprophylaxis and Vaccination:

Medication may be added to feed or water to reduce disease risk. Vaccination is commonly used to reduce the risk and/or consequence of infection among exposed individuals or populations. The main purpose of immunization is to prevent clinical illness by raising the ID₅₀ of the population. Vaccinations can be used to protect individuals from disease or to protect the next generation by limiting direct vertical transmission and enhancing maternal antibody transfer.

HANDLING DISEASE OUTBREAKS

Feed and water consumption and production should be carefully monitored at all times, as well as the typical sounds and behaviors of individual animals. Any deviation from normal indicates the possibility of infectious disease, and immediate action should be taken to prevent inadvertent spread of infection. Initial steps include setting up a quarantine of the pen, building, farm unit area, or entire farm, depending on its design and programming; designating separate caretakers for affected animals; and checking and examining sick animals last.

Owners should seek professional diagnostic assistance, rather than trying

to hide some disease because of possible public recrimination. Veterinarians and caretakers can and should help dispel this apprehension by maintaining high ethical standards and refraining from discussing one producer's problems with others. Yet, there comes a time when all producers must be apprised of a problem. Service workers visiting affected animals should wear protective footwear and clothing when they enter the facility, and no other farm should be visited without adequate decontamination.

It is important to reach a diagnosis as soon as possible. The nature of the disease will determine the course of action. Although it is not always possible to treat a disease or stop its deleterious effects, identifying primary and contributing diseases is important to plan effectively for the future. Veterinarians should be aware of the owner's economic plight and render advice and assistance as quickly as information is available or a judgment can be made.

In addition to causing serious economic and emotional loss, some diseases are hazardous for people. When zoonotic conditions are suspected or diagnosed, extra precautions must be taken to prevent infection of attending personnel. Notifiable diseases require that appropriate government authorities be alerted and that all in-contact personnel be carefully tracked and assessed. In some regions, certain diseases must be reported immediately to the state animal disease control authorities so that proper investigation and action can be taken to protect the affected industry.

Every effort should be taken to ensure appropriate nursing care, which plays a key role in improving the outcome of a disease outbreak. Therapeutic medication should be used only after the problem has been diagnosed and recommended/prescribed by the veterinarian. Therapy is not a sustainable method of disease control and should not be considered an ongoing part of any biosecurity program. The flock response to medication merely provides the time necessary to investigate, design, and implement further control measures to avert additional need for therapeutic medication. No drugs should be given until a diagnosis is made and a veterinarian consulted.

Sick animals should not be moved or handled until they have recovered/stopped shedding the disease-causing agent, unless the move is to a more favorable environment as part of therapy. It is important to consider that some healthy carriers may remain among apparently recovered animals.

CLONING OF DOMESTIC ANIMALS

The basic concept of cloning via nuclear transfer is that the nucleus of a cell, taken from a tissue sample of a donor individual, is transferred to an enucleated oocyte, and then the oocyte is stimulated to develop into an embryo. The embryo thus produced has the same genotype as the original donor individual.

TECHNICAL ASPECTS OF CLONING

Cells recovered from early embryos, up to the morula stage, work efficiently as donor cells for cloning. Cloning from embryonic cells was conducted successfully for more than a decade before the birth of the first mammal produced via nuclear transfer using adult somatic cells ("Dolly," a sheep reported by the Roslin Institute, Scotland, in 1997).

The most common tissue used for cloning from adult animals is subcutaneous connective tissue. The tissue is minced and cultured *in vitro*. Outgrowing fibroblasts are harvested and replated (passaged) in new dishes to continue proliferation until millions of cells have been produced. These are then typically cryopreserved for future use.

Mature oocytes from the same or closely related species are required for the nuclear transfer. The genetic value of the oocytes is not important, although their mitochondrial makeup may be, because the resulting clone will carry the mitochondria of the host oocyte (*see below*). Oocytes are typically recovered from slaughterhouse material and then matured *in vitro*, although in some species, meiotically mature oocytes (from preovulatory follicles or from the oviduct after ovulation) are collected.

Nuclear transfer is typically performed using a microscope with micromanipulators. The chromosomes of the oocyte are removed, creating an enucleated oocyte, or ooplast. The somatic cell used for cloning must be synchronized to early in the cell cycle (before DNA synthesis). The somatic cell is combined with the ooplast, either by membrane fusion using an electric pulse or by direct injection of the donor cell into the ooplast via micromanipulation.

The recombined oocyte, now containing the nucleus of the donor cell, is treated to

mimic the activation signal of fertilization, which stimulates it to develop into an embryo. After activation, the developing embryo may be transferred surgically to the oviduct of a recipient female or may be cultured *in vitro* to a stage at which it can be transferred to the uterus transcervically (nonsurgically), as for standard embryo transfer.

Health and Phenotype of the Cloned Animal: Several factors influence the health and phenotype of the cloned individual, including epigenetic effects, mitochondrial DNA, uterine and postnatal environment, mutations, and individual variation.

Epigenetic Effects: After nuclear transfer, the ooplast must reprogram the DNA from the somatic cell so that it functions like that of a zygote. This is controlled largely by methylation and demethylation of bases in the DNA and by modification of the histones, the proteins around which the DNA is wrapped. Controlling the transcription of DNA in this manner, without altering the structure of the DNA itself, is termed epigenetic control. The oocyte must reprogram the DNA of the donor cell initially at the time of cloning, and then maintain the normal patterns of epigenetic modification through the different stages of development. The amount and accuracy of reprogramming of the donor DNA is probably the major reason for success or failure of fetal development in cloning. Minor changes in epigenetic status may not affect the general health of the cloned individual but may still cause it to vary in phenotype from the donor animal. A visible example of this is seen in the first cloned cat, CC. CC expresses only brown coat color, whereas her genetic donor expresses both orange and brown (eg, calico). Because the X chromosome carries the gene for coat color in cats, this indicates that in CC, X chromosome inactivation is not random; rather, the same X chromosome is inactivated in all cells, presumably because of failure to reactivate the inactive X at the time of cloning.

Epigenetic effects may also influence the phenotype of the nuclear transfer-derived animal after birth; eg, an animal with growth-factor genes transcribed at high levels may grow larger than its cloned

sibling with less active genes, even though the actual number and makeup of the genes are the same. However, it has been shown in all species studied that major epigenetic anomalies are not passed on to the offspring of clones because of resetting of epigenetic status during sperm and oocyte development.

Mitochondrial DNA: The nuclear transfer embryo will have the nuclear DNA of the genetic donor but have the mitochondrial DNA of the recipient oocyte. A small number of mitochondria from the donor cell may also be present, but proportionately few. The impact of the source of mitochondria, or a mixture of mitochondria, on the traits of the progeny is currently unknown. Because mitochondria are the source of energy for the cell, differences in mitochondria could potentially have an effect on production, stamina, or other physical or behavioral traits.

The heterogeneous mitochondria present in a female produced by nuclear transfer will be passed down to the female's offspring, because they will be present in her oocytes. However, although sperm from a male produced by nuclear transfer will carry the heterogeneous mitochondria, these mitochondria will be eliminated after the sperm fertilize an egg, so a male clone can be considered to produce progeny that are genetically identical to those that the original donor animal would have produced.

Environment: Uterine size and health; milk production of the dam; nutritional, exercise, and training programs; and handling to which the neonate is exposed may all influence the animal as an adult. For example, the cloned cat, CC, is outgoing and gregarious, whereas her genetic donor was reserved. However, the genetic donor was a research cat, raised in a cage and unused to attention, whereas CC was raised with an overabundance of attention and stimulation.

Mutations: Genetic mutations are potentially more likely in cloned animals, because cultured cells are used as the DNA source. The donor cells are grown and passaged in vitro, and this is associated with an increasing number of chromosomal abnormalities with increasing passages. However, cells with chromosomal abnormalities are unlikely to produce viable embryos.

Individual Variation: Cell differentiation occurs in cascades, as differentiation of one cell type affects the status of the cells around it. During development, cell multipli-

cation and apoptosis occur in response to many environmental and internal stimuli. Thus, random individual variations will occur in the makeup of tissues, even in individuals of the same genetic background. A visual example of this is in the markings of cloned animals; individuals cloned from the same cell line tend to have white in similar places, but the markings can vary dramatically in size and shape.

STATUS OF CLONING DOMESTIC ANIMALS

Live young have been produced by nuclear transfer in all major domestic mammalian species: cats, dogs, horses, cattle, goats, sheep, and pigs. Cloning in cats appears to be repeatedly successful; oocytes may be obtained using tissue recovered from clinical ovariohysterectomies. Interspecies cloning of closely related nondomestic cat species using domestic cat oocytes has produced live young.

Cloning in dogs is complicated by several factors. Mature canine oocytes must be obtained from the oviduct after ovulation, because effective methods for in vitro maturation of canine oocytes have not been developed; additionally, bitches are in estrus only about once every 6 mo, so oocyte availability is low and synchronization of recipients is problematic. Cloning in horses results in a low blastocyst development rate (3%–10%), but viability after transfer is among the highest reported; ~30% of transferred embryos produce live foals, and postnatal survival is high (>85%).

Cloning in food animal species is facilitated by the ready availability of oocytes from slaughterhouse tissue. Cloning in sheep and cattle is inefficient (5%–15% of transferred embryos result in live young), and 30%–50% of live neonates die by 4 yr of age. Cloning in sheep and cattle is associated with frequent placental abnormalities, especially low numbers of atypically large cotyledons. There is a high incidence of large offspring syndrome in cloned calves and lambs (ie, fetal overgrowth with related abnormalities) and, in live calves, of transient metabolic abnormalities such as hypoglycemia or poor renal function. Cloning in goats has similar efficiency in production of live young per embryo transferred, but cloned kids tend to have greater viability. Goat oocytes are typically obtained by follicle aspiration ex vivo, and this may increase viability of resulting clones. In pigs, 1%–5% of transferred recombined oocytes produce live young, but cloning is made practicable

by the ready availability of large numbers of oocytes and the ability to transfer hundreds of recombined oocytes to the oviducts of a single recipient. Cloned piglets are generally healthy; they have a higher than normal incidence of stillbirth and of some abnormalities but do not develop large offspring syndrome.

RATIONALE FOR CLONING

Companion animals may be cloned for emotional reasons or as models for endangered species. Horses are cloned mainly to allow continued production of offspring from individuals with valuable genotypes or to retain a genetic type (eg, geldings that are exceptional performers). Cloning of farm animals may be performed for agricultural or biomedical applications. Agricultural applications include production of animals with valuable production traits, such as high-producing dairy cows, animals with superior carcass quality at slaughter, or production of additional sires of an established valuable genotype.

Biomedical applications of cloning are largely related to the ability to perform nuclear transfer using a cell line that is genetically altered (transgenic) and, thus, to produce an animal with those characteristics. Biomedical applications include generation of animals of specific genotypes as disease models, animals carrying genes for the production of medically important proteins that may be harvested from the milk or tissues, and animals having genetically altered organs (of low immunogenicity) for transplantation to people.

CONTROVERSIES

Ethical concerns about cloning may be broadly divided into two categories: concern about the effect of cloning on animal and human welfare, and objection to the principle of cloning, ie, to producing an animal by a means other than fertilization.

Currently, cloning is associated with an increase in animal suffering when compared with production of animals by standard breeding methods. This is due to surgeries performed to obtain oocytes or transfer embryos, pregnancy losses, sickness and death of neonates, low-level abnormalities in surviving young, and possible distress from disease in animals produced as disease models. These concerns are somewhat mitigated by the fact that most of these findings are not unique to cloning; they are also associated with other procedures that have been

generally accepted as worthwhile, such as in vitro fertilization and embryo production, oocyte transfer, and embryo transfer. In addition, the accepted normal fate of many species being cloned is to be housed for maximal production and then be slaughtered and eaten. A compelling argument for cloning is that the potential benefits of the procedure to the understanding of life processes and animal disease, to human health, and to food production outweigh the cost of the procedure in terms of animal welfare.

Additional concerns rest with the effect of cloning on the entire animal population, most commonly related to the genetic variation of the species. This is a legitimate concern in some species and uses, such as in dairy cattle, in which one bull may sire thousands of offspring. However, this is more related to the technology of semen freezing and distribution than to the fact that a bull itself was cloned. In companion animals, it is improbable that the very few pets likely to be cloned will have an effect on the population in general. In horses, cloning may in fact increase genetic variation, because a major proposed use is to clone geldings that have been found to be superior competitors, thus rescuing genetic types that would otherwise have been lost.

Concerns about human health focus mainly on consumption of food produced from cloned animals. After years of study, the FDA and the European Food Safety Authority have concluded that consumption of meat or milk from cloned animals poses no public health risk. Therefore, remaining concerns about consumption of food from cloned animals is likely based more on principle than on actual potential for harm. Because cloning is used to produce transgenic animals, many perceived concerns regarding cloning are actually concerns about transgenic animals, which present a completely different set of potential hazards to animal and human health and the environment. European nations have relaxed their position on use of cloned animals and their progeny in the food chain based on the lack of evidence of a human health risk and the difficulty in establishing a tracing or labeling system to identify such meat when coming from outside countries.

A key ethical question regarding the principle of producing animals by cloning is whether this technique is violating some moral prohibition, ie, that people are "playing God" by producing embryos without using fertilization. Similar questions have arisen with each new reproductive

technique that has been developed; however, many people feel that cloning is a special case. This general moral aversion of the public to the concept of cloning is enhanced by the portrayal of cloning as a malevolent force in science fiction books and films.

Counter-arguments to these moral concerns are that cloning occurs in nature in the form of identical twins; that people have been producing plants and animals by "unnatural" means from the first time they planted a seed in a new area or bred a cow to a selected bull, and that this is simply a new development in the same line. Embryonic cloning was being performed for more than 10 years before the birth of Dolly with essentially no public attention, and even the birth of two lambs cloned from cultured cells of embryonic origin, announced a year before Dolly, had no public impact. Thus, it appears that the main moral issue of public concern is not the production of embryos without fertilization, but the production of embryos from cells of an existing, known animal.

Arguments against cloning of companion animals have focused on the cost of producing a clone—tens to hundreds of thousands of dollars—when millions of unwanted dogs and cats are killed each

year. However, people currently buy purebred dogs and cats for thousands of dollars when they could get animals for no or low cost. American culture supports the concept that people can spend their own money on whatever they wish.

A related argument is that cloning turns animals into a commodity or an object, rather than a sentient being, and that producing an animal in this way shows a lack of respect for the animal as an individual. However, animals have been bought and sold since they were domesticated; currently semen and embryos are frozen, shipped across the country, and used to produce desired young. Cloning does not seem to offer any unique distinction in this area.

Commercialization of cloning brings with it the possibility of fraud and of preying on the emotions of bereaved pet owners. Cloning companies should state clearly that the technique will produce another individual with the same genetics as the original animal; it does not "resurrect" an animal. The best simile to draw is to that of an identical twin born later in time; just as with naturally occurring identical twins, they will be very similar but also different in many ways.

COMPLEMENTARY AND ALTERNATIVE VETERINARY MEDICINE

Complementary and alternative veterinary medicine (CAVM) as defined in 2001 by the American Veterinary Medical Association, is "...a heterogeneous group of preventive, diagnostic, and therapeutic philosophies and practices. The theoretical bases and techniques of CAVM may diverge from veterinary medicine routinely taught in North American veterinary medical schools or may differ from current scientific knowledge, or both." Although some of the myriad approaches have been used to treat animals for centuries, many have not. Instead, they have been extrapolated from human approaches without first undergoing assessment for safety and effectiveness in nonhuman animals.

Despite the popularity of CAVM among some segments of the public, along with intensive promotion by certain groups,

much remains unknown regarding the true therapeutic utility of many aspects of CAVM. Thus, to gain a legitimate foothold in modern medicine, CAVM must demonstrate a rational mechanism of action and withstand scientific scrutiny.

The diversity of approaches that constitute CAM range from the well-studied to the bizarre and baseless. Certain treatments, such as homeopathy, lack biologic plausibility. Others require belief systems more consistent with faith-based healing than medicine. Much of the material published regarding CAM promotes unreliable and potentially dangerous advice. CAM providers cannot always provide a scientific basis and critical perspective for what they practice.

The responsibility for protecting and benefiting veterinary patients remains with

the scientifically educated clinician. Veterinarians who consider referring patients for CAVM or practice modalities have a responsibility to distinguish tried-and-true from too-good-to-be-true. This is accomplished by conducting well-designed scientific trials to investigate relevant clinical questions and by regularly reviewing the medical literature to reassess which modalities have accumulated independently confirmed data. Even if a certain clinical application has not yet received research scrutiny, studies showing a plausible and unique mechanism of action, as well as a safety record, can help support a rational decision about whether to recommend it.

Although numerous modalities and treatments are associated with CAVM, the ones discussed below are some of the more well known or considered for veterinary use.

ACUPUNCTURE

Acupuncture refers to a method of inserting thin, sterile, solid needles into specific sites on the body. Its myriad applications span analgesia to treatment of organ dysfunction, neurologic abnormalities, myofascial restriction, immune disorders, and many other conditions. Although most think of needles when they hear the term, acupuncture actually incorporates an array of interventions intended to either augment the needle's effects or obviate the need for needling altogether. Such interventions include electrical stimulation (ie, electroacupuncture); moxibustion (in which a smoldering herb heats the acupuncture point or embedded needle); low-level laser stimulation (laserpuncture); pressing techniques (acupressure); and injection of vitamins, saline, or other solutions into sites (aquapuncture).

Practitioners of "traditional Chinese medicine" (TCM) adhere to principles developed in prescientific times, replete with mistaken interpretations about organ functions and suffused with metaphors such as "wind invasion" and "spleen damp heat" instead of modern medical knowledge.

Although the roots of Chinese medicine can be traced as far back as the Han dynasty (206 BCE to 220 CE) or earlier, the field of TCM as adopted by many veterinarians is recent. TCM was updated and compiled by order of Chairman Mao Tse Tung in the mid-twentieth century. Confronted with widespread epidemics and too few Western-trained physicians, Mao sought a

revised and simplified compilation of Chinese medical theories that would help address the public health needs of the ailing masses. He also eventually found it helpful to promote quintessentially Chinese approaches as a matter of national pride. Subsequently, he marketed TCM to Western doctors. An unfortunate mixing of western metaphysics with TCM transformed acupuncture into a pseudoscientific "energy medicine" practice that disavows science and its true underlying actions of neuro-modulation and connective tissue effects. Making matters worse, TCM practitioners cling to dubious diagnostic techniques such as tongue diagnosis and pulse diagnosis. No research supports the validity or reliability of these techniques, even for people for whom these practices were developed.

Fortunately, decades of scientific research on its mechanisms and indications now make it possible to practice acupuncture and related techniques without metaphors or belief systems. Patients receive diagnoses based on modern medical methods and informed palpation. Needling is regarded as a means of afferent stimulation that engenders modulation of central, peripheral, and autonomic nervous system function, as well as signal initiation and transfer among associated connective tissue structures. Objective outcomes can be measured and assessed through scientific research, as results from rigorous, controlled trials lend further sophistication and insights into treatment plans and physiologic outcomes, respectively.

Mechanisms of Action: The belief among TCM practitioners that acupuncture works by moving invisible energies began with a mistranslation of the Chinese word "qi" into energy in the 1930s. A French bankteller working in China, Georges Soulié de Morant, strongly believed that "energies" formed the basis of healing. For lack of a better word, Soulié de Morant translated the term "qi" into "energy." Thus began the misplaced notion in the West that acupuncture moved "energy." In reality, the term "qi" referred to dissolved gases and nutrients that circulated throughout the vascular system. Given that acupuncture was originally a blood-letting technique, this explains the correspondence between acupuncture channels and blood vessels. Over time, as needles became thinner and more refined, acupuncturists ceased bleeding patients. By the 1950s, Chinese scientists began accepting that the effects they found in patients occurred as a result

of the nerves being stimulated near the former blood vessel targets. Today, the term "neuromodulation" has been accepted by scientific acupuncturists around the world as explaining the basis for acupuncture's effects.

Research findings from physiologic studies show that acupuncture needles, or other devices, affect afferent nerve fibers in the skin, subcutaneous tissue, fascia, muscle, tendons, vascular walls, or periosteum, purportedly eliciting local or peripheral reflexes that have beneficial effects on the body.

Several explanations exist for how acupuncture reduces pain. Some assert that acupuncture interrupts nociceptive transmission at the level of the spinal cord, producing spinal segmental analgesia, or that acupuncture alters the processing and perception of pain centrally. Others have suggested that any pain-relieving effects may be more simply attributed to placebo effects, distraction, a diffuse noxious stimulus, or psychologic alteration of the perception of pain. Various neurotransmitter and neuroendocrine responses have been associated with acupuncture. Specific parameters important for optimal effects in acupuncture are emerging as research defines how treatment design impacts clinical outcomes. For example, targeting specific dermatomes corresponding to local pathology rather than remote sites leads to greater improvements in pain control, physical activity, and sleep quality. Frequency and duration of stimulus also influence the analgesic response. Mounting evidence reveals a multiplicity of mechanisms and clinical benefits from acupuncture. Research is expanding regarding the clinically relevant benefits that acupuncture confers on many problems, including those of inflammatory, musculoskeletal, neuropathic, neoplastic, or visceral origin.

Indications: Acupuncture holds value for treatment of acute and chronic pain, neurologic dysfunction, musculoskeletal disorders, GI motility disorders, circulatory problems and insufficiency, immune dysfunction, reproductive disorders, and the negative sequelae of conventional cancer treatment.

Contraindications: Acupuncture has a strong safety profile, and few contraindications exist. Although pregnancy is often considered a contraindication, based on concern that acupuncture might affect hormone levels or uterine innervation,

evidence of serious adverse effects is lacking, even in late pregnancy. Coagulopathies or immune compromise might represent contraindications if needling leads to excessive bleeding or local infection, respectively.

Acupuncture may be contraindicated if an animal cannot remain still enough to perform needling safely. High levels of anxiety, fear, or aggression could counteract health-promoting autonomic changes generated by acupuncture. In such cases, efforts to calm the animal may be warranted.

Some TCM-based acupuncture practitioners may claim that cancer is a contraindication for acupuncture, although no evidence exists to support their claims that unseen energies emanate from the point into the tumor and incite growth. The belief that acupuncture will encourage cancer metastasis because it can augment circulation is similarly unfounded; however, there is also no proof that acupuncture itself fights cancer.

Adverse Effects: Acupuncture provided by medically educated professionals such as veterinarians results in few adverse effects and is generally considered safe. The risks of invading a major organ or vessel with a needle are limited as long as the practitioner remains aware of the patient's anatomy. Extreme negative reactions to a needle may indicate that it has entered a nerve; in those cases, the needle should be withdrawn. Handlers of horses have been injured when horses have kicked during acupuncture treatment. Needle ingestion by the patient appears to constitute the most frequent concern in animals, although there are no published reports of injury. Adverse reactions that have been reported in people include fainting, skin infections, and hepatitis; such reactions have not been reported in animals.

Controversies: The fundamental tenets of energy-based acupuncture remain unproved. No evidence indicates that invisible meridians or qi energies exist. Due to the limited number of clinical studies in acupuncture for veterinary patients and the current disavowal of the scientific basis of acupuncture by TCM practitioners, acupuncture has not been recognized as a specialty by the American Board of Veterinary Specialties.

Gold bead implantation, the process of intentionally inserting small bits of metal into the body as a type of "permanent acupuncture," resembles a Japanese

technique in which acupuncturists buried acupuncture needles into tissue and cut them off at the surface, leaving a lifelong implant.

The medical literature contains cases in which acupuncture needle fragments or implants have migrated to the spinal cord, peritoneal cavity, heart, stomach, liver, breast, brain, bladder, kidney, and colon. In animals, radiographic evidence has shown that implants can migrate long distances, eg, from the hip to the thoracolumbar region or abdominal wall. Embedding ferromagnetic objects in tissue may compromise the quality of computerized scans such as CT and MRI, causing artifacts and obscuring diagnoses. So far, no studies of gold bead implantation justify the risks of migration and artifact-laden imaging studies.

Additional adverse effects of implants include activation of mast cells, argyria, contact dermatitis, and gold-induced myelotoxicity.

MANUAL THERAPY

Manual therapy is a general term that refers to treatment approaches involving the hands (such as massage or chiropractic). Treatments done with the hands may also be instrument-assisted. Although manual therapies are most commonly used for the treatment of somatic pain or other musculoskeletal maladies, other indications may include lymphedema, immunosuppression, or visceral discomfort.

Massage techniques vary widely, ranging from the traditional kneading and stroking to deep tissue work requiring concerted pressure. The most commonly researched technique is Swedish massage, also known as classic muscular massage. Swedish massage incorporates several maneuvers, including effleurage (stroking and gliding), tapotment (percussion), petrissage (kneading), and friction massage. Effleurage involves tissue compression. Tapotment vibrates tissue, petrissage stretches adherent fibrous tissue, and friction lengthens connective tissue to reduce contractures. Massage techniques are multicultural and share similarities; for example, Swedish massage has similarities to the Chinese manual therapy technique Tui Na. Other massage techniques include German connective tissue massage and Rolfing, a strong and sometimes painful form of "deep tissue" massage introduced in the USA. "Medical massage" addresses specific diagnoses with soft-tissue techniques, with the goal of treating certain conditions. It differs from relaxation

massage in its "manual medicine" approach, ie, using the hands to help heal conditions seen in practice.

Manual therapy frequently targets the spine. When people speak about "animal chiropractic," "veterinary manual therapy," or "animal adjusting," they are usually referring to forceful maneuvers directed to the back or neck in an effort to alleviate pain or, more generally, spinal dysfunction. Some interventions are borrowed from the human chiropractic field and incorporate mechanical devices known as adjusting tools or activators. When used, this hand-held device, which resembles a metal syringe with a rubber knob at the end, delivers a rapid "thump" to the patient, roughly mimicking the action of a person applying a thumb thrust to the body. More violent and less sophisticated methods applied to horses incorporate mallets and blocks of wood intended to "drive protruding spines into line"; all such methods have, as yet, failed to demonstrate therapeutic utility in animals.

Mechanisms of Action: Massage focuses on soft-tissue elements—namely, muscles and the enveloping fascia. Benefits such as stress and blood pressure reduction, normalized gastric motility, immune regulation, and amelioration of depression may share a common mechanism of action. That is, the neuromodulatory and homeostatic effects of massage likely pertain to parasympathetic nervous system stimulation.

Evidence now supports use of massage as an aid to muscle recovery after exercise or injury, a means to improved circulation, and a way to bolster immune function. It also addresses GI motility dysfunction and neonatal issues such as failure to thrive. Massage also can improve lymphatic drainage in cases of lymphedema, although the effects may be transient.

In contrast to massage, the rapid thrusts in chiropractic have many theoretical—but no proven—mechanism(s) of action. The lack of current knowledge tends to be extrapolated into speculation, and chiropractic theories may be presented as fact. Claims are made that chiropractic manipulation activates muscle spindles, Golgi tendon organs, joint capsule mechanoreceptors, and receptors in the skin, and that simultaneous firing of multiple types of receptors modifies CNS activity, blunting nociception and normalizing muscle tone, joint mobility, and sympathetic nervous system activity. However, there is inadequate basic science

data to substantiate any of these claims. No chiropractic technique has been shown to be superior to another; little chiropractic research has been done in veterinary patients.

Indications: For massage and chiropractic in veterinary patients, indications may include neck or back pain or stiffness, inability to sit straight, reduced flexibility, muscle spasms, poor performance, difficulty going up or down stairs, inability to walk or run in a straight line, and abnormal tail carriage. However, there are no data from well-designed scientific trials to support the utility of such interventions in dogs, cats, or horses. The evidence for massage in human babies and adults suggests support for including this approach in animals with stress, pain, arthritis, sluggish digestion, or spinal cord injury.

Contraindications: Because adverse events of complementary therapies are underreported, the true range and incidence of risks from massage remain unknown. Patients who are especially fragile or ill generally require briefer and gentler treatments with less digital pressure and compression. Soft-tissue techniques would not be applied directly over areas of infection, acute inflammation, tumor, recent surgical procedures, or thrombosis. Similarly, massage may not be ideal in areas of acute inflammation, skin infection, bone fracture, burn, deep vein thrombosis, or cancer.

Contraindications for chiropractic might include conditions that weaken bone or other structural elements such that applying a thrust to a vulnerable spine or limb could lead to serious injury. Examples of deossifying or destabilizing conditions include hyperadrenocorticism, neoplasia, secondary renal hyperparathyroidism, degenerative joint disease, and disk disease. Some animal chiropractors have advocated chiropractic for a gamut of problems, including idiopathic lameness, intervertebral disc disease, Wobbler syndrome/cervical vertebral insufficiency, spondylosis, cauda equina syndrome, urinary incontinence, neuropathies, postsurgical rehabilitation, trauma, and organ pathology. However, many of these may actually constitute contraindications. One research-based human CAM reference places joint hypermobility, arthritis, and neurologic problems from disc disease under the heading of contraindications to chiropractic, along with cancer, infectious disease,

fractures, clotting disorders, osteopenia, and osteoporosis.

Adverse Effects: Excessive pressure from massage and forceful thrusts from chiropractic both have the potential to injure organs, vessels, neural tissue, or bones. Deep massage of the abdomen may damage organs (rupture/bleeding) and nerves (from direct pressure onto nerves); intense pressure could dislodge a stent or catheter or embolize thrombi. With chiropractic manipulation, thrusts are not always innocuous. A heavy-handed individual can seriously harm or even kill an animal. Even milder thrusts may injure animals weakened by age, joint pathology, osteopenia, or neoplasia.

Injuries from chiropractic usually result from trauma to the spinal cord or brain arising from impacted blood vessels, discs, or nervous tissue. Human neurologic and neurosurgical reports have revealed an association between stroke and upper cervical manipulation. In addition to high velocity techniques, deep massage or other pressing techniques in the suboccipital region have damaged vessels and caused neurologic impairment and death. Although rare, stroke from cervical chiropractic manipulation of human patients is well recognized and likely occurs more often than is reported. The mechanism of injury typically involves arterial dissection or spasm.

A study of human patients with neck pain showed that 25% of patients reported increased neck pain or stiffness after chiropractic treatment, and adverse reactions were more likely to follow higher force techniques. The study concluded that because high-force techniques failed to demonstrate superior effectiveness to low-force maneuvers, chiropractors should consider conservative manipulative procedures. Especially in geriatric or otherwise fragile animals, manual therapy techniques from the soft-tissue therapy repertoire constitute safer approaches than forceful, high-velocity techniques.

Controversies: From a mechanical standpoint, extrapolating human chiropractic theories to animals raises questions. Biomechanical forces on the spine of a quadruped differ from those in bipeds. Furthermore, the vertebrae of horses are the size of a human fist and are surrounded by muscle, tendon, and ligament layers several inches thick, leading to questions as to whether equine vertebrae can be manipulated at all.

Claims that spinal joints or other bones move “out of place” have not been substantiated. Even if such lesions exist, the diagnostic measures commonly used to detect them are not reproducible or reliable. The overall utility of manipulative therapy for the treatment of a condition (including its most common indication, musculoskeletal pain) has not been established.

Finally, additional controversy arises from the fact that manual therapies may be delivered by nonveterinarians. Manual therapies pose potential risks; when they are practiced by overzealous therapists with insufficient education about anatomy and pathology, the risk of injury to the patient or the practitioner increases. Lack of familiarity with animal behavior, zoonotic illness, and proper restraint techniques can pose risks to the therapist or bystanders. Furthermore, nonprofessionals may not have suitable liability insurance for such incidents.

State laws may or may not allow nonveterinarians to treat animals. Some may allow a human chiropractor or massage therapist to treat nonhumans but require a certain level of supervision by a veterinarian. Because state laws differ, veterinarians should check into the legal framework that allows or specifically disallows this form of care by nonveterinarians before referring or delegating care to them.

LASER THERAPY

The term “laser” originated as an acronym that describes its process, ie, light amplification of stimulated emission of radiation. Like acupuncture and massage, laser therapy lessens pain, relaxes muscles, and improves circulation. It accomplishes this by altering the physiology of cells and tissue by means of light (photons) instead of an acupuncture needle or manual pressure. Therefore, treatment effectiveness and the types of responses seen depend heavily on if and how light enters living tissue.

Mechanisms of Action: For tissue to absorb light and alter its physiology, a photochemical or photobiologic event must occur. Ideally, this event would take place within the target tissue(s), whether it be skin, muscle, fascia, nerves, vessels, bones, and/or joints. A “photoacceptor” molecule, also known as a “chromophore,” responds to light by initiating a series of physiologic responses that engender healing and improved tissue homeostasis. When a chromophore (such as cytochrome c oxidase in the mitochondria respiratory

chain) absorbs a photon from laser-treated tissue, an electron within the chromophore becomes excited and jumps from a low- to a higher-energy orbit. This increased electron energy provides the impetus for the system to perform cellular activities geared toward growth and repair.

The effects of laser on mitochondria, cells, and tissue is called “photobiomodulation.” This collective process encompasses not only the effects of lasers but also those of light-emitting diodes (LEDs) and other light sources. Light therapy also causes vasodilation by relaxing endothelial smooth muscle, likely through nitric oxide mechanisms. Vasodilation improves tissue oxygenation and supports the migration of immune cells into tissue, further aiding recovery.

Treatment Parameters: Many factors impact how light influences tissue, including its power, wavelength, strength, pulse characteristics, tissue contact, and the nature of its beam. As indicated above, photobiomodulation entails changes at the subcellular, cellular, and tissular levels. Within the mitochondria, activated photons engender increases in production of ATP; modulation of reactive oxygen species; and induction of transcription factors. These factors encourage cell proliferation and migration, normalized cytokine levels, enhanced production of growth factors, modulated levels of inflammatory mediators, and improved oxygenation of tissue.

Power and Dose: The term “low level laser therapy” (LLLT) refers to the use of light at much lower levels than those used for tissue ablation or photocoagulation. Newer, high-powered therapy devices that deliver power similar to surgical lasers (but with a less concentrated beam) no longer constitute LLLT. Some even heat tissue, meaning that the term “cold laser” is also inaccurate.

The specific dose(s) of laser required to heal tissue and treat pain remains unclear. Calculating actual joules of energy delivered requires calculations of considerable complexity. Fortunately, a wide range of doses shows benefit for people and experimental animals, despite the wide variety in size, color, and hair coat.

Wavelength: Most therapy units use red or near infrared light, from 600 nm to 1070 nm. This range constitutes the “optical window” wherein effective absorption into tissue is maximal. That said, units with green, blue, and violet light (~400 nm range)

are becoming more popular. Visible light ranges from 390 to 760 nm, progressing from violet to blue, green, yellow, orange, and red at 600 nm.

The types and depth of tissue that respond to light therapy depend on the wavelength delivered. Certain molecules, such as melanin and hemoglobin, preferentially absorb light in the 600 nm range. To reach deeper tissues, wavelengths (810 nm, 980 nm) that absorb less in superficial tissue can be used, leaving more light to reach for deeper sites such as bone, the brain, and internal organs.

Certain laser therapy units emit two or more beams to target a variety of tissues.

Laser beams differ from other types of light therapy, including LEDs, by being monochromatic (existing within a narrow band of wavelengths), coherent (tightly aligned), and collimated (photons travel in parallel). The more light scatters within tissue, the less intense the biologic impact, which may or may not be the desired outcome. However, debate continues about the relative value and differences between laser light and LEDs.

Pulsed Therapy: It remains unclear whether pulsed wave or continuous wave treatment is preferable for certain conditions. Pulsing reduces tissue warming, which is especially important to deliver light to deeper tissue; this requires more power to provide adequate energy supply to the deep tissue target(s). Furthermore, pulsing limits damage to nerves and surrounding tissue.

Pulsing may also improve tissue responses by resonating with a fundamental frequency to which cells innately respond, commonly exhibited by neural structures.

Indications: For more than half a century, scientists have recognized the potential for photomedicine approaches to reduce inflammation, pain, and swelling, as well as to speed wound healing. More recently, medical researchers have uncovered additional benefits pertaining to serious conditions, such as myocardial infarction, spinal cord injury, traumatic brain injury, and stroke. Additional applications include alleviation of pain, trigger point pathology, and joint dysfunction.

Contraindications: Contraindications to direct laser treatment include carcinoma, thyroid gland, active hemorrhage, and autonomic nerve centers. Laser therapy should be avoided in patients in which immune stimulation is not desired, including those with lymphoma or on

immunosuppressant medications. In immature patients, higher powered laser therapy devices may stimulate premature closure of epiphyses. Thus, caution is warranted over long bones in animals <1 yr old.

Adverse Effects: Properly used, laser therapy appears to be very safe. However, higher powered lasers run the risk of inducing thermal burns when improperly used. Tattoos, when lasered, can cause intense pain due to the high amount of light absorption by deposited pigment. Questions remain about the ability of laser therapy to stimulate neoplastic growth and, if so, at what wavelength(s) and power(s).

Laser light can damage the retina, whether reflected off shiny surfaces or shown directly into the eye. Laser goggles protect against indirect exposure but not against direct. One should never look into the applicator of a laser therapy device.

Laser light longer than 760 nm is invisible to the human eye. As such, unless a treatment applicator produces a visible finder beam or audible signal, the practitioner will not know when the laser is emitting light. This could cause inadvertent eye exposure and retinal damage. It also could cause confusion about where the beam is pointing. For this reason, infrared laser devices that lack a clear indicator of when the beam is on pose potential safety hazards.

Drug Interactions: The immunostimulatory effects of laser therapy may counteract immunosuppressive actions of certain medications. In addition, photosensitizing agents such as hypericin in St. John's wort may augment the dermatologic impact of laser light.

Controversies: The main controversies surrounding laser therapy involve questions and unproven claims related to pulsed therapy, the advantage of low- or high-powered units, and the longterm safety of high-powered treatment.

HERBAL MEDICINE

Herbal (botanical) medicine involves the practice of prescribing plant products, or products derived directly from plants, for the treatment of disease. Herbal medicine has survived since prehistoric times, in part because, until recently, there were no effective alternatives. Some plants do contain biologically active ingredients, and some pharmaceuticals in widespread use

today are identical to, or derivatives of, bioactive constituents of historic folk remedies. Indeed, herbal and botanical sources form the origin of as much as 30% of all modern pharmaceuticals.

Evidential support concerning use of plant products in veterinary patients is scarce and ranges from effective and safe to ineffective and risky. However, the methodologic quality of primary studies on herbal medicines for many species is generally poor. Trials usually lack firm endpoints, and periods of observation are usually short; the clinical relevance of the observed effects is not always clear. In addition, data that directly compare herbal remedies with well-established pharmaceutical products are often not available. However, as the database on herbs continues to grow, veterinarians seeking to prescribe natural, plant-based compounds should inspect the latest scientific literature for information on the compound or product of interest.

Making a rational decision about an herbal product requires knowledge of its active ingredients, its safety and adverse effects, and whether the herb has been shown to be as good as or better than pharmaceutical products available for the same purpose. This information is incomplete or unavailable for most herbal products. In addition, there are no standards or quality control testing of the products regularly recommended for animals. Risk versus benefit questions must be considered for products with unclear constituents and unknown active ingredients.

Preparations: Botanical products come in a variety of preparations intended either for ingestion or external application. They may be fresh, dried, or freeze-dried; extracted and preserved in oil, alcohol, or water; and delivered as liquids, capsules, pills, poultices, or powders. Other forms of plant-derived substances include essential oils—volatile, rapidly evaporating oils obtained from the leaves, stems, flowers, seeds, or roots of a plant, commonly used in aromatherapy or massage.

Philosophical or Cultural Approaches:

The philosophical approach of the practitioner tends to dictate the type(s) of herbs prescribed. For example, North American botanical medicine evolved from European and Native American traditions relies more on pharmacologic actions than on folklore and metaphysics. In comparison, traditional Chinese veterinary medical (TCVM) herbology considers the supposed

“energetic” nature of herbs. Western herbal prescribing practices incorporate physical examination findings akin to standard medical assessments, whereas TCVM recommendations depend heavily on the appearance of the tongue and the feel of the pulse. Instead of considering the pharmacologic effects of plants, TCVM practitioners rely on prescientific metaphors to describe the mechanisms of action of products prescribed. This, by definition, leaves them unaware of the actual biochemical processes occurring and is inconsistent with modern medical principles and ethics.

Mechanisms of Action: As aforementioned, herbs are plant-based drugs. However, they differ from pharmaceuticals by having a multiplicity of active, inactive, and unknown constituents with additive, synergistic, and/or balancing properties. The medicinal effects of herbs may vary from batch to batch as growing, harvesting, processing, and storage conditions change from year to year. These factors highlight the challenges of not only characterizing but also anticipating patient responses to plant-based prescriptions.

Indications: Herbalists recommend herbs for a wide range of disorders. For some conditions, the effects of plant-based drugs rival those of pharmaceuticals. There is evidence of effectiveness of botanical medicine for conditions ranging from digestive ailments to inflammatory conditions and immune support. Many herbs exhibit anticancer and antioxidant benefits. Veterinarians should consult the latest publications in medical literature to assess the strength of research for a condition in question, because the field and evidential support for a variety of conditions is growing rapidly.

Contraindications: Contraindications to the use of herbal products are mostly empirical and depend on the health status of the animal and the putative actions of the herb(s) under consideration. Situations warranting special caution include pregnancy, presurgical states in which the antiplatelet actions of plants interfere with coagulation, and cancer. That is, unforeseen herb-drug interactions could interfere with conventional care and cause unexpected results.

Adverse Effects: Rightly or wrongly, most herbal medicines are generally considered safe. However, because of the lack of manufacturing standards, quality

control, and known effects in veterinary patients, herbal medicines probably present a greater risk of adverse effects and interactions than any other CAVM therapy. Harmful effects of herbs arise from intrinsic toxicity of the plant, herb-drug or herb-herb interactions, contaminants introduced during processing (eg, heavy metals, microbial contaminants, chemical toxins, or pesticides), intentionally added adulterants (eg, pharmaceuticals), or inappropriate prescribing. Examples of especially risky herbs with known toxicities include those containing pyrrolizidine alkaloids (eg, comfrey and chaparral); natural flea treatments made from pennyroyal, known to be lethal for small animals; and skin treatments containing tea tree (melaleuca) oil, which can cause severe neurologic manifestations and hepatotoxicity in cats if absorbed or consumed in sufficient concentrations. For many herbal poisonings, no antidote exists, making death from "natural" treatments such as herbs frustrating. Many Chinese mixtures have toxic components; their amount may be kept "secret" by the manufacturer as a proprietary ingredient. Substances such as strychnine (a neurotoxin) and aconite (a cardiotoxin) are not uncommon and pose particular risks to veterinary patients. The unwillingness of manufacturers to appropriately label bottles with the amounts of these toxic constituents raises the danger to patients and public health.

Controversies: Before the development of modern pharmaceuticals, botanical-based treatments for veterinary patients were common, as evidenced by veterinary texts of the 19th and early 20th centuries. However, significant differences exist between historical and current use of these products. In the past, herbal products were used as treatment because underlying disease conditions had yet to be identified. Treatment "success" reflected elimination (or spontaneous resolution) of the problem. Because the underlying pathology was either vague or completely unknown, diseases with similar signs could not be differentiated. Veterinarians had few other approaches from which to choose. These factors make it exceedingly difficult to objectively evaluate the true utility of historically used herbal remedies; they also highlight the imprudence of placing undue faith in the prescribing practices of the past to determine treatments today.

Animal-based ingredients such as testes, penis, placenta, and horn found in Chinese

"herbal" medicines harbor potential for zoonotic disease transmission. In addition to health concerns, animal-derived products in Chinese herbs contribute significantly to animal mistreatment and the endangerment of certain species. The unknown benefits of most mammal or insect ingredients currently do not appear to justify administering these agents to veterinary patients.

NUTRACEUTICALS AND DIETARY SUPPLEMENTS

Nutraceuticals comprise foods, or extracts from foods, that supposedly confer medicinal benefits. Nutraceuticals have become popular with the veterinary community; worldwide estimates of sales approach \$100 billion. Such economic success has, for the most part, not been accompanied by scientific evidence of efficacy. As with herbs, a broad and continually expanding spectrum of nutraceuticals exists, but the mechanisms of action, indications, contraindications, adverse effects, and evidential support vary with the product and species. It is beyond the scope of this brief summary to discuss specific nutraceutical products.

One type of nutraceutical in particular warrants mention. "Glandulars," "tissue extracts," or other scientific-sounding equivalent names purportedly improve the health of animals in which the same glands or tissues have become dysfunctional. Although these products are not FDA approved for veterinary usage, veterinary glandulars and related supplements are heavily promoted in the lay animal health literature. Their usage began in the USA during the late 19th century when the practice arose of giving fresh thyroid glands to patients as treatment for hypothyroidism. Subsequently, tissues and extracts from other organs (ovary, adrenal, testis, thymus, brain, etc) became popular treatments. Once standardized medications and hormonal replacements became available, medical practitioners largely ceased prescribing glandular derivatives because medication offered more reliable effects without the unpredictable hormonal effects of extracts and concentrates. The use of raw bovine pancreas in some dogs with exocrine pancreatic insufficiency is a notable exception. Of specific concern with spinal cord and brain "glandulars" is the potential for these CNS derivatives to transmit spongiform encephalopathy.

HOMEOPATHY

Homeopathy, a form of practice initiated in the late 18th century by the German physician Samuel Hahnemann, refers to treatment of disease with sometimes extreme dilutions of substances that in undiluted form might cause symptoms of that same disease; these substances supposedly promote healing. The substances are said to possess vital healing energies that are unchanged, or even strengthened, through the dilution process. Homeopathic remedies usually consist of lactose pills or liquids.

No known, or even credible, mechanism of action exists by which extremely dilute homeopathic preparations might have a therapeutic effect. Controlled studies have demonstrated that the homeopathic “provings”—sessions in which individuals record the symptoms caused by ingestion of the remedies—cannot distinguish between homeopathic dilutions and placebo. Indeed, no study has been able to distinguish homeopathic remedies from control solutions, by any method of analysis. As a result, most authorities consider that any clinical effects obtained from homeopathic remedies are actually placebo effects.

Indications: Although largely unsupported by research, homeopaths typically feel that their remedies can be prescribed for most medical conditions, including cancer. Reported veterinary uses have included inappropriate urination in cats; babesiosis, atopic dermatitis, idiopathic epilepsy, and paroxysmal tachycardia in dogs; fattening of, stillbirths, and diarrhea in pigs; postpartum fertility, mastitis, anestrus, and control of ticks in cattle; diarrhea in calves; salmonellosis in broiler chickens; and helminth parasitism in sheep.

Contraindications: Conditions for which regular medical treatment would provide a more meaningful diagnosis and effective treatment, and for which delay of proper care could prove injurious, should not be treated by homeopathy. Adjunctive homeopathic remedies, which may be prescribed as “complementary” treatments to more conventional therapies, have been shown to be no different from placebo in improving the quality of life of children with mild to moderate asthma when prescribed in addition to conventional treatment in primary care.

Adverse Effects: Chances of homeopathic remedies causing direct toxicities are slight, given their extreme dilution. Homeopathic literature does describe a situation involving a transient worsening of signs called a symptom aggravation or healing “crisis.” Homeopaths may regard this as a treatment breakthrough and sign of impending improvement.

Some practitioners advocate giving homeopathic “vaccines” or nosodes instead of conventional vaccines to avoid perceived health risks of standard vaccines. However, homeopathic vaccines have consistently failed to provide reliable protection against infectious agents in scientific studies of both people and animals.

Controversies: A preponderance of evidence indicates that effects of homeopathy cannot be distinguished from placebo. Therefore, the question remains whether it is ethical or misleading to offer an ineffective treatment to patients and their caregivers. The unscientific premise of homeopathy calls into question its legitimacy as a medical treatment.

MANAGEMENT OF THE NEONATE

LARGE ANIMALS

Appropriate management in the peripartum period can substantially reduce morbidity and mortality for large animal dams and their offspring. As much as 5% of foals, 5%-10% of calves, and 10%-15% of the annual lamb crops die before weaning in the USA, with 50%-70% of neonatal mortality occurring in the first 3 days of life. A key

aspect of managing the large animal dam includes appropriate nutrition and body conditioning in the pre- and postpartum periods to reduce the risk of pregnancy-related diseases such as pregnancy toxemia, hypocalcemia, and vaginal prolapse; as well as to optimize hygiene, colostrum quality, and fetal and neonatal growth. Appropriate anthelmintic therapy and vaccination of the dam several weeks before parturition will

further protect dam and offspring from subsequent disease.

Particular conditions affecting large animal neonates in the immediate postpartum period include prematurity, failure of passive transfer, sepsis, perinatal asphyxia, predation, mismothering, meconium impaction, and various congenital diseases. Substantial losses can occur in flock or herd situations, and altering problematic aspects of management can therefore be of great benefit. Generally, equine and camelid neonates can be managed more intensively than neonatal calves, pigs, or lambs because of economic considerations. However, rapid assessment and appropriate management of all large animal neonates in the immediate postpartum period can substantially reduce the need for intensive and expensive measures in any species.

Growth rates of neonates are particularly rapid during the first month of life. For example, the average Thoroughbred foal is born at ~68% of its mature height and 10%–11% of adult weight, with an average weight gain of 1.5–1.7 kg/day. Regular monitoring of weight gain can thus be a practical aid in determining healthy growth and development. Foals that lack maturity can display a spectrum of clinical and clinicopathologic abnormalities that include short silky hair coat, “floppy” ears, incomplete ossification of the tarsal and carpal bones, hyperextended fetlock joints, domed forehead, abnormal temperature regulation (normal to low body temperature), depressed mentation, weakness, poor suckle reflex, and respiratory dysfunction.

See also NEONATAL INTENSIVE CARE AND EMERGENCIES IN FOALS, p 1708, and DIARRHEA IN NEONATAL RUMINANTS, p 275.

FAILURE OF PASSIVE TRANSFER

Large animal neonates are born with limited energy reserves and are considered immunocompetent but immunologically naive at birth (ie, agammaglobulinemic). Thus, ensuring the provision of good-quality colostrum by the dam and adequate colostrum intake by the neonate are critical influences on neonatal survival. Good-quality colostrum tends to be sticky, yellow, and thick with a specific gravity of >1.060 in mares. All factors that might compromise colostrum quality, volume, and delivery to the neonate should be recognized; these include maternal factors (disease during gestation, premature lactation, maiden dam), delivery factors (abnormal parturition, placental abnormalities), and neonatal

factors (prematurity, dysmaturity, maternal rejection, multiple birth, or any other condition limiting neonatal mobility and strength). Manually stripping the teats of the dam to remove wax plugs and to check for the presence of colostrum may facilitate successful nursing attempts. The neonate should be examined for any obvious congenital problems that may inhibit the ability to stand or to nurse effectively, including signs of prematurity, musculoskeletal abnormalities, and cleft palate (and in crias, choanal atresia).

Healthy foals begin sucking colostrum within 1–2 hr after birth, and maternal antibodies are detectable in the foal's blood within 6 hr. Although adequacy of passive transfer of immunoglobulin is generally assessed at 18–48 hr, neonates at high risk of failure of passive transfer (FPT) and/or sepsis may be tested as early as 6–12 hr after birth. Weak or abnormal neonates that do not stand or nurse successfully within 2–4 hr should be supplemented with colostrum early (commonly tube or bottle fed). A 50-kg foal requires a minimum 1.5–2 L (ideally 5%–12% of body wt) of good-quality colostrum (~70–75 g of IgG), fed over multiple feedings in the first 12–18 hr after birth. Colostrum of other species has been used (such as cow colostrum for foals, crias, kids, and lambs) but will not necessarily provide pathogen-specific immunity. Commercial colostrum substitutes have similar limitations and may increase the risk of adverse immunologic reactions if a subsequent plasma transfusion is needed. Oral administration of colostrum or colostrum substitutes has only minimal benefit in neonates >18–24 hr after birth because of the limited capacity of the neonatal small intestine to absorb macromolecules.

Complete FPT in foals is defined as a serum IgG concentration of <400 mg/dL at 24 hr of age, with partial FPT being associated with a serum IgG concentration of 400–800 mg/dL. Healthy, vigorous foals with complete FPT (<400 mg/dL) and high-risk foals with partial or complete FPT (IgG ≤800 mg/dL) should receive equine plasma (IV) that contains an IgG concentration of >1,200 mg/dL. The average IgG concentration in 1 L of equine plasma will typically increase the serum IgG concentration of a 50-kg foal by 200–300 mg/dL; therefore, 2–4 L of plasma may be necessary to achieve a final serum IgG concentration of >800 mg/dL in a foal with complete FPT (initial IgG <200 mg/dL).

Frozen plasma should be thawed and warmed slowly to room temperature using

warm water, and subsequently administered slowly through an aseptically placed jugular catheter, using an appropriate blood filter set. Initially, plasma is administered at 0.5 mL/kg over 10–20 min (~20–30 mL to an average foal) while monitoring for transfusion reactions. Clinical signs of transfusion reactions may include muscle fasciculation, increased heart or respiratory rates, fever, respiratory distress, laryngeal swelling, abdominal pain, pale mucous membranes, or collapse. If no adverse reactions are observed during the initial slow infusion, the remainder of the transfusion may be administered at rates up to 40 mL/kg over 60–90 min (eg, 2 L throughout 60 min for a 50-kg foal).

Although serum IgG is measured less commonly in ruminants, concentrations >1,600 mg/dL are ideal. Serum total protein may also be used as a rough estimate of colostral transfer in ruminants and should exceed 5–5.5 g/dL. An IgG concentration >1,000 mg/dL is considered adequate in neonatal camelids. Administration of camelid plasma (either IV or IP) is an acceptable treatment of FPT in llamas and alpacas, although IP administration should be limited to vigorous neonates, to minimize the risk of secondary complications.

SEPSIS IN FOALS

Sepsis is a clinical syndrome defined by the development of a systemic inflammatory response syndrome (SIRS) in response to proven or suspected infection. The condition implies an extensive, whole body insult after invasion of bacteria into tissue or a body fluid or cavity. The presence of viable bacteria in the bloodstream is termed bacteremia. Sepsis and SIRS are two of the most common problems of equine neonates, while bacterial infection accounts for nearly one-third of all foal mortality.

Etiology and Pathogenesis: Gram-negative bacteria, particularly Enterobacteriaceae with a predominance of *Escherichia coli*, remain the most common isolates (60%–70%) from neonatal foals with sepsis. However, the prevalence of gram-positive bacteria has increased throughout time, and blood cultures remain important in diagnosis and treatment. Common gram-negative pathogens include *E. coli*, *Klebsiella* spp, *Enterobacter* spp, *Actinobacillus* spp, *Salmonella* spp, and *Pseudomonas* spp. Approximately 25%–40% of infections also involve gram-positive bacteria, with *Streptococcus* spp being the predominant isolate. Anaerobic pathogens,

especially *Clostridium* spp, are reported in <5% of systemic neonatal infections. The routes of entry for these bacteria may include the placenta, umbilicus, and respiratory and GI tracts.

All sepsis syndromes (eg, sepsis, severe sepsis, septic shock, multiple organ dysfunction) have a common pathogenesis that also includes endotoxemia related to gram-negative infections. Endotoxins stimulate macrophages to release an array of cytokines (eg, IL-6, IL-1, TNF- α) and activate pro-inflammatory enzymes (eg, phospholipase A₂). Together, these factors lead to signs of inflammation (fever, vasodilation, myocardial depression), impaired microcirculation, capillary leak, and intravascular coagulation. Sepsis initially triggers a procoagulant state, which may lead to disseminated intravascular coagulation and secondary consumptive coagulopathy. A variety of other pathogen-derived molecules can set off similar host responses. Thus, toxic shock syndromes resulting from streptococcal or *Staphylococcus aureus* infection are hyperinflammatory septic syndromes that closely resemble diseases characterized by endotoxemia.

A variety of immunologic and management factors predispose foals to sepsis. Although foals can respond immunologically in utero to bacterial or viral infections, their ability to do so is less than that of adults. Deficits in the physiologic response to infectious agents in neonates relate to reduced chemotaxis and killing capacity of neonatal neutrophils, the presence of antigenically naive T cells, and a decreased concentration and impaired function of monocytes. However, the major risk factor for sepsis in foals is failure to receive an adequate quality or quantity of colostral antibodies. If colostrum intake is insufficient and IgG levels remain low, the foal is not only deprived of specific antibody protection, but neutrophil function is also seriously impaired. Other factors that influence disease incidence include unsanitary environmental conditions, low gestational age of the foal (prematurity or immaturity), poor health and condition of the dam, difficulty of parturition, and the presence of new pathogens in the environment against which the mare has no antibodies.

Clinical Findings and Lesions: The clinical presentation of sepsis depends on the duration of illness, the integrity of the host immune system, the affected body systems, and the severity and route of infection. Frequently affected organ systems include the umbilical remnants,

and CNS, respiratory, cardiovascular, musculoskeletal, renal, ophthalmic, hepatobiliary, and GI organs. In the early stages of sepsis, clinical signs are often vague and nonspecific, with affected neonates merely displaying some degree of depression and lethargy. Owners report that foals appear to lie down more than usual. The mare's udder is often distended with milk, indicating that the foal is not nursing at a normal frequency.

Clinical signs can progress to a complete loss of suckle reflex, hyperemic mucous membranes with a rapid capillary refill time due to peripheral vasodilation, tachycardia, and potentially early petechiae related to capillary leak. In the advanced stage of illness, when the infection overwhelms the host's immune system and compensatory responses, septic shock ensues. Affected foals are severely depressed, recumbent, and hypovolemic, which manifests as cold extremities, thready pulse, and poor capillary refill time. Foals may be hyper- or hypothermic, tachycardic, or bradycardic. In the face of sepsis, bacteria spread hematogenously to various organs, manifesting as respiratory distress, pneumonia, diarrhea, uveitis, meningitis, osteomyelitis, or septic arthritis. Dysfunction of two or more organs is termed multiple organ dysfunction syndrome.

Hypoglycemia commonly accompanies systemic infection and is associated with bacterial consumption and reduced glycogen reserves. Severely hypoglycemic foals may be unable to rise and show depression, convulsions, and eventually death. Furthermore, clinical signs suggestive of relative adrenal insufficiency have been identified in animals with prolonged sepsis. Primary relative adrenal insufficiency can occur after a direct insult to the adrenal glands (hemorrhage or adrenal ischemia), whereas chronic, illness-induced stress may exhaust the adrenal reserve and deplete the production of cortisol. Septic neonatal foals are often neutropenic with a high ratio of band (immature) to segmented neutrophils. The neutrophils may exhibit toxic changes, which are highly suggestive of sepsis. Fibrinogen levels >600 mg/dL in a foal <24 hr old are indicative of an in-utero infection. Other chemistry abnormalities may include azotemia due to inadequate renal perfusion or perinatal asphyxia, and increased bilirubin secondary to endotoxin damage to the liver. A high anion gap (>20 mEq/L), hyperlactatemia, hypoxemia, hypercapnia, and a mixed respiratory and metabolic acidosis may be present with arterial blood gas analysis.

Diagnosis: Currently, there is no ideal diagnostic tool to detect early sepsis. However, a scoring system has been developed for neonatal foals to establish the likelihood of neonatal infection and aid the identification of sepsis at a treatable stage. This "sepsis score" incorporates a combination of historical, clinical, and laboratory variables and may also serve as an indicator of whole body insult, SIRS, or multiple organ dysfunction. However, the specific definition criteria for both SIRS and sepsis are most rigorously validated in people and have been conceptually applied to equine neonates only recently. Based on pediatric human and general veterinary guidelines, SIRS may be clinically defined by the presence of at least two of the following five clinical criteria, one of which must be abnormal temperature or leukocyte count: 1) core temperature below or above the normal range for the animal's age; 2) tachycardia, defined as a mean heart rate >2 standard deviations (SD) above normal for the animal's age in the absence of external stimulus, chronic drugs, or painful stimuli; 3) bradycardia, defined as a mean heart rate below the normal range for the animal's age, in the absence of external vagal stimulus, β -blocker drugs, or congenital heart disease; 4) mean respiratory rate >2 SD above normal for age, or animals undergoing mechanical ventilation for an acute process not related to general anesthesia or underlying neuromuscular disease; 5) leukocyte count increased or depressed for age (not secondary to chemotherapy-induced leukopenia) or $>10\%$ immature neutrophils. Infection itself may be suspected or proven (by positive culture, tissue stain, or PCR) and caused by any pathogen, or refer to a clinical syndrome associated with a high probability of infection. Evidence of infection includes positive findings from clinical examination, imaging, or laboratory tests (eg, WBCs in a normally sterile body fluid, perforated viscus, chest radiograph consistent with pneumonia). Ultimately, sepsis refers to the presence of SIRS with suspected or proven infection.

Depending on the specific organ systems involved, an umbilical, abdominal, and synovial ultrasound examination; arterial blood gas analysis; arthrocentesis; cerebrospinal centesis; and chest, abdominal, and distal limb radiographs are indicated. Advanced diagnostic imaging techniques (eg, CT of the distal limbs in foals with septic arthritis) may also help with prognosis.

Serum IgG levels should be measured in any questionably sick neonate to eliminate inadequate transfer of passive immunity as

a risk factor for sepsis. IgG levels <200 mg/dL indicate complete failure of passive transfer of maternal antibodies, whereas IgG levels >800 mg/dL are considered normal.

A positive blood culture confirms the presence of bacteremia in septic foals, but a negative culture does not exclude the possibility of infection. Differential diagnoses include neonatal encephalopathy (see p 2094), hypoglycemia, hypothermia, neonatal isoerythrolysis (see p 11), white muscle disease (see p 1172), prematurity or immaturity, neonatal pneumonia, and uroperitoneum (see p 1506).

Treatment, Control, and Prevention:

Foals suspected of being septic should be placed on broad spectrum antibiotics active against both gram-positive and gram-negative organisms. Penicillin (22,000 IU/kg, IV, qid) in combination with amikacin sulfate (20–25 mg/kg/day, IV) provides good initial coverage until culture results are available. Metronidazole (10–15 mg/kg, PO or IV, tid) may be necessary if an anaerobic infection (eg, *Clostridium*) is suspected. A third-generation cephalosporin (eg, ceftiofur, 4.4–6 mg/kg, IV, bid-qid) may also be used as a broad-spectrum agent in foals with renal compromise. Cefpodoxime proxetil (10 mg/kg, bid-qid) has been recommended for treatment of bacterial infections in equine neonates. Cefepime (11 mg/kg, IV, tid) is a fourth-generation cephalosporin with enhanced antibacterial activity.

Early goal-directed IV fluid therapy is needed to restore tissue perfusion, attenuate the cytokine response, and reverse cellular injury. Volume expansion should be achieved using a balanced electrolyte solution (crystalloid) or plasma (colloid). Immunologic support in the form of IV plasma transfusion (1–2 L) is also indicated to raise the IgG level to >800 mg/dL. Fluid resuscitation is aimed at normalizing specific cardiovascular variables (central venous pressure, mean arterial pressure, urine output, and central venous oxygen saturation), while improving clinical parameters. Severe septic shock may require initial fluid rates of 40–80 mL/kg/hr. Because many foals are hypoglycemic, slower continuous infusions of 2.5%–5% dextrose-containing solution should be administered simultaneously with rehydration fluids.

Treatment with hyperimmune antiendotoxin serum may be considered in foals with endotoxemia. Antiprostaglandin drugs have been found to counteract several of the

clinical and hemodynamic changes associated with endotoxemia and septic shock. Low doses of flunixin meglumine (0.25 mg/kg, IV, tid-qid) may help reduce signs of endotoxemia. Additionally, administration of low doses of polymyxin B (6,000 IU/kg, diluted in 300–500 mL of saline, slowly IV) is an investigational treatment used to neutralize systemic endotoxin.

Nutritional support is important, because sepsis creates a catabolic state in foals. If the foal is not nursing adequately, it should be fed mare's milk or a mare milk substitute at 15%–25% of its body weight throughout each 24-hr period. An indwelling nasogastric tube should be placed in foals with a decreased suckle reflex. Parenteral nutrition may also be helpful to provide adequate nutrients in the face of GI dysfunction. Administration of gastric protectants (eg, ranitidine, cimetidine, omeprazole) has been proposed as an adjunct therapy in sick neonates.

System-specific therapy includes lavage of septic joints with sterile fluids, regional limb perfusion, and nasal oxygen support (2–10 L/min) or ventilation for foals with respiratory failure or central hypoventilation. Corneal ulceration may be treated with low doses of topical atropine (although it may cause ileus), NSAIDs, and broad-spectrum topical antimicrobials. Entropion generally requires mattress sutures of the lower eyelid. Surgical removal of infected umbilical remnants may be indicated.

Prognosis: Recovery from neonatal sepsis depends on the severity and manifestation of the infection. Currently reported survival rates are 50%–81% in referral centers, depending on the underlying disease. Severe neonatal pulmonary disease has been associated with a higher mortality (35%–50%). Early recognition and intensive treatment of neonatal sepsis improves the outcome, although an average of 1–4 wk of intensive care should be expected. If the foal survives the initial problems, it has the potential of becoming a healthy and useful adult. One report documented that surviving bacteremic Thoroughbred foals were as likely to start races as their siblings, although their earnings were lower. The latter retrospective case series (n=423) further identified that odds of survival were negatively associated with age at admission, band neutrophil count, and serum creatinine concentration, and positively associated with rectal temperature, neutrophil count, and arterial blood pH. Additionally, in a

recent prospective multicenter study, septic foals had increased odds of nonsurvival for each 1 mmol/L increase in L-lactate concentration at admission.

SPECIFIC CLINICAL MANIFESTATIONS OF SEPSIS

Neonatal Pneumonia

See also ENZOOTIC PNEUMONIA OF CALVES AND SHIPPING FEVER PNEUMONIA, p 1431, and ACUTE BRONCHIOINTERSTITIAL PNEUMONIA IN FOALS, p 1452.

Hematogenous infection of the lung occurs in association with sepsis, which may be acquired in utero from placental infection or perinatally through environmental contamination (eg, omphalitis, omphalophlebitis), and is more common in neonates with failure of passive transfer (FTP). *Escherichia coli*, *Klebsiella* spp, *Actinobacillus equuli*, *Salmonella* spp, and *Streptococcus* spp are some of the more common bacteria involved in neonatal pneumonia in foals. Descending respiratory infections may be related to inhalation pneumonia (transmission of viral, bacterial, or fungal airborne pathogens), aspiration of infected amniotic fluid due to placental infection, aspiration of gastric reflux, iatrogenic aspiration (oil, medication, oral supplements), and aspiration of milk and meconium. Aspiration of meconium occurs in utero in foals that experience fetal distress.

Early in life, localizing clinical signs of lung infection may be absent even in the presence of extensive disease. Dyspnea may be seen in severely affected foals and manifest as an increase in respiratory rate, effort, or thoraco-abdominal asynchrony (paradoxical breathing). However, signs of respiratory distress and hypoxemia are frequently vague. Even some severely hypoxemic foals may show only restlessness or considerable resistance/struggling during handling or restraint. Auscultation of the lung fields in newborn foals can be very misleading. Fluid sounds are normal immediately after birth, as are crackles due to simple atelectasis of the "down" lung during lateral recumbency. Conversely, foals with significant pneumonia can have minimal abnormal findings on auscultation. Mucous membranes should be examined for color, moisture, injected vessels, and the presence of cyanosis (which likely indicates severe hypoxemia with a $\text{PaO}_2 < 40 \text{ mmHg}$). Additionally, weakness, depression, anorexia, weak or absent suckle reflex, dehydration, and fever may be noted in foals with respiratory disease. Cough and nasal discharge are usually absent in the early

stages of neonatal pneumonia. Apparent signs of lung dysfunction may also be associated with nonrespiratory conditions such as metabolic derangements (eg, severe acidosis), pain, abdominal crisis, fever, high environmental temperatures, or excitement.

Diagnosis: Thoracic radiographs are often essential to establish the presence of respiratory disease and determine the type and extent of lung involvement in neonates. Arterial blood gas analysis is preferentially used to assess the degree of hypoxemia and hypercarbia. The more common arterial blood sampling sites in neonatal foals include the dorsal metatarsal artery, the brachial artery on the medial aspect of the elbow, the carotid artery, and the transverse facial artery. Thoracic ultrasonography may further identify the presence and location (affected side) of peripheral lung consolidation, pleural effusion, and abscesses in foals with pneumonia.

Treatment: Broad-spectrum antibiotic treatment of septic pneumonia should be initiated before culture results are available and is targeted toward the most common pathogenic bacteria (see above). Additionally, intranasal oxygen therapy and cardiovascular support (including goal-directed fluid therapy) are essential in treatment of compromised foals. Specific respiratory support may further include judicious suctioning, coupage, bronchodilators (eg, albuterol inhalants), and mucolytic agents. Recumbent foals should be maintained in a sternal position to limit positional atelectasis.

Omphalitis, Omphalophlebitis, and Patent Urachus

A patent urachus is the most common umbilical abnormality in neonatal foals. Diagnosis may be based on visual appearance (urine dripping from the umbilicus) or on umbilical ultrasound examination, which can also exclude umbilical infections. Clinical signs of infection may include discharge, pain, and heat and swelling of the umbilicus, although some infections of deeper structures may only be confirmed via ultrasound. The normal equine umbilical stump is usually $< 18 \text{ mm}$ in diameter at 24 hr of age, and it decreases to $< 15 \text{ mm}$ at 7 days of age. The umbilical vein (as it courses cranially to the liver) should be $< 10 \text{ mm}$ in diameter at 24 hr after birth and is slightly smaller than the arteries, which can be followed via ultrasound as they course caudally on either side of the bladder. Ultrasonographic abnormalities consistent

with omphalitis or omphalophlebitis in foals include enlargement of the vessels beyond normal limits, asymmetry of arteries with enlargement, abscessation of stump or single vessel, gas shadowing indicative of an anaerobic infection, edema of structures, and hematoma formation.

Treatment and Prognosis: A congenital patent urachus and many milder cases of patent urachus secondary to omphalitis may respond to local therapy (chemical cautery with silver nitrate, topical procaine penicillin G, and thermocautery) and systemic antimicrobials. However, caution must be used not to place caustic agents further than 1 cm into the stump, because ensuing tissue necrosis may predispose to further bacterial infection. Treatment of umbilical infections may include both medical (long-term systemic antimicrobials) and surgical options (umbilical resection). Foals that should be referred to surgery include those with substantial abscessation or venous involvement that extends as far as the liver. Mixed infections are likely, and common isolates include gram-negative bacteria (eg, *E. coli*, *Klebsiella*), and *Enterococcus*), gram-positive organisms (especially β -hemolytic *Streptococcus*), and anaerobes (including *Bacteroides* and *Clostridium*), similar to organisms identified in generalized neonatal sepsis.

Overall survival rate with appropriate treatment is reported as 87%. However, severe concurrent disease such as secondary hepatic abscessation, sepsis, or multiple joint arthritis are suggestive of a poorer outcome. Septic peritonitis or uroperitonitis are considered rare complications. Umbilical infections are generally less common in neonatal camelids than in neonatal foals.

Prevention: After an uncomplicated birth, it is ideal to allow the umbilical cord to break spontaneously when the dam rises. In foals, the cord is narrowest at ~5 cm from the body wall, which is the natural separation (break) point. If the cord has to be manually separated, it is best to provide steady traction on the cord while supporting the foal's abdomen at the umbilicus. Sharp transection of the cord with a clamp or ligature prevents retraction of the umbilical structures and may be associated with a greater incidence of subsequent umbilical complications. However, excessive hemorrhage can be addressed by transient ligation with umbilical tape or a clamp. After birth, 1% iodine or 0.5% chlorhexidine solution (preferred) should be applied 2–4

times daily to the umbilical stump until the umbilical remnant is dry.

Neonatal Uveitis

Neonatal sepsis may initiate intraocular seeding or endogenous inflammation due to uveal tissue injury. Secondary ocular infection as well as endotoxemia, free radical formation, tissue hypoxia, and alterations in pH may trigger vascular damage at a cellular level and induce clinical uveitis. Various chemical mediators, including histamine, serotonin, plasmin, kinins, complement, and arachidonic acid derivatives mediate acute vascular changes. The ensuing increase in vascular permeability of the blood-ocular barrier allows cellular components, fluid, and plasma proteins to escape into the surrounding extravascular uveal stroma (edema), ocular fluid compartments (aqueous flare, plasmoid vitreous), and subretinal space (retinal detachment). Congenital and acquired adnexal disease, prolonged lateral recumbency, dehydration, and a decreased menace response in the neonate may also induce a reflex-mediated uveitis due to corneal trauma. Reflex-mediated uveitis is generally transient and leaves the uveal tract unaltered once the corneal insult resolves.

Clinical signs of **anterior uveitis** are more evident and generally consist of conjunctival hyperemia, ciliary flush, corneal edema, aqueous flare, hyperemia and swelling of the iris, miosis, and a decrease in intraocular pressure. Signs of ocular pain, blepharospasm, increased lacrimation, and photophobia are variable, whereas hyphema, hypopyon, and intraocular fibrin deposition are seen in cases of severe inflammation. Intraocular fibrin formation occurs due to egress of essential clotting factors into the aqueous and vitreous humor during uveal inflammation. Furthermore, the regulation of fibrinolysis is altered in endotoxemic animals. A prolonged increase in the activity of plasminogen activator inhibitor may favor coagulation and impede intraocular fibrinolysis.

Acute posterior uveitis is often overlooked if unaccompanied by apparent changes in the anterior chamber. Retinal vascular congestion, hemorrhage, edema, cellular infiltration, or retinal detachment may be seen. The vitreous also tends to appear hazy, with blurring of fundus details, due to cellular infiltration and proteinaceous debris. The type of inflammatory cell reaction is generally classified as

neutrophilic (suppurative), granulomatous, or lymphocytic-plasmacytic. Neutrophilic inflammation is an acute response to bacterial infection and sepsis, although intraocular bacteria may not be present. Neutrophils can accumulate in the anterior chamber in the form of hypopyon, which is often sterile and thus indicative of inflammation rather than local infection. Proteases released from neutrophils may also induce corneal endothelial damage, thereby resulting in corneal edema. Lymphocytic-plasmacytic inflammation is often suggestive of an immune-mediated reaction and indicates some type of chronicity.

Septic Arthritis

See SEPTIC ARTHRITIS, p 1062.

NEONATAL ENCEPHALOPATHY

(Neonatal maladjustment syndrome, Hypoxic ischemic encephalopathy, Barker, Wanderer, Dummy)

Neonatal encephalopathy (NE) is a common, noninfectious CNS disorder of neonatal foals, resulting in clinical signs such as lethargy, inappropriate behavior, seizures, and other neurologic deficits. The condition is associated with the broader syndrome of **perinatal asphyxia syndrome**, which is believed to result from unrecognized in-utero or peripartum hypoxia, and can injure multiple organ systems. In this context, asphyxia is caused by impaired oxygen delivery to cells, most often resulting from a combination of hypoxemia or anemia (leading to decreased blood oxygen content), and ischemia (decreased blood perfusion).

Pathogenesis and Risk Factors: Species-specific information on the pathogenesis of NE in foals is exceedingly scarce and mostly extrapolated from nonequine species. Primary neuronal cell death may be related to cellular hypoxia, energy failure, and cellular membrane depolarization, whereas delayed neuronal cell death is associated with reperfusion injury (oxidative stress), excitotoxicity, accumulation of intracellular calcium, activation of numerous enzymes and pathways, cytotoxic actions of activated microglia, inflammation, and apoptosis. In this context, excessive activation of glutamatergic neurotransmission (ie, excitatory amino acids and neurotransmitters), increased production of reactive oxygen and nitrogen species, as well as fetal systemic inflammatory responses with production of pro-inflammatory cytokines

(eg, IL-1, IL-6, TNF- α) may all contribute to cell injury and/or death.

Risk factors for perinatal asphyxia may include maternal (eg, respiratory disease, endotoxemia, hemorrhage/anemia, surgery/cesarean delivery), placental (eg, bacterial, fungal- or endophyte-associated placentitis, chronic or acute premature uteroplacental separation), and fetal causes (eg, twinning, congenital abnormalities, dystocia, meconium aspiration, sepsis, prematurity, dysmaturity). Fetal and maternal factors are those that induce hypotension or reduced tissue oxygenation, whereas placental pathology will impair uteroplacental perfusion. Areas of chronic placental separations may thus lead to chronic hypoxia of the fetus. However, the most acute cause of perinatal asphyxia is complete premature placental separation at birth ("red bag" delivery).

Clinical Findings: CNS signs are most prominent in cases of perinatal asphyxia, but renal, cardiac, GI, and pulmonary systems may also be affected. A detailed, systematic examination of foals with NE is therefore warranted. Renal compromise of foals with NE may present as anuria or oliguria, whereas GI effects of perinatal asphyxia may include colic, transient ileus, meconium impaction, gastric ulcers, gastric reflux, bloat, diarrhea, and necrotizing enterocolitis. Cardiac arrhythmias, edema, poor cardiac output, and systemic hypotension may result from hypoxia of the myocardium. A decrease in pulmonary perfusion may impair surfactant production and lead to ventilation-perfusion mismatch and secondary pulmonary atelectasis. Hepatic and endocrine dysfunction may also be seen. For example, perinatal asphyxia syndrome may cause lower T_3 and T_4 concentrations in affected foals than in age-matched healthy control subjects.

The neurologic signs of foals with NE are variable and may include weakness (hypotonia), mental depression (stupor, somnolence, difficult to arouse, coma), seizure activity, tremors, and hypertonia. Seizures are relatively common and may range from mildly abnormal movement of the face and jaw to generalized seizures with recumbency and paddling. Other clinical signs include an inability to find the udder, loss of suckle reflex, loss of affinity for the dam, loss of recognition of the environment, abnormal vocalization (hence "barker foals"), dysphagia, weak tongue tone or persistent tongue protrusion, central blindness, opisthotonos, irregular respiratory pattern (apnea, abnormally slow

respiratory rate), and proprioceptive deficits. Clinical signs can be asymmetric and may include a head tilt, circling, and asymmetric pupillary reflexes. Foals may appear healthy at birth but often exhibit CNS abnormalities within hours of delivery or by 1–2 days of age. Affected foals are usually afebrile unless secondary infection or sepsis occurs.

Diagnosis: Diagnosis is based on compatible clinical findings and exclusion of differential diagnoses. A history of dystocia, premature placental separation, or placentitis may support a diagnosis of NE. The foal's CBC is usually unremarkable unless sepsis is present. A serum chemistry may also be normal but often indicates organ dysfunction secondary to hypoxic or cytokine-mediated injury. For example, a markedly increased CK concentration may correlate with a recent hypoxic-ischemic muscle insult, whereas an increased GGT concentration can accompany hepatic injury. Transient or spurious hypercreatininemia may indicate adverse maternal and/or placental conditions, or suggest ingestion of creatinine-rich fetal fluids in neonatal foals experiencing periods of peripartum asphyxia. Creatinine in affected foals decreases by >50% within 24 hr of standard neonatal support and generally normalizes within 72 hr. However, if creatinine values remain high, then renal dysfunction must be considered. Hypoxemia, hypercarbia (due to respiratory depression), acidemia, and hypocalcemia may also be seen in foals with NE. CSF may be normal or show an increased RBC count and protein concentration. CNS necrosis, edema, and hemorrhage are found in some cases at necropsy; however, these findings are inconsistent.

Differential diagnoses for NE include bacterial meningitis, equine herpesvirus 1 infection, metabolic abnormalities (eg, hypoglycemia, electrolyte derangements), acid-base disturbances, kernicterus subsequent to massive hemolysis (ie, neonatal isoerythrolysis), brain or spinal trauma, congenital defects (eg, hydrocephalus, hydranencephaly), and nutritional myodegeneration (white muscle disease).

Treatment and Prognosis: Treatment of NE is primarily supportive. Maintenance of adequate blood pressure and perfusion is vital for supporting cerebral blood flow and avoiding further ischemic injury. This can be accomplished by cautiously administered, goal-directed IV fluid therapy and inotrope or vasopressor support, if needed, while avoiding hypertension. Mild hypothermia,

use of barbiturates, and mild hypercapnia have been suggested to decrease cerebral metabolic rate and preserve energy. Because foals have minimal energy reserves, IV glucose administration may be necessary to maintain normal blood glucose concentrations. If the foal is unable to nurse, nutrition can be supplied via an indwelling nasogastric tube. Total parenteral nutrition is indicated in foals with GI dysfunction.

Mannitol (0.25–1 g/kg, IV, as 20% solution over 20 min every 12–24 hr) has been used to reduce cerebral edema. Anticonvulsants (phenobarbital 2–10 mg/kg, IV, bid; diazepam 0.1–0.4 mg/kg, IV, as needed; midazolam 0.04–0.1 mg/kg, IV, as needed or 0.02–0.06 mg/kg/hr constant-rate infusion) are implemented to treat seizures that can otherwise increase cerebral oxygen consumption and contribute to ongoing injury. Self-trauma during seizures should be limited by providing a protected or padded environment. Trauma to the eye and corneal ulceration is particularly common; the eyes should therefore be monitored closely and treatment implemented if necessary. In recumbent foals, ophthalmic lubricants may be used to reduce the incidence of corneal injury.

Magnesium sulfate supplementation administered as a constant-rate infusion (0.05 mg/kg/hr, IV, loading dose, then 0.025 mg/kg/hr maintenance) has been suggested to block the release of glutamate, whereas antioxidants such as vitamins E (5,000 IU/day, PO) and C (100 mg/kg/day, IV or PO) can be administered along with thiamine (10 mg/kg slowly IV or SC every 12–24 hr) to support cellular metabolism. DMSO 10% solution (0.5 g/kg, IV) has been used as a free radical scavenger. Allopurinol (44 mg/kg, PO, within the first 4 hr), a xanthine oxidase inhibitor, can also be administered to decrease free radicals, whereas pentoxifylline (10 mg/kg, PO, bid) may inhibit TNF- α production in foals with NE.

Most foals with NE will benefit from intranasal administration of humidified oxygen (3–5 L/min), whereas mechanical ventilation may be required in cases of severe respiratory depression. Doxapram (0.02–0.05 mg/kg/hr constant-rate infusion) and caffeine (10 mg/kg, PO or per rectum loading dose, then 2.5 mg/kg as needed) may be used as a central respiratory stimulant. Availability of hyperbaric oxygen therapy is limited, but it has also been used to treat NE in foals. Foals with NE appear to be predisposed to sepsis. Whether this is due to an underlying infectious process, impaired immune function, or increased

exposure to pathogens (ie, indiscriminant nursing behavior) is unclear. In addition, foals neurologically abnormal at birth often fail to nurse and commonly have failure of passive transfer of immunity (see p 819). For these reasons, broad-spectrum antimicrobials, plasma transfusion, and anti-inflammatory management are commonly indicated.

Most foals with NE have a good to very good prognosis. In uncomplicated cases, the reported survival rate is 70%–75%, with complete recovery in most cases. Sepsis and related complications adversely affect the prognosis. Foals that remain comatose or difficult to arouse, show no improvement in neurologic function during the first 5 days of life, or demonstrate severe, recurrent seizures have a guarded to poor prognosis.

MECONIUM IMPACTION

Meconium is the earliest feces of newborn foals. It is composed of intestinal secretions, swallowed amniotic fluid, and cellular debris; it has a sticky, caramelized appearance. Most foals pass their meconium within the first 9–12 hr of life. If sufficient quantities of meconium are not evacuated, meconium impaction can lead to clinical signs of colonic obstruction, which usually manifest in the first 12–96 hr. These signs may include abdominal pain (colic), tachypnea and tachycardia, tail “swishing,” restlessness, straining to defecate, and abdominal (gas) distention. Published reports suggest that meconium impaction may be more likely in foals born after >340 days of gestation and in colts. Meconium can usually be identified either by plain or contrast abdominal radiography or ultrasonography, or by careful digital rectal examination with adequate restraint or sedation. On radiographs, meconium often appears as granular contents in the ascending or descending colon, with fluid- or gas-distended intestine proximal to the obstruction.

Treatment: Many cases of meconium impaction respond to medical therapy, including judicious use of analgesics, IV fluid therapy, oral laxatives (4–8 oz mineral oil administered via a nasogastric tube; 1–2 oz milk of magnesia), and enemas as the mainstay of therapy. Warm-water liquid detergent (eg, Palmolive®) enemas (½ teaspoon liquid detergent added to 500 mL water) are preferred, although commercial phosphate (Fleet®) enemas can also be used (repeated administration may increase risk of phosphate toxicity). Acetylcysteine retention enemas may also be highly

effective, because acetylcysteine is hypothesized to cleave disulfide bonds in the mucoprotein molecules of meconium, which decreases its overall tenacity. A 4% acetylcysteine solution is made by adding 20 g of baking soda and 8 g of acetylcysteine to 200 mL of water. A 30-french Foley catheter with a 30-mL balloon is inserted ~2.5–5 cm into the rectum, and the balloon is slowly inflated to occlude the rectum. Subsequently, 100–200 mL of the 4% acetylcysteine solution is administered by gravity flow and retained for 30–45 min. If needed, treatment can be repeated in 12 hr. Occasionally, repeated enemas can result in significant mucosal irritation and persistent straining beyond the resolution of the meconium impaction, thereby confounding the assessment of treatment success.

Surgical intervention should be considered if medical therapy is unsuccessful, especially in the face of persistent pain unresponsive to analgesics, persistent tachycardia, progressive abdominal enlargement, or increased peritoneal fluid protein and/or nucleated cell count.

The prognosis of uncomplicated meconium impaction is generally considered good to excellent.

SMALL ANIMALS

Average reported canine and feline neonatal mortality rates (greatest during the first week of life) vary, ranging from 9%–26%. Prudent veterinary intervention in the prenatal, parturient, and postpartum periods can increase neonatal survival by controlling or eliminating factors that contribute to puppy morbidity and mortality. Poor prepartum condition of the dam, dystocia, congenital malformations, genetic defects, injury, environmental exposure, malnutrition, parasitism, and infectious disease all contribute to neonatal morbidity and mortality. Optimal husbandry impacts neonatal survival favorably by managing labor and delivery to reduce stillbirths, controlling parasitism and reducing infectious disease, preventing injury and environmental exposure, and optimizing nutrition of the dam and neonates. Proper genetic screening for selection of breeding animals minimizes inherited congenital defects.

Immediate Postpartum Resuscitation:

Optimal neonatal resuscitation (if needed after birth or cesarean section) involves the same “ABCs” as any cardiopulmonary resuscitation. Prompt clearing of airways

("A") by gentle suction with a bulb syringe, and then drying and stimulation of the neonate to promote respiration ("B") and to avoid chilling are performed. Neonates should not be swung to clear airways because of the potential for cerebral hemorrhage from concussion. The use of doxapram as a respiratory stimulant is unlikely to improve hypoxemia associated with hypoventilation and is not recommended. Spontaneous breathing and vocalization at birth are positively associated with survival through 7 days of age. Intervention for resuscitation of neonates after vaginal delivery should be done if the dam's actions do not stimulate respiration, vocalization, and movement within 1 min of birth.

Cardiopulmonary resuscitation for neonates that do not breathe spontaneously is challenging yet potentially rewarding. Ventilatory support should include constant flow O_2 delivery by facemask. If this is ineffective after 1 min, positive pressure with a snugly fitting mask or endotracheal intubation and rebreathing bag (using a 2-mm endotracheal tube or a 12- to 16-gauge IV catheter) is advised. Cardiac stimulation ("C") should follow ventilatory support, because myocardial hypoxemia is the most common cause of bradycardia or asystole. Direct transthoracic cardiac compressions are advised as the first step; epinephrine is the drug of choice for cardiac arrest/standstill (0.2 mg/kg, administered best by the IV or intraosseous route). Venous access in neonates is challenging; the single umbilical vein is one possibility. The proximal humerus, proximal femur, and proximomedial tibia offer intraosseous sites for drug administration. Atropine is not advised in neonatal resuscitation. The mechanism of bradycardia is hypoxemia-induced myocardial depression rather than vagal mediation, and anticholinergic-induced tachycardia can actually exacerbate myocardial oxygen deficits.

Chilled neonates may not respond to resuscitation. Body temperature drops rapidly when a neonate is damp. Keeping the neonate warm is important during resuscitation and in the immediate postpartum period. During resuscitation, placing the chilled neonate's trunk into a warm water bath (95°–99°F) can improve response. Working under a heat lamp or within a Bair hugger warming device is helpful. After resuscitation, neonates should be placed in a warm box (a styrofoam picnic box with ventilation holes is ideal) with warm bedding until they can be left with their dam. Neonates delivered by cesarean section should be left with the dam only

after she is fully recovered from anesthesia and exhibiting good maternal behavior; otherwise, nursing should be directly monitored and permitted every 2 hr.

Neonates lack glucose reserves and have minimal capacity for gluconeogenesis. Providing energy during or just after prolonged resuscitation efforts becomes critical. Clinical hypoglycemia (blood glucose levels <30–40 mg/dL) can be treated with dextrose solution IV or intraosseously, at a dosage of 0.5–1 g/kg (0.0005–0.001 g/g body wt) using a 5%–10% solution, or a dosage of 2–4 mL/kg (0.002–0.004 mL/g body wt) of a 10% dextrose solution. A 500-g neonate would get 1–2 mL. Single administration of parenteral glucose is adequate if the hypoglycemic puppy can then be fed or nurses. If a neonate is too weak to nurse or suckle, 0.05–1 mL of warmed 5% dextrose can be administered orally by stomach tube every 15–30 min until the neonate is capable of suckling. If colostrum can be acquired from the dam, it can be administered in the same way. Dextrose solution (50%) should be applied to the mucous membranes only because of the potential for phlebitis if administered IV; however, circulation must be adequate for absorption from the mucosa. Neonates administered dextrose should be monitored for hyperglycemia because of immature metabolic regulatory mechanisms.

When to Stop Resuscitation: Resuscitation may be stopped when there has been no response after 15–20 min of effort (continued agonal respiration, bradycardia) or when a serious congenital defect has been detected (cleft palate, loud murmur, gastroschisis, large omphalocele, large fontanel).

Husbandry in the First Days of Life:

After resuscitation or within the first 24 hr of a natural delivery, a complete physical examination should be performed. Lack of cleft palate, a normal umbilicus, and functional urethral and anal openings should be established. A fontanelle, if present, should be small. The oral cavity, hair coat, limbs, umbilicus, and urogenital structures should be visually inspected. The mucous membranes should be pink and moist, a suckle reflex present, the coat full and clean, and the urethra and anus patent. A normal umbilicus is dry without surrounding erythema. The thorax should be ausculted; vesicular breath sounds and a lack of murmur are normal. The abdomen should be pliant and not painful. A normal neonate will squirm and vocalize when examined, and nurse and sleep quietly when returned to the dam. Healthy neonates will attempt to right themselves and orient by

rooting toward their dam. Neonates are highly susceptible to environmental stress, infection, and malnutrition. Proper husbandry is critical and should include daily examination of each neonate for vigor and recording of weight.

Warmth: Puppies and kittens lack thermoregulatory mechanisms until 4 wk of age; thus, the ambient temperature must be high enough to facilitate maintenance of a body temperature of at least 97°F (36°C). Hypothermia negatively impacts immunity, nursing, and digestion. Exogenous heat should be supplied, best in the form of an overhead heat lamp. Heating pads run the risk of burning neonates incapable of moving away from excessively hot surfaces.

Chilled neonates must be rewarmed slowly (30 min) to avoid peripheral vasodilation and dehydration. Tube feeding should be delayed until the neonate is euthermic. Hypothermia induces ileus, and regurgitation and aspiration can result.

Immunity: Incompletely developed immune systems during the first 10 days of life make neonates vulnerable to systemic infection (most commonly bacterial and viral). Puppies must ingest adequate colostrum promptly after birth to acquire passive immunity. The intestinal absorption of IgG generally ceases by 24 hr after parturition. Colostrum-deprived kittens given adult cat serum at a dosage of 150 mL/kg, SC or IP, developed serum IgG levels comparable to those of suckling littermates. However, colostrum-deprived puppies given 40 mL/kg of adult dog serum orally and parentally did not match IgG levels of suckling littermates. Neonates should be encouraged to suckle promptly after resuscitation is completed; this usually necessitates close monitoring after a cesarean section, because the dam has not fully recovered from anesthesia. Maternal instincts (protecting, retrieving, grooming, nursing) usually return within 24 hr.

The umbilicus of neonates should be trimmed 1 cm from the abdominal wall, ligated, and treated with 2% tincture of

iodine immediately after birth to reduce contamination and prevent ascent of bacteria into the peritoneal cavity (omphalitis-peritonitis).

Neonatal bacterial septicemia can cause rapid deterioration and result in death if not recognized and treated promptly. Predisposing factors include endometritis in the dam, a prolonged delivery/dystocia, feeding of replacement formulas, the use of ampicillin, stress, low birth weight (<350 g for a medium-size breed dog), and chilling with body temperature <96°F. The organisms most frequently associated with septicemia are *Escherichia coli*, streptococci, staphylococci, and *Klebsiella* spp. Premortem diagnosis can be challenging, because sudden death may preclude recognition of clinical signs. Commonly, a decrease in weight gain, failure to suckle, hematuria, persistent diarrhea, unusual vocalization, abdominal distention and pain, and sloughing of the extremities indicate septicemia may be present. Prompt therapy with broad-spectrum, bactericidal antibiotics; improved nutrition via supported nursing, tube feeding, or bottle feeding; maintenance of body temperature; and appropriate fluid replacement are indicated. The third-generation cephalosporin ceftiofur sodium is an appropriate choice for neonatal septicemia, because it alters normal intestinal flora minimally and is usually effective against the causative organisms. Ceftiofur sodium should be administered at a dosage of 2.5 mg/kg, SC, bid, for no longer than 5 days. Because neonates <48 hr old have reduced thrombin levels, presumptive therapy with vitamin K₁ at 0.5–2.5 mg/kg can be used (0.01–1 mg/neonate, SC) if a coagulopathy is suspected (umbilical bleeding, hematuria, epistaxis).

Nutrition: Neonates have minimal body fat reserves and limited metabolic capacity to generate glucose from precursors. Glycogen stores are depleted shortly after birth, making adequate nourishment from nursing vital. Even minimal fasting can result in hypoglycemia. Hypoglycemia can also result from endotoxemia, septicemia, portosys-

TABLE 1 NORMAL RECTAL TEMPERATURE OF SMALL ANIMAL NEONATES

Period	Normal Rectal Temperature
Wk 1	95°–99°F (35°–37.2°C)
Wk 2–3	97°–100°F (36.1°–37.8°C)
At weaning	99°–101°F (37.2°–38.3°C)

TABLE 2 ENVIRONMENTAL WARMTH REQUIRED FOR SMALL ANIMAL NEONATES

Period	Temperature
Wk 1	84°–89°F (28.9°–31.7°C)
Wk 2–3	80°F (26.7°C)
Wk 4	69°–75°F (20.6°–23.9°C)
Wk 5	69°F (20.6°C)

temic shunts, and glycogen storage abnormalities. Oral fluid and glucose replacement may be preferable if the neonate has an adequate swallowing reflex and is not clinically compromised. The neonatal caloric requirement is 133 cal/kg/day during the first week of life, 155 cal/kg/day for the second, 175–198 cal/kg/day for the third, and 220 cal/kg/day for the fourth. Commercially manufactured milk replacement formulas are usually superior to homemade versions, but none is equal to the dam's milk. The use of milk obtained from the dam can be considered and is superior if available. An osmotic diarrhea (usually yellow, curdled fecal appearance) can result from overfeeding formula, necessitating diluting the product 50% with water or a balanced crystalloid solution. Neonates should gain weight steadily from the first day after birth (a transient mild loss from birth weight is acceptable on day 1), with puppies gaining 1–3 g/day/lb (2.2 kg) of anticipated adult weight and kittens 50–100 g/wk. Neonatal weights should be recorded daily for the first 2 wk, then every 3 days until 1 mo old. Healthy, well-nourished neonates are quiet and sleep when not nursing. The normal neonatal weight gain is an increase of 5%–10% body wt/day.

Neonatal Anesthesia: Anesthesia of the neonate may be necessitated by an emergency or for an elective procedure. The distribution and metabolism of drugs are different in neonates than in adults. Neonates have decreased protein binding and increased permeability of the blood-brain barrier. Decreased protein binding is due to lower albumin levels with a lower affinity for drugs. Neonates have higher body water content and lower fat content than adults. This results in a greater initial volume of distribution for some drugs. In most neonates, the ability to metabolize drugs (via conjugation, hydrolysis, oxidation, and reduction) is reduced, as is renal clearance mechanisms. Nephrogenesis in puppies is not complete until the third week of life; the outer cortical

nephrons are the last ones to become fully functional. The ability of the neonatal kidney to produce a concentrated urine is less than that of the adult, and so fluid balance is more labile in neonates. The differences in neonatal respiratory function mean that inhaled agents will have a more rapid onset and recovery. Neonates have immature central and peripheral nervous systems and immature neuromuscular junctions, such that less general/local anesthetic is required to produce anesthesia/local block than in adults.

Fluid support is indicated with neonates, but fluid overload is simply because of the capacity of the fluid lines used for larger animals. To avoid this problem, tubing with a much smaller internal diameter should be used. Care must also be taken to ensure that the lines do not contain any air, because these very small patients may still have communication between the left and right atrium, making it possible for IV air to result in coronary or cerebral emboli.

Core body temperature should be monitored, and hypothermia treated as soon as possible. A supplemental source of heat should be available (circulating water blanket or warm air blanket) to prevent hypothermia, because many of the anesthetic drugs eliminate the ability of the neonate to thermoregulate, and neonates are more prone to hypothermia than adults. Premedication with an anticholinergic is acceptable and usually sufficient by itself. Most neonates tolerate a simple mask induction with an inhalant such as isoflurane or sevoflurane. Propofol can be used as an induction drug in young animals. Maintenance by mask avoids the potential for trauma during intubation in tiny neonates, but less control of the airway is achieved.

During anesthesia of neonates, supporting and monitoring cardiopulmonary function is especially important. Cardiac output in neonates depends on heart rate; preventing bradycardia is more important than in adults. Monitoring blood pressure is also important. If hypotension is detected or

tissue perfusion judged inadequate, treatment should be instituted. Initial therapy should include reducing the amount of anesthetic, if possible, and increasing the rate of fluid administration. If these treatments are ineffective, it is probably better to use a positive inotrope/chronotrope than a peripheral vasoconstrictor to try to increase blood pressure (unless it is very low, and a vasoconstrictor is needed to raise the pressure long enough to allow other therapies to work). Dopamine has been shown to increase blood pressure in puppies <10 days old at 5–10 mcg/kg/min but has little effect on heart rate or cardiac output. Dobutamine appears to have little effect at clinical doses.

CARE OF ORPHANED NATIVE BIRDS AND MAMMALS

If an orphaned bird or mammal is found, further information should be sought before attempting wildlife rehabilitation. Specialized books about hand-rearing wild and domestic mammals and birds and the National Wildlife Rehabilitators Association Web site (www.nwrawildlife.org) are valuable resources. The following is a general overview, and all species require more information for a full course of captive care. Correct species and age identification is crucial for determination of behavioral considerations, weaning diets, and adult fate. It is illegal to keep most species of North American wild animals as pets. Permits are required, even by veterinarians, to care for most wild species beyond initial medical care. The USA Fish and Wildlife Service and state natural resource agencies should be contacted for applicable rules. Injured limbs of wild animals should never be amputated without consultation with regulatory agencies, because permanent captive placement for disabled wildlife may be difficult to find. Euthanasia should be considered when injury resolution will result in a disabled, unreleasable animal. When hand-rearing for wild release, infants should be raised with conspecifics to avoid human imprinting, using techniques that avoid habituation. Wild infants must be isolated from domestic animals.

The first step is to determine whether young are truly orphaned. If chicks are returned to nests or mammals are left alone and monitored from afar, the parent may return and resume care. Human handling does not preclude most parents accepting returned offspring. Neonatal wildlife, especially unidentified species, have the

best chance of survival if kept warm and taken to local wildlife rehabilitation centers. Skunks, raccoons, foxes, and bats should only be rehabilitated by professionals because of potential zoonotic diseases. Marine mammals and seabirds require specialized care facilities (*see* p 1856).

All neonates require physical examination and assessment of hydration, body temperature, and weight. Warmth, hydration, and energy are critical. Because most orphans initially cannot maintain or regulate their body temperature, supplemental heat should be provided with heating pads, hot water bottles, incandescent light bulbs, or brooders. A heat gradient for ambulatory young allows orphans to select their own comfort zone. Thermal support of altricial species must be closely regulated. Most placental mammals and birds have normal body temperatures warmer than that of people, and should feel warm to the human hand. Maintaining humidity of 50%–70% in housing reduces dehydration, and insulating orphans from direct heat prevents burns. Hypothermic orphans should be warmed until body temperature is near normal and administered warm fluids to maintain hydration or correct deficits. Once the infant is warmed and well hydrated, species-appropriate diets can be fed to provide energy. Initial feedings should be conservatively sized and dilute until it has been determined that the infant's excretory systems are functioning. Infants of most species have a stomach or crop capacity of ~50 mL/kg. Overfeeding may result in aspiration pneumonia or diarrhea. Once infants are stabilized, the advice of a permitted rehabilitator should be obtained.

Hair, feathers, skin, and eyes should be kept free of spilled food or excreta, and foods maintained hygienically. Nests/housing should be cleaned regularly and secured against vermin. Treatment for ecto- and endoparasites or fly strike may be necessary. Products deemed safe for infants of domestic species should be used, and an exotic animal formulary consulted for dosing information.

Metabolic bone disease may develop quickly in wild orphans fed inadequate diets. Corvids, other passerines, herons, egrets, shorebirds, raptors, opossums, and canids are especially susceptible, including when transitioned off formulas onto inadequately supplemented animal protein diets before skeletal maturity. Ground meat or poultry must be supplemented with calcium carbonate at 5 g/0.5 kg of meat.

Growing chicks require a dietary ratio of elemental calcium:phosphorus of ~2:1 by weight.

Birds

Nest replacements should be constructed so as to provide nonambulatory chicks with a comfortable upright posture with the head elevated and legs underneath the body. Housing chicks on flat surfaces may result in splayed legs. Fractured bones are considered life-threatening injuries because of the requirement of functionality for release. Trauma to soft tissues can be minimized by stabilizing fractures promptly. Elbow, carpus, spine, stifle, and hock fractures or luxations carry a poor prognosis for release. Mid-shaft long-bone fractures often heal well. Humerus and femur fractures heal best with a simple intramedullary pin, and pinning may be successful even in extremely young or small-bodied chicks. Minimally restrictive splints and wraps for other fractures result in fastest recovery and release. Chicks should be allowed to use stabilized, fractured limbs as normally as possible during recovery. Stable callus formation occurs in 5–7 days in nestling passerines and in 10–21 days in larger-bodied species, well before radiographic changes occur. Some species form joint contractures easily and require physical therapy after the fracture and then continuing intermittently for return to function. Chicks may heal rapidly from seemingly severe soft-tissue injuries. Lacerations should have primary closure to minimize time in captivity and reduce adverse effects on growing plumage. Antibiotic therapy against gram-negative bacteria is advisable for predator-injured chicks; it should be continued until wounds have completely healed. Meloxicam and butorphanol are commonly used for pain. Chicks with head injuries may recover well; changes in neurologic signs can be used as prognostic indicators while giving supportive care. Beak or jaw injuries must resolve with beak tips well aligned to ensure ability to forage normally after release.

Nearly all North American bird species feed vertebrate or invertebrate prey to their chicks. Milk and bread, hamburger, condensed milk, or uncooked rice should not be fed. Soaked dog kibble and monkey biscuits are inadequate for most species. All species require 8–12 hr uninterrupted sleep. Self-feeding requires daylight-level lighting in diurnal species. All growing chicks

should gain weight every day, so weight should be monitored closely.

Altricial Species: Chicks should be warmed to normal body temperature, hydrated until droppings are produced, and then fed. Tiny, unfeathered chicks require environments as warm as 100°F (37.8°C); larger-feathered chicks do well initially in temperatures of 90°–95°F (32.2°–35°C). Overheated chicks may hold perpetual open-mouthed postures, droop heads over nest edges, and cease producing droppings if dehydrated. Not all species gape/beg (swifts, nightjars). Some species stop begging when full (corvids); some do not and may dangerously overeat (finches, goldfinches). Crops should empty between feeds; not all species have crops (insectivores, owls). Hatchlings require more water than older chicks. Common problems that cause lack of gaping include too cold, hot, weak, or dehydrated; untreated illness or injury; and misidentified species. Overfeeding may cause droppings that appear as undigested diet.

Higher protein/fat, lower carbohydrate diets are desirable for most species. Puréed, high-quality kitten or ferret kibble is an acceptable temporary food for most altricial chicks, supplemented with elemental calcium at 150 mg/kg/day, PO, until on a balanced diet. Puréed, skinned prey animals (quail or adult mice, including bones and organs, minus feet and heads) form an adequate diet for many species. Bone fragments must be completely pulverized to avoid GI trauma. A diet of thawed-frozen prey requires vitamin supplementation. Vitamin E and thiamine supplementation is necessary for species ingesting frozen-thawed fish. Feeding prey frozen >6 mo should be avoided. Vitamin A may be inadequate in insect prey, and deficiency may occur if prey are fed with viscera removed. Pinky mice, insects, and small-bodied fish often contain inadequate calcium for growing birds; hence, supplementation is necessary.

Songbirds and Woodpeckers: A simple hand-feeding diet consists of 1 cup (116 g) Purina Pro-Plan® kitten kibble, 1.25–1.5 cup (300–360 mL) water, 2 tbsp (14 g) powdered egg white, 750 mg calcium from CaCO₃, and ½ tsp (1.4 g) Avi-Era® powdered avian vitamins. Do not delete or substitute ingredients haphazardly, soak kibble and blend until smooth, and feed with appropriately sized syringe. For hatchlings/nestlings, feed 50 mL/kg every 20–45 min (by age)

12–14 hr/day (16 hr/day for insectivores). For fledglings, hand-feed 50 mL/kg every 1–2 hr, 12 hr/day, offering appropriate self-feeding diet.

Hummingbirds: A temporary diet consists of 1 part water to 6 parts table sugar or 5% dextrose, fed every 20 min. This diet does not meet hummingbird chick nutrient requirements. These chicks should be transferred to an experienced caretaker immediately. Sugar water should not be spilled on the bird.

Doves and Pigeons: Commercial diets for hatchlings are Roudybush™ Squab Diet and Lafeber's® Emerald® Carnivore; for nestlings/fledglings, Kaytee® Exact® Hand Feeding Formula. Crop capacity is 100–120 mL/kg. Birds should be fed when crop empties, 12–14 hr/day, every 1–2 hr until eyes open and then every 3 hr until ambulating and ingesting seed. Palpating the crop before each feeding will assess self-feeding and prevent overfilling.

Raptors: Hatchlings can be fed small pieces of warm, water-dipped meat every 2 hr, 12 hr/day, with blunt-tipped forceps; tiny bone pieces can be included by day 3 after hatch, and casting material (skin/hair) by day 5. The crop should empty between meals. Most species will pick up chopped prey from a dish by day 14. Feeding with a puppet parent can be done once the eyes open.

Hérons and Egrets: Thawed-frozen fish (5–20 g, sliced diagonally if larger), live insects, or thawed-frozen chopped mice, should be offered hourly until self-feeding, then several times daily. Hatchlings may require force feeding; older chicks may eat from a dish. Using a feeding puppet reduces habituation.

Precocial Species: Once warm and secure, many species drink and eat independently. Solitude stresses chicks; a mirror, small stuffed animals, clean feather duster, or chicks of closely related species can be companions. Uncommon species and debilitated hatchlings require professional rehabilitative care for a positive outcome. Placing pebbles in water dishes may prevent quail/ducklings from drowning. Hatchling quail/killdeer require habitat brooders kept at 95°–100°F (35°–37.8°C).

Shorebirds (Killdeer, Sandpipers, Avocets): Live, fresh-frozen, and freeze-dried small invertebrate prey (tubifex worms, brine shrimp, mosquito larvae, tiny

krill, small freshly shed mealworms, fly larvae, or cichlid mini-pellets) should be offered in shallow water at least four times daily.

Waterfowl (Geese, Ducks, Swans): Natural duckweed or watercress, small invertebrates, crushed hard-boiled egg, small minnows, and waterfowl starter (Mazuri®) should be offered. Access to shallow water should be controlled; chicks must be able to easily exit water to warm under a heat source. Chicks may lose waterproofing and become chilled if plumage becomes contaminated with food or droppings.

Gamebirds (Pheasants, Quail, Turkeys): Soaked puppy kibble, small-bodied invertebrates, small clumps of grass or weeds with soil, or commercial gamebird starter can be offered.

Mammals

Hypothermia and dehydration must be corrected before feeding neonate mammals. Hairless neonates require ambient temperatures of 85°–90°F (29.4°–32.2°C), while haired infants may be housed at cooler temperatures depending on maturity and body condition. Once warm and hydrated, milk replacer should be introduced using this regimen: 100% oral electrolyte solution, gradually increasing the strength of milk replacer in one to several feedings to ¼ strength, then ½, then ¾, and finally to full strength. During this process, if the neonate develops digestive upset (vomiting, diarrhea, bloating), feeding should return to the last well-tolerated ratio. Overfeeding or sudden diet changes may cause bloating or diarrhea. Neonates need to be stimulated to eliminate by gently stroking the perineal area with warm moist gauze or tissue. Dorsal side up is normal nursing posture; infants should not be put on their backs to feed. The environment should be quiet.

Fawns: Fawns should be raised in groups with minimal human contact and kept away from dogs. Newborn to 2-day-old fawns should be fed colostrum, such as Colostrx®, for the first 24–48 hr. After reconstitution, one 454-g package can be administered via bottle or stomach tube over 8–10 hr (5 meals/day, 30–40 mL/kg). Acceptable milk replacers include Fox Valley® Milk Replacer, lamb's milk replacer, or goat's milk. Fawns 2–7 days old should be fed four times daily, gradually increasing volume to 50 mL/kg. From 8 to 14 days of age, up to 300

mL should be fed, reaching a goal of 300 mL, tid. From 2 to 4 wk, the amount should be increased to 460 mL, tid, adding solid food (eg, goat chow, calf manna, and alfalfa hay). Indigenous natural browse should always be available. By 7 wk, fawns should be eating solid food and fed one 480 mL bottle daily. By 8–10 wk, fawns should eat solid food exclusively.

Squirrels: For squirrels, syringe-feeding is preferred; Catac® nipples work well. Eastern gray and fox squirrel neonates should be fed every 2 hr until 2 wk old. From 2 to 3 wk, feeding should be every 3 hr, eight times/day. At 4 wk, the late-night feed is eliminated. At 5–6 wk, feedings are reduced to five and then to four times/day, at 7–8 wk to three times/day, and at 10 wk to once a day. Weight should be monitored daily, and the squirrel fed 50 mL/kg initially, gradually increasing to 70 mL/kg by 3 wk. Acceptable milk replacers (ratios by volume) include 2:3 Fox Valley®, 32/40:water, or 1:½:2 Esbilac®, MultiMilk®, and water. When eyes are open and squirrels are ambulatory, natural foods and rodent block can be offered; fruit should be strictly limited. Ground squirrels wean at 6 wk old, and Western gray squirrels at 12 wk.

Rabbits and Hares: Neonatal rabbit stomachs hold 100–125 mL/kg. Healthy neonates should be fed twice a day, although feedings up to four times a day may be needed. Use of a slip-tip syringe is preferred. If suckling response is poor, meals should be tube fed, with the volume reduced by 30% and an extra feeding to ensure adequate intake. Acceptable milk replacers (ratios by volume) include 2:1 parts KMR® powder:water (with pinch of acidophilus) or 1:1 parts Esbilac® powder:water. When the eyes open, a variety of chopped leafy greens and grass (orchard, timothy, or oat) hay should be provided. Because hares are precocial (born furred with eyes open), forage should be offered immediately in addition to milk replacer. Fruits and high-sugar vegetables (eg, carrots) should be avoided.

Opossums: Infant opossums weighing <20 g have a poor prognosis. Infants weighing 20–35 g should be fed 50 mL/kg, six times a day; those weighing 40–100 g, 50–60 mL/kg, five times a day. An acceptable milk replacer (ratio by volume) is 1:½:2 parts Esbilac®, MultiMilk®, and water. Tube-feeding is preferred, and a size

3.5 French red rubber catheter measured to the caudal rib may be used. If syringe feeding, a cut smoothed tomcat catheter can be attached to the syringe and the infant fed drop-wise. When eyes open (~45 g), infants can be taught to lap formula from a shallow dish. When infants weigh ~60 g and are walking, kitten kibble soaked in Esbilac® can be offered. Once the infant is eating soaked kibble (~80–100 g), 10% other natural food items (crickets, worms, chopped mice, local fruits, high-calcium vegetables) can be introduced. Most opossums self-feed by the time they weigh 100–120 g. Adequate calcium intake must be ensured to prevent metabolic bone disease.

Raccoons: Gloves should always be worn when handling raccoons. Raccoons are the definitive hosts for *Baylisascaris procyonis*, a roundworm parasite that may be transmitted to people or other animals, primarily via feces, and result in sometimes fatal infection. Raccoons also may carry rabies.

Newborns weigh 60–75 g with eyes and ears sealed. Incubators are necessary until weight is >500 g. The preferred milk replacer is KMR® or Zoologic® 42/25 (1:2.25 parts powder:water). Infants should be fed via 8 French gavage tube, or drop by drop into the mouth (using a cut smoothed tomcat catheter attached to a syringe) until they are stronger and/or eyes are open. Over-feeding should be avoided. The stomach should be plump but not taut. Four Paws™ large squirrel nipple on a 6-mL syringe may be used. Infants should be stimulated to urinate/defecate after each feed until they eliminate without stimulation. Infants should be weighed daily, and fed 50 mL/kg, six times a day, until they weigh 200 g. They can then be fed using a premie nipple on a bottle or from a dish at the rate of 42.5 mL/kg, five times/day, until they weigh 500 g. At a weight of 400 g, if infants are strong enough and their eyes are open, in addition to the milk replacer, “mush” made of soaked puppy chow, high-protein baby cereal, and KMR® powder (with water added to create oatmeal consistency) can be offered. At 500 g, one of four feeds should be mush in a dish. At 850 g, small bits of cut fruit and soaked puppy chow should be added, decreasing milk replacer to three times a day. As the infants mature, hard puppy chow, prey items (mice, fish), egg, and 10% fruits and vegetables can be offered and formula feeds reduced.

PAIN ASSESSMENT AND MANAGEMENT

Pain delays recovery, impacts negatively on patient well-being, and can affect the client-veterinarian relationship. Behaviors suggestive of pain are routinely used to diagnose injuries and diseases, guide therapy, and provide prognostic information. Obvious signs of pain alert owners and veterinarians of a problem with the animal. Certainly, there is nothing novel about considering pain clinically relevant in the overall evaluation of an animal. What is relatively new is our understanding of the complexity of pain and the emphasis on ethical and medical obligations to treat pain in animals. Although limited survey data and anecdotal evidence suggest that the management of pain is receiving more attention in veterinary medicine than before, the assessment, prevention, and treatment of pain has yet to become an integral part of every physical examination and treatment plan.

PAIN PERCEPTION

Pain serves a protective role that alerts an individual to injury from the environment or from within. Based on current knowledge, all vertebrates, and some invertebrates, experience pain in response to actual or potential tissue damage. Many types of pain are encountered, with the most common being acute, chronic, cancer, and neuropathic. Acute pain is sudden in onset and can be severe. However, it disappears when the stimulus is removed or in a short period of time, and it tends to be self-limiting. Acute pain has a biologic function, because it serves as a warning that something is wrong while leading to protective behavioral changes. Acute pain is a symptom of disease, whereas chronic pain in and of itself, is a disease of altered neuroprocessing. Chronic pain lasts for several weeks to months and persists beyond the expected healing time. Chronic pain does not serve a biologic function and imposes severe detrimental stresses. Cancer pain is the result of primary tumor growth, metastatic disease, or the toxic effects of chemotherapy and radiation. Cancer pain can be acute, chronic, or intermittent and is related to the disease itself or the treatment. Neuropathic pain originates from injury or after injury of the peripheral or central nervous systems, such as trauma (eg, amputation and crushing

injury), vascular injury (eg, thromboembolic disease), endocrinopathy (eg, diabetes mellitus), or infection (eg, post-herpetic neuralgia), possibly associated with motor, sensory, or autonomic deficits.

For an animal to experience pain, nociceptive information must be sent to higher centers in the CNS to be integrated, modulated, and interpreted into the conscious perception of pain. Noxious stimuli (heat, cold, mechanical, chemical) activate free sensory nerve endings known as nociceptors. A- δ and C-fibers transmit sensory information from nociceptors to the dorsal horn of the spinal cord, which directs and modulates input from the periphery and higher centers. Nociceptive information arriving in the dorsal horn of the spinal cord may activate motor neurons responsible for the reflex responses to noxious stimuli (such as withdrawing a limb). Importantly, nociceptive sensory input may be amplified or inhibited by spinal interneurons and glial cells.

Sensory information is relayed to higher centers in the CNS along a variety of pathways that differ according to species. In general, nociceptive information ascends the spinal cord along superficial and deep pathways to the brain stem with connections to the thalamus, reticular formation (responsible for level of arousal), and limbic system (responsible for emotions). From these areas of the brain, nociceptive information is relayed to the cortex, where it is perceived as pain. Activity in spinal nociceptive pathways is strongly influenced by descending antinociceptive systems that originate in the brain stem. Endogenous antinociceptive neurotransmitters (eg, endorphin, enkephalin, dynorphin, serotonin, and norepinephrine) inhibit the transmission of nociceptive information in the spinal cord and brain.

The neuroanatomic components of the nociceptive/pain pathways and pain-suppressing systems can change in response to sustained sensory input. Peripheral sensitization of nociceptors and central sensitization of nociceptive pathways in the dorsal horn, spinal cord, and brain can develop as a result of extensive tissue trauma or nerve injury. The process of peripheral and central sensitization has been termed "wind-up" and refers to the neuroanatomic changes (plasticity) that

result in heightened or exaggerated pain states. Additionally, these exaggerated pain states often do not respond to conventional analgesic therapy. The use of opioids is especially limited, likely because of a down regulation of opioid receptors, a phenomenon that has been reported in the dorsal root ganglion and the dorsal horn. Thus, changes in the CNS in response to repeated and sustained nociceptive input (ie, pain) complicate the clinical management of pain.

RECOGNITION AND ASSESSMENT OF PAIN IN ANIMALS

Pain is a complex, multidimensional experience with sensory and affective elements. All mammals process the neuroanatomic and neuropharmacologic components involved in transduction, transmission, and perception of noxious stimuli; therefore, it is expected that animals experience pain even if they cannot exactly perceive or communicate it in the same way people do. Recognizing pain in animals is not intuitive, particularly for those unfamiliar with normal species-specific or individual behaviors. In recent years, there has been an increased focus on determining and measuring such specific pain behaviors. These efforts should improve recognition and treatment of pain in animals as validated pain assessment tools are developed. Nevertheless, the accurate assessment of pain in animals remains a subjective and challenging undertaking. Numerous factors complicate evaluation of pain in animals. Veterinary pain scales should consider the following characteristics: species, breed, environment and rearing conditions, age, gender, origin of pain (eg, trauma, surgery, pathology), body region affected (eg, abdominal pain, musculoskeletal pain), type of pain (eg, acute, chronic), and pain intensity. Any pain scale or methodology used for pain assessment must be able to distinguish individual sensitivities. Differences in pain tolerance have been demonstrated experimentally in people and animals and play an important role in the clinical management of pain. For example, the existence of a lower threshold for pain in an individual does not obviate the necessity of treatment, nor does a particularly stoic nature.

There is no "gold standard" to assess pain in animals. Many scoring methods that include physiologic and behavioral variables have been published, but few have been validated. Most veterinary pain scales

rely on the recognition and/or interpretation of some behavior and are subject to some degree of variability among observers. Pain scales based on the presence or absence of species-specific behaviors, and that minimize the interpretation of those behaviors, are likely to be more accurate than generic scales that rely heavily on subjective assessment and interpretation. All current methods used to measure pain in animals are prone to errors of under- or overestimation. Even if the amount of pain is correctly estimated, determining how well the individual animal is coping with pain may be difficult. This is particularly true if the animal is removed from its normal environment. Assessment systems must also consider the different types and sources of pain, such as acute versus chronic or neuropathic pain and visceral pain versus somatic pain. Finally, all current methods assess the effects of physical pain; none has been designed to evaluate mental or psychological dimensions of pain in animals.

Physiologic parameters (eg, changes in heart rate, respiratory rate, arterial blood pressure, pupil dilation) may be used to assess responses to an acute noxious (painful) stimulus, particularly during anesthesia, and to assess pain in some clinical situations (eg, horses with acute colic pain). However, physiologic measurements often do not differentiate between animals that have undergone surgery and are experiencing pain and those that did not undergo surgery. Likewise, animals experiencing chronic pain may have normal physiologic parameters. Lack of change in physiologic responses should not be construed to mean there is no pain if other clinical signs suggest otherwise. Physiologic parameters are not specific enough to differentiate pain from other stressors such as anxiety, fear, or physiologic responses to metabolic conditions (eg, anemia).

Lack of familiarity with normal behaviors typical of a particular species or breed makes recognition of pain-induced behaviors difficult or impossible. **Behavioral changes** indicative of pain may be too subtle or take too long to recognize under routine clinical situations in both large and small animals. Sporadic observation of animal behavior may not reveal signs of pain. Except in the most severe circumstances, signs of pain may be "masked" by behavior that is stereotypical of the species being observed. For instance, dogs may wag their tails and greet observers despite being in pain. Flock animals, such as sheep, may be startled when an observer approaches and attempt

to conceal signs of pain by staying bunched up with the rest of the flock. Behavioral changes indicating pain may not be what we expect. A cat sitting quietly in the back of the cage after surgery may be in pain; however, pain would not be recognized if the caregiver expects to see more active signs of pain such as pacing, agitation, or vocalization. Because it is difficult to detect sudden behavior changes, recent research has focused more on sudden changes in facial expressions. The mouse and rodent grimace scale appears to offer a means to assess postoperative pain in mice and rats as effectively as manual behavioral-based scoring, without the limitation of such schemes in the latter.

In general, responses to acute surgical and traumatic pain are likely to be more marked and readily recognizable than clinical signs associated with chronic pain. Often, clinical criteria used to assess chronic pain (eg, lack of activity, lack of grooming, decreased appetite, weight loss) are not specific signs of pain and point only to an underlying problem in need of further diagnosis. A significant time commitment is required in the diagnosis and formulation of a treatment plan for animals in chronic pain. Observations by owners are essential to detect more subtle signs of chronic pain in animals, such as changes in attitude or interaction with family members or members of the herd or flock. The Helsinki Chronic Pain Index and the Canine Brief Pain Inventory are owner-completed questionnaires designed to quantify the severity and impact of chronic pain in companion dogs. They have been validated for canine osteoarthritis. The Canine Brief Pain Inventory, which is based on the human Brief Pain Inventory, also has been validated for canine bone cancer. A thorough history and physical examination are integral to the

evaluation. Evaluating the degree of lameness and sensitivity to manipulation are also critically important when assessing chronic orthopedic pain and pain of spinal origin. A comprehensive neurologic examination must be included for complete assessment and accurate diagnosis of any chronic pain syndrome. Lastly, response to therapy, such as increased activity after administering an NSAID, may provide important diagnostic information regarding the role of pain in behavioral changes.

Cancer pain may have components of acute pain (eg, expansion of a tumor or secondary responses to surgical, radiation, or chemotherapy treatment), chronic pain, and neuropathic pain (eg, nerve entrapment). Thus, assessment of cancer pain requires methods capable of detecting behavioral changes associated with both acute and chronic pain.

PAIN ALLEVIATION

Acute perioperative, traumatic, and disease-related (eg, cancer, pancreatitis, pleuritis, otitis externa) pain is generally treated pharmacologically with one or more analgesics. The optimal drug or drug combinations are determined principally by the anticipated severity of pain, health status, and available drugs for the given species. The more extensive the tissue trauma or disease-induced tissue damage is, the greater the need to use analgesics from more than one drug class (multimodal or balanced analgesia). Multimodal analgesia maximizes the beneficial analgesic effects of multiple drugs through additive or synergistic interactions while minimizing adverse drug effects by lowering the dose of any individual drug.

A perioperative approach to managing surgically induced pain should be used,

TABLE 3 SELECTED ANALGESICS FOR USE IN DOGS AND CATS

			Dosage (mg/kg)	
Class	Drug	Pain Category	Dogs	Cats
Opioids				
Agonists	Morphine	Moderate to severe	0.1–2	0.1–0.5
	Hydromorphone	Moderate to severe	0.05–0.2	0.025–0.2
	Oxymorphone	Moderate to severe	0.05–0.2	0.025–0.1
	Methadone	Moderate to severe	0.1–1	0.1–0.5

beginning with the administration of an analgesic before surgery (preemptive analgesia) and continuing with appropriate analgesia throughout the intraoperative period. Three days is a useful guideline for the duration of analgesic therapy after acute surgical pain. Depending on multiple factors (eg, procedure performed, rehabilitation plan, species, breed), some animals require a shorter duration of therapy, whereas other animals require analgesia for longer periods. Aggressive analgesic therapy of several days' duration should be tapered rather than stopped abruptly. As-needed dosing schedules are less effective than scheduled analgesic dosing to treat pain. As-needed protocols require the animal to demonstrate overt pain behaviors to the extent they are recognized by the veterinarian and/or owner. Aggressive prevention and management of acute pain often prevents wind-up of the nociceptive pathways, hastens return to normal function, and decreases the risk of development of chronic pain syndromes.

Minimizing stress and ensuring that overall care and husbandry are in accordance with the needs of the animal improve pain management. Proper housing conditions, nutritional support, and interaction with other animals and/or people should be optimal for the given species and breed. For example, separating a sheep from the flock for pain management may be quite stressful, whereas separating a companion animal from other animals may not be stressful, provided there is sufficient interaction with human caregivers.

Appropriate analgesia after surgery or trauma allows animals to rest. For example, dogs and cats often sleep but should be arousable after surgery if their pain is controlled. The use of pain as a means of restraint (ie, to prevent the animal from

injuring a surgical site) is inappropriate; many efficacious chemical and physical restraint modalities are available.

Managing painful and distressed animals requires a combination of good nursing care, nonpharmacologic methods (eg, bandaging, ice packs or heat, physical therapy), and pharmacologic methods. Pharmacologic methods available for the treatment of acute pain may include opioids, NSAIDs, corticosteroids, local anesthetics, α_2 -agonists, and N-methyl-D-aspartate (NMDA) receptor antagonists such as ketamine. Many animals benefit from the management of anxiety. Acepromazine is an effective anxiolytic in small animals but should be used only after appropriate analgesics have been administered. Acepromazine does not have analgesic properties and is not reversible.

ANALGESIC PHARMACOLOGY

Opioids: Opioids continue to be the cornerstone of effective pain treatment in veterinary medicine. The opioids are a diverse group of naturally occurring and synthetic drugs used primarily for their analgesic activity. Despite some well-known adverse effects and disadvantages, opioids are the most effective analgesics available for the systemic treatment of acute pain in many species, particularly dogs and cats. Opioid receptors are part of a large superfamily of membrane-bound receptors that are coupled to G proteins. Each opioid receptor has a unique distribution in the brain, spinal cord, and periphery. Opioids combine reversibly with these receptors and alter the transmission and perception of pain. In addition to analgesia, opioids can induce other CNS effects that include sedation, euphoria, dysphoria, and excitement. The clinical

effects of opioids vary between the mu opioid receptor agonists (eg, morphine, hydromorphone), partial mu agonists (ie, buprenorphine), and agonist-antagonists (eg, butorphanol). Species and individual differences in the response to opioids are marked, necessitating the careful selection of opioid and adjustment of dose for

different species. For example, a 30-kg dog may receive a preoperative dose of morphine (15–30 mg) that is similar to that for a 500-kg horse. Likewise, although butorphanol is widely used as an effective analgesic in horses, its use as an analgesic in small animals is falling out of favor because of its expense, relatively poor

somatic analgesic effect, and short duration of action. The clinical effect of an opioid depends on additional patient factors, including the presence or absence of pain, health status of the animal, concurrent drugs administered (eg, tranquilizers), and individual sensitivity to opioids.

Recent information regarding the peripheral endogenous opioid system (PEOS) has presented a unique opportunity to use the powerful analgesic effect of opiates while minimizing untoward systemic effects. The PEOS includes peripheral opioid receptors (POR) and peripheral leukocyte-derived opioids

(PLDO); endomorphins, endorphins, enkephalins, and dynorphins. To activate the PEOS, tissue must have sufficient numbers of leukocytes able to secrete PLDO as well as functional POR in sufficient numbers. Inflammation due to tissue damage results in accumulation of PLD O-secreting leukocytes at the site of injury. Inflammation also increases the number and efficiency of POR. These receptors, inactive under normal conditions and expressed on primary sensory neurons, are synthesized in the dorsal root ganglion and transported distally to peripheral sensory nerve endings due to tissue injury and inflammation. Experimental trials and clinical studies show that peripheral opiates are effective, particularly in the presence of inflammation. For example, preservative-free morphine has been instilled into canine and equine joints after arthroscopy or arthrotomy.

Nonsteroidal Anti-inflammatory Drugs and Corticosteroids: NSAIDs are useful adjuncts in the treatment of postsurgical pain in a variety of species, because they block prostaglandin synthesis mediated by inhibition of cyclooxygenase (COX). Decreasing inflammation after surgery or trauma can greatly improve analgesia. Inflammation is a key component in both peripheral and central sensitization leading to wind-up. Early and aggressive control of wind-up is critical in the prevention of chronic pain syndromes. NSAIDs appear to confer synergism when used in combination with opioids and may demonstrate an opioid-sparing effect. Significant advantages of NSAIDs include availability, a relatively long duration of action, low cost, and relative ease of administration. Lack of CNS alteration (sedation or dysphoria) make NSAIDs ideal for treating acute and chronic pain in animals. Careful patient selection is critical.

Although a number of NSAIDs have been approved for use in dogs and horses, only meloxicam and robenacoxib are FDA approved for use in cats in the USA. Meloxicam is approved for a single dose and robenacoxib for up to 3 days. As with all analgesic agents, special attention to drug withdrawal times is necessary when using NSAIDs in production animals.

Corticosteroids also reduce inflammation and provide analgesia. Depending on the product, they are administered PO, IV, IM, SC, and intra-articularly. Corticosteroids are used less frequently in the postoperative period because of the potential to decrease

immune function and because of other well-known adverse effects (eg, polyphagia, polydipsia, polyuria) after repeated dosing. However, they are used occasionally in chronic pain syndromes, including PO for degenerative disc disease in dogs and intra-articularly for unresponsive osteoarthritis. Corticosteroids and NSAIDs should not be administered concurrently.

For pharmacology of NSAIDs and corticosteroids, *see* p 2707.

α_2 -Agonists: Xylazine, medetomidine, dexmedetomidine, detomidine, and romifidine are potent analgesics. α_2 -Agonists are used in large animals for inducing restraint and provide both analgesia and sedation, although there is evidence to suggest that sedation lasts longer than analgesia. Combination therapy with α_2 -agonists and opioids induces profound analgesia and sedation that is additive or synergistic as compared with the effects of either drug alone in both large and small animals. The mechanism of action is through G protein-coupled receptors. Alpha 2_A and alpha 2_C receptors mediate analgesia. α_2 -Agonists are used as part of multimodal analgesia in the perioperative period in many species. α_2 -Receptors play an important role in the modulation of pain by the CNS. α_2 -Agonists may be used to induce analgesia when administered as anesthetic premedications (preemptive analgesia), as a constant-rate infusion intraoperatively, and to supplement postoperative analgesia. In general, postoperative doses of α_2 -agonists are considerably lower than would be required preoperatively.

Caution is advised to prevent excessive sedation and concomitant ataxia, particularly in large animals. Furthermore, even at relatively low doses, these agents cause profound reductions in cardiac output and may cause significant arrhythmia in all species. Ruminants in particular require lower doses, and arterial hypoxemia and pulmonary edema have been described in sheep. Careful patient selection is warranted.

Xylazine, medetomidine, and dexmedetomidine (the pure *s*-enantiomer of the racemic medetomidine) may be reversed in small animals after surgery to hasten recovery and minimize cardiopulmonary depression. Once reversed, however, these drugs provide no analgesia.

Ketamine: Ketamine has long been known to provide excellent somatic analgesia but rather poor visceral analgesia. Interest in ketamine has increased because

of its role in preventing sensitization of central nociceptive pathways. Ketamine is an antagonist at the NMDA receptors in the spinal cord and brain. Inhibition of the NMDA receptors prevents or decreases central sensitization (wind-up) in laboratory animals and people. Ketamine may be incorporated into the anesthetic protocol either as a bolus or a constant-rate infusion to prevent development of exaggerated or chronic pain states.

Other Analgesic Agents: **Tramadol**, a synthetic codeine analogue, is a weak mu opioid receptor agonist. In addition to opioid activity, it inhibits neuronal reuptake of norepinephrine and 5-hydroxytryptamine (serotonin) and may facilitate serotonin release. It is recommended for acute and chronic pain of moderate to severe intensity. Because of its inhibitory effects on serotonin uptake, tramadol should not be used in animals that may have received monoamine oxidase inhibitors such as selegiline, in animals on selective serotonin reuptake inhibitors, or in animals with a recent history of seizure activity. In people, the principal active metabolite (O-desmethyl tramadol, M1) is more active at mu receptors than the parent drug. Cats produce significant amounts of M1, whereas dogs produce minimal amounts. Oral bioavailability is 93% in cats but only 65% in dogs. Dogs eliminate and clear tramadol more rapidly than cats. The dosing interval must be adjusted in cats. Adverse effects include decreased seizure thresholds, nausea/vomiting, and in some animals, altered behavior.

There are few clinical studies examining the use of tramadol in animals. However, it has been shown to reduce minimum alveolar concentration of sevoflurane in cats and is reported to have an analgesic effect after ovariectomy similar to that of morphine in dogs. Tramadol may be used alone to treat mild pain and adjunctively in a multimodal plan to treat moderate to severe pain.

Gabapentin was originally developed and licensed as a human anticonvulsant agent and has been approved by the FDA since 1993. Reports of its antihyperalgesic effects in rodent experimental pain models and case reports involving human patients suffering from neuropathic pain suggest increasing evidence for its use in neuropathic pain. The mechanism of action appears to be voltage-dependent Ca^{2+} channel blocker, and it may increase central inhibition or reduce the synthesis of glutamate, even though it does not appear to interact directly with

NMDA receptors. Adverse effects are usually mild and self-limiting (drowsiness, fatigue, and weight gain with chronic administration).

Amantadine, an antiviral agent developed to inhibit the replication of influenza A in human patients, has efficacy in the treatment of drug-induced extrapyramidal effects and in treatment of Parkinson disease. It exerts its analgesic effects through antagonism of NMDA receptors. Amantadine seems most efficacious in the management of chronic neuropathic pain with signs of hyperalgesia and allodynia. Animals suffering from opioid tolerance may also benefit. A 2008 study demonstrated improved activity in dogs with NSAID-refractory osteoarthritis when amantadine was added to meloxicam.

Acetaminophen is not approved for use in animals but has been used effectively for the treatment of breakthrough pain in dogs at a dosage of 10–15 mg/kg, bid, for as long as 5 consecutive days. The exact mechanism of action is unclear, although recent evidence suggests indirect activation of the cannabinoid CB(1) receptor. The so-called COX-3, splice variant of COX-1, has been suggested as an additional mechanism for acetaminophen in dogs. Acetaminophen is not considered a classic NSAID partly because of its low anti-inflammatory action; as such, the risk of thrombocytopenia, bleeding, and GI adverse effects is minimal. Hepatopathy is of concern, and routine serum chemistry evaluation is warranted. Acetaminophen should not be used in cats because of inadequate cytochrome P_{450} -dependent hydroxylation (glucuronidation) and subsequent fatal methemoglobinemia.

Maropitant is a potent selective neurokinin (NK1) receptor antagonist that acts in the CNS by inhibiting substance P, the key neurotransmitter involved in vomiting. It provides visceral analgesia for conditions such as pancreatitis, cholangitis, and painful GI disorders.

LOCAL AND REGIONAL ANALGESIC TECHNIQUES

Local and regional anesthetic techniques are used extensively in large animals for a variety of minor and major surgical procedures. Local anesthetics are used in small animals much less frequently and primarily to facilitate suturing of minor lacerations. Because of the relative ease and safety of inducing general anesthesia in small animals, local and regional anesthetic techniques are often overlooked. Nevertheless, these techniques provide an excellent alternative

to general anesthesia for select cases and are being used increasingly in conjunction with general anesthesia to improve postoperative analgesia. Local anesthetics used before surgery may decrease the requirement for potent injectable and/or inhalant general anesthetics.

Conduction blockade of nerve fibers by local anesthetics is related to the size of the nerve, amount of myelination, and frequency of activity. Small sensory and autonomic fibers tend to be anesthetized before larger motor and proprioceptive fibers. Nerves that are repetitively stimulated are more sensitive to local anesthetics than resting nerves. The most commonly used agents are lidocaine, mepivacaine, bupivacaine, and ropivacaine.

Lidocaine, the prototype aminoamide local anesthetic, decreases minimum alveolar concentration of isoflurane in a variety of species. It also has the potential to decrease ileus in horses after general anesthesia and is used commonly as an adjunct in colic surgery. This has become the theoretical basis for its systemic use as an analgesic agent. Constant-rate infusion of lidocaine has been advocated for pain management in a number of species; notably, a number of combination analgesic protocols (eg, morphine, lidocaine, ketamine [known as MLK]) have been developed for dogs. The use of constant-rate infusion lidocaine during anesthesia is not recommended for cats because of their increased sensitivity and its negative cardiovascular effects.

Lidocaine transdermal patches have been developed for the treatment of neuropathic pain in people. Systemic absorption of lidocaine in dogs and cats has been reported to be minimal, while local tissue concentration is reported to be as much as 100 times greater than plasma concentration. The low systemic absorption rate coupled with high local lidocaine concentrations on the skin support the safe use of lidocaine patches in dogs and cats. These patches appear to result in a differential blockade, preserving sensory function of the skin and motor function of regional muscles while inducing analgesia at the site for as long as 72 hr. However, further clinical efficacy studies are warranted. Patches must be applied close to the site of pain, and toxicity is of concern if the patch is orally ingested.

EMLA cream, a eutectic mixture of 2.5% lidocaine and 2.5% prilocaine, has been used to decrease venipuncture pain in children and has been evaluated for use in dogs, cats, rabbits, horses, and pigs. Significant results are not achieved until the cream has been in

place for 60–90 min beneath an occlusive dressing. Nonclinical methemoglobinemia, lasting as long as 24 hr, has been reported in children. Repeated dosing of neonatal or small animals should be done cautiously.

Bupivacaine is the preferred drug for postoperative analgesia because of its relatively long duration of action (~3–8 hr). Bupivacaine (0.25–0.75%), with or without epinephrine, is administered in a dosage not to exceed 3 mg/kg (dogs) for line or ring blocks of an incision, ring blocks before declaw in cats (epinephrine-containing solutions should not be used for distal extremity ring blocks), intercostal nerve blocks and intrapleural local anesthesia (diluted to twice the volume) after a thoracotomy or the management of pain associated with pancreatitis, proximal nerve infiltration during limb amputations, regional anesthesia in which a nerve proximal to the surgical site is targeted, tissue infiltration for lateral ear resections, and local blocks of facial nerves (maxillary, infraorbital, mental, and mandibular). Bupivacaine is frequently administered into the epidural space at the lumbosacral space for pelvic limb and perianal procedures. Bupivacaine is cardiotoxic if administered IV.

Ropivacaine is a long-lasting amide-type local anesthetic. Its duration is similar to that of bupivacaine, but it has lower potential to induce cardiovascular and CNS toxicity.

Topical capsaicin, the active component in chili peppers, has been used extensively to treat pain associated with diabetic neuropathy, post-herpetic neuralgia, and osteoarthritis in people. Capsaicin binds to the TRPV1 receptor on nonmyelinated primary afferent pain fibers, causing increased firing through the release of substance P. With repeat application, desensitization occurs due to degeneration of these pain fibers with resultant hypoalgesia. Reinnervation occurs when use is discontinued. No controlled studies have been published in veterinary species; however, one study using intrathecal resiniferatoxin, a potent analogue of capsaicin, reported encouraging results for palliative treatment of pain in a canine osteosarcoma model. The benefits of these TRPV1 ligands include specific loss of pain sensation without concomitant loss of motor and nonpain sensation.

CHRONIC PAIN

The treatment of chronic pain relies on pharmacologic and nonpharmacologic methods. Commonly treated chronic pain

syndromes include osteoarthritis, nonsurgical intervertebral disc disease, and laminitis. Some chronic pain responds to drugs used to treat acute pain, such as opioids and NSAIDs; however, other types of chronic pain require the addition of novel drugs such as gabapentin, tramadol, acetaminophen, and amantadine. Regardless of the cause or the species, chronic pain is itself a dynamic disease process requiring careful assessment and frequent reassessment. Therapy is rarely monomodal, and adjustments in therapy are necessary over time.

The nonpharmacologic treatment of chronic pain depends on the underlying cause and the species. Among these therapies are acupuncture, rehabilitation, nutraceutical supplements, low-level laser, massage, transcutaneous electric nerve stimulation, and herbal supplements. The body of literature critically examining these is relatively small. (See *also* COMPLEMENTARY AND ALTERNATIVE VETERINARY MEDICINE, p 2078).

Osteoarthritis Pain: Osteoarthritis is the most common reason for persistent pain in people, dogs, cats, and horses. The nonpharmacologic goals to manage osteoarthritis pain include increasing mobility, limiting disease progression, and possibly facilitating tissue repair within the joint. Weight control or reduction and mild to moderate daily exercise are beneficial. Excessive and strenuous exercise should be avoided, because it may further strain the joints and exacerbate pain, thus limiting the ability to exercise routinely. Providing warmth during cold and damp weather and extra bedding or padding may also improve comfort. Surgical removal of bone fragments and osteochondritic lesions and the restoration of joint stability is often necessary to slow the progression of disease and reduce pain. Joint replacement or arthrodesis may be indicated in severe cases. Orthotic bracing may be beneficial in small

animals when surgical intervention is not appropriate. A number of studies using chondroprotective agents such as polysulfated glycosaminoglycans, chondroitin sulfate, glucosamine, and hyaluronic acid suggest a benefit through stimulation of cartilage matrix synthesis and inhibition of enzymatic degradation of cartilage. However, the efficacy of these agents may vary with specific product used, route of administration, and underlying conformational, pathologic, and neurologic issues. Recent work in regenerative medicine, including the use of autologous adult stem cells, may prove highly effective as well. Finally, acupuncture and rehabilitation therapy have been used to treat chronic osteoarthritis pain in a number of veterinary species with promising results.

Cancer Pain: Cancer pain presents a unique clinical challenge. Components of cancer pain are tumorigenic (tumor-related products), inflammatory, and neuropathic. Similar to other forms of chronic pain, it does not always respond adequately to common therapies. Opioids remain a cornerstone of treatment and are usually one part of a multimodal plan. Other analgesics include NSAIDs, tramadol, acetaminophen (in dogs), and amantadine for its ability to decrease wind-up. An opioid and an NSAID are routinely used in combination because of their synergistic analgesic effect. Recently, bisphosphonates have been used to treat osteolytic pain associated with bony metastasis. Pamidronate is the synthetic analogue of inorganic pyrophosphate. It has proved useful in pain palliation because of its ability to adsorb to bone mineral matrix, inhibit pathologic lysis induced by osteoclasts, and delay progression of bony metastatic lesions.

Similar to all chronic pain syndromes, cancer pain management requires frequent assessment and reassessment combined with appropriate adjustments in therapy.

STRAY VOLTAGE IN ANIMAL HOUSING

The term stray voltage describes a special case of voltage developed on the grounded-neutral system of a farm and is defined as <10 volts (measured as the root-mean-square value of 50 or 60 Hz alternating voltage, V_{rms}) between two points that can be contacted simultaneously by an animal

(animal contact voltage). The grounding and neutral systems on a farm or in a home wiring system should be properly bonded to ensure electrical safety. As a result, some level of voltage between the grounded-neutral system and the earth (neutral-to-earth voltage) is always present as a normal

consequence of the operation of properly installed electrical equipment. The term stray voltage is often applied incorrectly to other electrical phenomena such as electric fields, magnetic fields, electric current flowing in the earth (earth currents), or electric current flowing on a grounding conductor (ground currents). Electric currents flowing in the earth or on grounded metal objects will affect animals only if sufficient animal contact voltage is developed.

If stray voltage reaches sufficient levels, animals coming into contact with grounded devices may receive a mild electric shock that can cause a behavioral response. At voltage levels that are just perceptible to the animal, behaviors indicative of perception (eg, flinches) may result, with little change in normal routines. At higher exposure levels, avoidance behaviors may result. Contact voltages <10 Vrms are not lethal to farm animals or people. If neutral-to-earth voltages >10 Vrms are measured on a farm, the safety of the farm wiring system should be carefully evaluated by a competent electrician.

Animals respond to the current flowing through their bodies. Ohm's law describes the relationship between voltage exposure and current conducted through an animal: $\text{current} = \text{voltage} / \text{resistance}$ or $\text{amps} = \text{volts} / \text{ohms}$

This simple relationship has been a source of much confusion and resulting controversy. Ohm's law indicates that if the voltage across animal contact points is increased, the current flowing through the animal will increase. If the resistance of the circuit is increased, the current flowing through the animal will decrease. The current measurement used in most studies is the milliamp (mA) or 1/1,000th of an amp. Applying Ohm's law to a circuit with contact voltage of 1 Vrms across a resistance of 500 ohms results in current flow of 2 mA.

In most situations, cows are less sensitive to current and more sensitive to voltage than are people. While the resistance of bovine and human tissues is similar, the contact resistance is often lower for cows than for people, particularly in wet environments. The resistance of a cow's body plus the contact resistance with the floor is estimated as 500 ohms for a cow standing on a wet floor. Cows standing on a dry surface typically have body plus contact resistance of $\geq 1,000$ ohms. Cows standing or lying on dry bedding have a resistance many times higher than this. The resistance of a person can be as low as 1,000 ohms for wet hand-foot contact to >10,000 ohms for dry

hand-foot contact. The contact voltage to produce sensation can therefore be higher for people than for cows, depending on the conditions of the contact points. The standard measurement circuit used for field investigations uses a 500-ohm "shunt" resistor to simulate the combined resistance of a cow's body plus a conservative (lowest or worst case) estimate of the resistance of the two contact points (cow + contact resistance).

A great deal of research on the effects of stray voltage on dairy cows has been conducted throughout the past 50 yr. The most sensitive cows (<1%) begin to react to 60 Hz electrical current of 2 mA (measured as the root-mean-square average, or rms) applied from muzzle to hooves or from hoof to hoof. This corresponds to a contact voltage level of ~1 Vrms in wet locations or >2 Vrms in dry locations. Numerous studies have documented that avoidance behaviors occur at exposure levels well above this first behavioral reaction threshold. As the current dose increases above 2 mA, an increasing percentage of cows show mild behavioral responses, and some cows start to show avoidance behaviors. The median avoidance threshold for 60 Hz current flowing through a cow is ~8 mA (or 4 Vrms contact voltage in wet locations and >8 Vrms in dry locations). Even when the threshold is exceeded, all cows do not respond behaviorally all the time, nor do they exhibit the same signs; however, as the voltage increases, signs in the herd become more widespread and uniform. Cows have resumed normal behaviors within 1 day of removal of aversive voltage and current levels.

The only studies that have documented reduced water or feed intake in cows had both sufficient current applied to cause aversion and forced exposures (ie, cows could not eat or drink without being exposed to aversive voltage and current). It is typical for voltage levels to vary considerably through the normal daily operation of electrical equipment on a farm. Decreased feed and/or water intake will result only if current exposure levels at watering and feeding locations are sufficient to produce aversion at these locations and they occur often enough to interfere with drinking and eating behaviors. If an aversive current occurs only a few times per day, it is not likely to have an adverse effect on cow behavior. The more often aversive current exposures occur in areas critical to drinking or feeding, the more likely it is to affect the cows.

Studies investigating the effects of high-frequency or short-duration transient voltages on cows clearly indicate that as the

duration of a current pulse gets shorter (or the frequency increases), more voltage and current is required to cause behavioral responses. The main cause of short-duration electric pulses on farms is improperly installed electric fences and electrified crowd gates. These devices are designed to produce a powerful electric impulse that is used to control animal behavior. Improper installation of these devices can cause these pulses to appear in unintended areas on the farm. The other common source of high-frequency events is a switching transient that occurs when electric equipment is turned on or off. These high-frequency pulses decay quickly and do not travel far from their source, and it is extremely rare for them to reach problematic exposure levels.

Research suggests that swine respond to voltage/current exposure in a way similar to that of cows. Behavioral modification in swine has been seen above 60 Hz exposures of ~5 Vrms, with avoidance behaviors at exposures >8 Vrms. The body plus contact resistance for swine appears to be somewhat higher than for cows, and 1,000 ohms appears to be a conservative value for measurement purposes. Ewes have been shown to avoid electrified feed bowls when 60 Hz exposure levels exceed 5.5 Vrms, whereas lambs showed this same preferential behavior when exposure levels exceeded 5 Vrms. Exposures to voltages as high as 18 Vrms had no effect on hens' production and behavior. This is likely because of the very high electrical resistance of poultry, which has been documented to be between 350,000 and 544,000 ohms.

Clinical Findings: A wide variety of behavioral signs have been reported in cows exposed to voltage and current. No one sign is pathognomonic, however, because these behaviors can also be caused by other factors in the animal environment. The only way to determine whether stray voltage is a potential cause of abnormal behaviors is to perform electric testing.

The direct effects of stray voltage can range from mild behavioral reactions indicative of sensation to intense behavioral responses indicative of pain. The severity of response depends on the amount of electric current flowing through the animal's body, the pathway it takes through the body, and the sensitivity of the individual animal. The indirect effects of these behaviors can vary considerably depending on the specifics of the contact location, level of current flow, body pathway, frequency of occurrence,

and many other factors related to the daily activities of animals. All of the documented effects of excessive voltage exposure have been behaviorally mediated.

Results of studies to investigate direct physiologic effects that may be produced at levels both above and below those required to produce behavioral responses have shown that blood cortisol concentrations and other stress hormones do not increase at levels below behavioral response levels. Increases in stress-related hormones have been documented in some, but not all, cows at voltage/current exposures substantially higher than the threshold required for behavioral modification. A large body of research clearly indicates that at levels of voltage exposure typically used as regulatory limits (1 volt at cow contact locations, or 2 mA of current flow through a cow) will not result in increased somatic cell counts or incidence of mastitis.

Diagnosis: Several common situations are of concern in animal environments, including 1) changes in drinking behavior, such as decreased number of drinks of water per day and increased length of time per drink; 2) avoidance of locations that may result in reduced feed or water intake; and 3) difficulty of moving or handling animals in some areas. If these behaviors are seen, electric testing indicating cow contact exposure in excess of 4 mA (2 Vrms in wet locations with a 500 ohm cow + contact resistor, or 4 Vrms in dry locations with a 1,000 ohm cow + contact resistor) is necessary to confirm a stray voltage diagnosis. Signs in pigs, ewes, and poultry are similar, although threshold response levels are higher than for cows.

It is critically important to use a realistic value of animal resistance to relate voltage exposures to the level of current conducted through an animal and the resulting effects on nerve stimulation, sensation, and behavioral reaction. A competent field investigation will include voltage measurements at cow contact locations both with an appropriate "shunt" resistor (cow contact voltage) and without a shunt resistor (open circuit voltage). The shunt resistor is meant to represent the resistance of the body resistance of a cow plus the contact resistance representative of the exposure location. Both animal-contact and open circuit voltage measurements are required to determine the "source resistance" of the electric parts of the circuit. Note that source resistance is different from the cow contact resistance and can be used as a diagnostic to determine the voltage source.

Animal-contact voltage levels should be monitored at different times of the day and on different days to represent the normal operating conditions of the farm electrical system. Point-to-reference ground measurements can be useful for diagnostic purposes. A reference ground can be established with a copper-clad rod driven into the ground at least 25 ft (8.5 m) from any part of the grounding network on the farm. The other contact point is typically the ground-neutral interconnection in the barn service entrance panel or some other part of the grounded-neutral system. Cow contact measurements are typically $\frac{1}{2}$ to $\frac{1}{3}$ of point-to-reference voltage levels.

Long, insulated meter leads (6–10 ft [2–3 m]) facilitate measurements on the farm and give a reasonable estimate of power frequency (60 Hz and 50 Hz) events but introduce considerable noise to higher frequency measurements. The measurement of high frequency events requires proper equipment and careful measurement technique. Details on measurement techniques are available through electric power suppliers and extension publications.

Prevention and Control: Off-farm sources of stray voltage are most often related to improper function of the grounded-neutral system of the electric utility. On-farm sources of stray voltage are most often due to wiring systems that do not meet wiring codes and standards. Deficiencies may include loose or corroded connections; ground faults (shorts); undersized wiring; or wiring damaged by animals, accidents, moisture, or corrosion.

The first step in a competent stray voltage investigation is to determine the source of neutral-to-earth voltage. Faults or electric code violations that could pose an electrocution hazard should be corrected immediately to protect both animals and people. If stray voltage levels are excessive, a competent electrician should assess the situation to determine the most practical, safe, and efficient way to reduce neutral-to-earth voltage. Equipotential planes are required at critical animal contact locations in animal confinement facilities and effectively eliminate contact voltage even if substantial levels of neutral-to-earth voltage are present.

VENTILATION

Ventilation is often associated with respiratory health of animals; the quality of the air that animals breathe directly influences animal health and disease. Ventilation, directly and indirectly, impacts many other aspects of animal health as well. Good ventilation in the lying area of lactating animals helps bedding stay dry, a factor in favor of good mammary health. Good ventilation along alleys helps to keep walking surfaces dry, which contributes to healthy feet. Good ventilation may lead to greater productivity, eg, maintaining air movement in the eating area makes animals more comfortable, especially important during hot weather as an aid to maintaining dry matter intake. A comfortable, well-ventilated lying area encourages animals to lie down, an important contribution to many aspects of animal health.

During ventilation, outside air is brought into a barn where it collects moisture, heat, and other contaminants. Air is then exhausted to the outside. To determine ventilation rates, the focus is on the

moisture content of the air, measured by relative humidity.

AIR QUALITY

Air quality is not easily defined. It is related to ventilation and the absence (or presence) of contaminants in the air. For animals, good air quality generally implies that the ambient air causes no harmful effects on the animals in the space. Ambient air contains varying amounts of water vapor. Moisture in the air becomes a problem when it exceeds the relative humidity range of 60%–75% preferred for animals; above this level, it is considered to be an air contaminant. Other contaminants may include pathogens, harmful gases, dust, and undesirable odors. Concern arises from the concentration of a contaminant above some predetermined level rather than the mere presence of the contaminant itself.

Numerous viral pathogens known to survive in aerosols are apparently spread by the airborne route. Two factors can be

significant in the relationship between microbial aerosols and disease incidence: 1) the survival time of the aerosolized pathogen, and 2) the total number of pathogens per volume of air (ie, concentration). Survival is influenced by conditions of the ambient air; conditions of the ambient air and concentration are related to ventilating air.

Relative humidity is the most important factor influencing pathogen survival and concentration, but its effects vary greatly between pathogens—some survive best in humid conditions, others survive best in dry air. Maintaining a relative humidity in the range of 60%–75% apparently results in the shortest survival time for the greatest number of potential pathogens. Ventilation is used to remove moisture from an animal space with the intention of maintaining relative humidity in this range. Inside air is diluted with outside air, reducing moisture levels. Continuous replacement of contaminated air with fresh, outside air is also the most effective way to reduce the concentration of aerosol pathogens.

Most likely, reducing the concentration of any air contaminant, including gases and dust, is important to reducing its detrimental effect. For example, ammonia is produced by the decay of feces and urine and is probably the most significant air pollutant in cattle barns. Allowed to accumulate, ammonia's irritating effects on the respiratory epithelium appear to directly reduce the number of ciliated cells and thus decrease the efficiency of mucociliary transport.

THE DILUTION EFFECT OF VENTILATION

Dilution reduces heat and concentrations of moisture, as well as concentrations of airborne disease organisms, harmful gases and dust, and undesirable odors. The dilution rate of ventilation is often expressed in air changes per unit time. For example, a ventilation rate of 4 air changes/hr implies that the entire volume of the ventilated space is replaced 4 times every hour. In fact, some of the air may bypass the occupied zone in the barn, depending on geometry of the space, design of diffusers controlling inlet air, etc. Therefore, the effectiveness of ventilation is not 100% but perhaps approaches 65%. Ventilation effectiveness becomes important to the actual dilution achieved by a particular rate of ventilation (ie, to the ability of ventilating air to reduce the concentrations of contaminants in the animal space). For

a ventilation effectiveness of 1.0, one air change would achieve a complete change of air in the space, yielding a 100% reduction in contaminant levels (if the condition of the outside air is considered to be the reference standard). But if ventilation effectiveness is only 0.65, one air change will reduce contaminant levels by only 65%. As ventilation effectiveness diminishes, the ventilation rate required to achieve a certain air change rate increases.

When ventilation is reduced below recommended levels—usually in a misguided effort in cold climates to warm the barn using animal heat—less moisture is removed. Sometimes the consequences of the resulting moisture buildup and lack of proper ventilation (eg, condensation) are masked by insulating the barn, using a greenhouse effect, providing supplemental heat, or dehumidifying the inside air. For example, adding heat to the air reduces relative humidity, without the need for air exchange. It is quite possible to maintain substantial quantities of moisture in the air and, if accompanied by heating, keep the relative humidity within an acceptable range. If relative humidity is the only measure of air quality, it may be deemed to be satisfactory. However, even though excess moisture may not be apparent, the reduced dilution does result in increased concentrations of airborne disease organisms, harmful gases and dust, and undesirable odors. If these increases are ignored, animal health problems are inevitable. In addition, heating of barns is rarely economical in cold climates.

COLD WEATHER VENTILATION

A minimal ventilation rate is required in animal housing in cold weather, regardless of outside temperature. This minimal rate is necessary whether the barn is designed to be a warm barn or a cold barn in winter. In addition, the minimal ventilation should be continuous to maintain concentrations of contaminants in the air at minimal levels. The minimal rate depends on outside weather, design conditions, animal factors (number, type, age, and size), and whether the barn is intended to be cold or warm.

Barn Categories and Winter Temperatures

Barn environments can be categorized according to temperatures maintained in the barn in winter. The particular environment, based on desired indoor temperature, must be established before

ventilation system design can begin. In **cold barns**, indoor temperatures are allowed to fluctuate with outdoor temperatures. Ventilation is sufficient to maintain indoor temperatures within 3° – 6°C of outdoor temperatures. Ventilation is largely unregulated, except to adjust for seasonal changes. In general, a cold barn with natural ventilation has no insulation, an open ridge and eaves, and sidewalls and endwalls that open. Providing an open ridge along with open eaves has long been recognized as a way to use a stack effect to cause air exchange, especially to control moisture in winter. Indoor temperatures are expected to be a few degrees warmer than outdoor air temperature because of the heat given off by the animals being housed. Current recommendations call for providing a ridge opening of 5 cm per 3 m of barn width and equivalent open area divided between the two eaves. Raised ridge caps are to be avoided. Their performance is unpredictable because of local wind patterns, which often channel winds into the structure and increase the entry of snow and rain. The combination of the open ridge and eaves should be viewed as the sole source of ventilation only during the most severe winter weather, ie, during periods when temperatures reach the lowest levels or times when conditions are especially windy or stormy. During all other times in winter, additional ventilation should be provided.

Warm barns are well insulated and, by necessity, have well-controlled ventilation systems. These barns are designed to provide a relatively uniform environment throughout the winter. Tie stall barns for dairy cows (indoor temperatures at least above freezing) and farrowing and nursery barns for swine (indoor temperatures 25° – 30°C) are examples of this type of housing. Keys to success include ventilating fans and controls chosen to match the needs of the animals being housed, a well-insulated building, supplemental heating (if required), and a ventilation system that is well managed and regulated to compensate for changing outside climatic conditions.

Some barns do not fit into either the warm or cold category. **In-between or modified environment barns** usually have indoor temperatures in winter above freezing. These buildings have some insulation, perhaps only under the roof, and are naturally ventilated (usually with an open ridge, eaves, and sidewalls). Unfortunately, even though a minimal

ventilation rate is always necessary, ventilation openings may be closed or blocked during extreme weather to keep manure from freezing and for other reasons. This practice can result in inside temperatures rising 10° – 20°C above the outside temperature, significantly higher than the 3° – 6°C temperature difference limit considered acceptable for cold barns. This alone can create problems because of excess moisture buildup and a high relative humidity. Even more seriously, openings remain closed or blocked after severe weather conditions have passed. As a consequence, blocked ventilation openings restrict airflow during less severe conditions, resulting in underventilation and poor environmental conditions. A properly designed and managed in-between barn is more like a warm barn, in terms of both design and operation, than a cold barn. Thus, to avoid problems, the design and management of in-between barns should follow the guidelines for a warm barn.

Consequences of Mismanaged Ventilation in Winter

Underventilation in winter is one of the most serious threats to the environment of animals. Both improper design and improper management of the ventilation may compromise animal health. In colder climates, problems are most likely during winter, spring, and fall, especially during rainy weather and warmer days coupled with cold nights.

Reduced Dilution of Ambient Air:

Adjusting ventilation for severe winter weather and not readjusting to allow increased ventilation for milder winter weather appears to be a major reason for air quality problems in barns in winter. This is especially true for cold barns with manually controlled natural ventilation. For example, ventilation openings are closed in anticipation of a windy, cold, blustery night, but are not opened the next day when, although the temperature may still be cold, the wind subsides and the sun shines. The lack of wind reduces ventilation and thus air exchange and the positive effects of dilution.

Sometimes, good ventilation system management does call for openings to be reduced. For example, a slot inlet in a mechanically ventilated tie stall barn may be adjusted, or fabric may be placed over an open sidewall to match the lower ventilation rate in winter. All openings should

never be covered, however, because this leaves no means of air exchange for moisture control.

Building Components Affected by Poor Ventilation: In addition to adversely affecting the animal environment, the design and operation of naturally ventilated barns also influence moisture-related deterioration in wood members and metal fasteners. In naturally ventilated dairy free-stall barns in Michigan, where air exchange in winter was defeated by blocking ventilation openings, average wood moisture contents >30% dry basis (capable of supporting wood decay and corrosion in metal fasteners) were found after 2–3 mo of cold weather operation. Moreover, restricted air movement in these barns inhibited drying and allowed wood moisture content to remain high even during warm weather. Warm, moist conditions favor growth of mold, bacteria, and decay fungi and accelerate metal corrosion. The presence of insulation under the roofing in these barns fostered the situation. In barns in which design details and management efforts allowed optimal air exchange rates, increases in moisture were minimal. Even if free water from precipitation and condensation caused slightly increased moisture contents, adequate air exchange, especially during warm weather, promoted drying of wood truss components so that deterioration was not a problem.

WARM WEATHER VENTILATION

In barns with natural ventilation, the combination of the open ridge and eaves is the source of ventilation during the most severe winter weather, ie, during periods

when temperatures reach the lowest levels or times when conditions are especially windy or stormy. During all other times in winter, however, additional ventilation must be provided. Typically, doorways are left open, portions of the end wall sections of the gable roof may be left uncovered, or sidewalls away from prevailing winter winds may be left open for this purpose. Then, as temperatures rise into spring and summer, sidewalls and end walls are fully opened. As a general rule, too much ventilation is preferred over too little.

Hot, muggy summer weather is one of the most critical times for animal health, comfort, and productivity. For barns with natural ventilation, completely open sidewalls and end walls allow wind to blow through the animal zone for heat stress reduction. However, when winds are calm, providing adequate air movement to avoid heat stress is difficult. Supplemental cooling can be provided in several ways. Fans are commonly used to increase air movement. The increased air velocity over the skin increases the rate at which animals are able to dissipate excess body heat. Two other methods rely on evaporative cooling to either cool the air around the animals or wet the animal's skin and allow body heat to evaporate the water. However, water should be added to the animals' environment only if ample air movement is present.

Barns with mechanical ventilation require staged fans to provide ventilation ranging from the minimal continuous rate, through an intermediate rate for spring and fall, to a high rate for summer. An air exchange rate of 60 air changes/hr is considered the absolute minimum for summer. Often, ventilation rates of 90–120 air changes/hr are provided for hot weather.

HEALTH-MANAGEMENT INTERACTION: BEEF CATTLE

BEEF CATTLE BREEDING HERDS

Several managerial practices increase productivity within cow-calf herds when they can be implemented economically and practically. These practices are mostly associated with reproduction, because improvements in herd fertility generally offer potential for increased profitability

in cow-calf operations. They include a restricted breeding season, identification of the optimal calving season, a good heifer replacement program, heifer reproductive tract scoring, proper nutrition, good herd health, bull breeding soundness examinations, crossbreeding, and maintaining good records. Other management practices associated with increased beef herd profitability include decreasing unit cost

of production, use of growth promotants in calves, internal and external parasite control, improved calf management, management-intensive grazing, preconditioning of calves, and having a marketing plan.

REPRODUCTION

In most regions of the world, there is an optimal period for females to calve, suckle, and rebreed. This period is mostly related to nutritional opportunity, although other environmental factors such as cold or heat stress and parasite populations may play a role. Producers have traditionally aimed for females to calve during this optimal period because they tend to breed back faster, and their calves are more likely to thrive, than females that calve at less opportune times. Benefits of restricted breeding seasons (65–80 days) include enhanced production potential, favorable environmental factors, a concentrated calving season and more homogeneous calf crop to sell, increased opportunities to perform prebreeding management procedures and monitor nutrition, improved female replacement and culling procedures, and the ability to detect problems early, using herd pregnancy diagnosis and breeding season evaluation. (See *also* MANAGEMENT OF REPRODUCTION: CATTLE, p 2171.)

Pregnancy Testing: The longterm goal is to develop a beef herd of uniform, low-maintenance cows that thrive in their given environment. This goal is strengthened by having a restricted breeding season in which open cows are culled from the herd. Often, these cows are too big, produce too much milk, or lack inherent fertility compared with cows that are pregnant year after year. In herds that are years away from this goal, instead of simply calling cows pregnant or open, cows should be sorted by projected calving date and body condition score (BCS). The herd pregnancy diagnosis represents an important starting point for beef herd diagnostics and advice and is a pivotal component for informed decision making. It allows analysis of group patterns for problem solving (breeding soundness evaluation, *see* below), as well as sorting of animals into groups for specific purposes such as strategic feeding, calving supervision, culling, or rebreeding. Herd pregnancy diagnosis facilitates the selection of replacement females and culling for infertility.

Breeding Soundness Evaluation:

Reproductive performance is influenced by

many factors, including sire fertility, herd health aspects, and opportunities to mate. Breeding soundness evaluation is a technique to assess the reproductive performance of the cow herd. It includes obtaining relevant information, analysis and interpretation, and recommendations for improvement. One measure of reproductive performance is the number of bred females that actually raise a live calf. Other valuable information may be obtained from an analysis of the distribution of pregnancies (and calvings) that resulted from a particular breeding season. This distribution may be studied on the basis of timing (eg, 21-day estrus periods), breeding groups, female age or parity, nutritional opportunity (eg, BCS), etc. Such analyses provide the basis for evaluation of either the breeding or calving season. For evaluation of the breeding season, good records must be obtained at the time of pregnancy testing for the subsequent analysis to be valid.

Because reproductive performance is an important economic trait in the cow herd, the reproductive capabilities of breeding bulls assume great importance. The best assurance that a bull is likely to be fertile is a successful breeding soundness evaluation (*see* BREEDING SOUNDNESS EXAMINATION OF THE MALE, p 2230). A rule of thumb for bulls is that they can breed ~1 cow/mo of age in a breeding season of 65–80 days. For example, a 38-mo-old bull that passes his breeding soundness examination should be able to breed 38 cows in 65–80 days. This rule can be applied to bulls approximately 14–50 mo old, with 50 cows per bull being the maximum.

CULL COW SELECTION AND MANAGEMENT

Culling of cattle in a beef operation usually implies removing those that cannot meet or maintain performance and economic criteria for the herd. Other reasons may include physical or temperament problems in animals, as well as judicious culling during periods of environmental hardship or economic necessity. The judicious removal of nonperforming females is also important to maintain or improve herd fertility. However, the assumption that cull cows are necessarily infertile may not always be correct; recent surveys indicate that ~43% of cull cows in the USA are pregnant at the time of culling. All “open” females are not necessarily infertile. Identification of appropriate candidates for

culling is critical and should be an important component of pregnancy testing.

NUTRITIONAL MANAGEMENT

Nutrition is the most important limiting factor of beef herd reproductive performance. An understanding of the principles underlying the nutritional management of breeding females is necessary, including a working knowledge of the different energy measuring systems commonly used and their applications for different classes of animals, activities, and feedstuffs. (*See NUTRITION: CATTLE*, p 2248.) Increasing stocking rate tends to cause increased gain per unit land area but can result in decreased gain per animal. The key is to have these two factors in balance so that pasture land is optimally grazed and gain per animal is adequate. Overgrazed pasture is detrimental to the environment and can severely reduce gain per animal.

Nutritional requirements vary throughout the year. The most critical periods for reproduction are immediately precalving, when fetal growth is maximal along with lactation preparation, and early postcalving, when maximal lactation is combined with the need for rebreeding. (*See also* MANAGEMENT OF REPRODUCTION: CATTLE, p 2171.)

Environmental conditions can strongly influence the nutritional requirements and intake of cattle. For example, cold weather increases energy needs, whereas hot or inclement weather can reduce foraging opportunity. The quality and quantity of range forage varies greatly throughout the year and between years, influenced by moisture, soil fertility, plant species, and grazing pressure. Seasonal changes in the nutrient density of rangeland forages are mainly associated with the degree of plant maturity. In general, the greatest nutritional value of plants develops before maturity. Good nutritional management involves matching, as far as possible, the nutrient requirements of cows and nutrient density of the pasture by careful consideration of factors such as the types of animals involved, stocking rates, plant species available, season of grazing, fertilization, and grazing methods used.

Body Condition Score: Accurate and timely determination of the nutritional status of grazing animals represents a challenge for beef producers, because many variables can influence a cow's response to a given level of nutrition. The use of a BCS is an effective indirect method to determine

nutritional status in breeding females. The BCS represents a subjective assessment of body fat (or energy reserves) that is strongly related to female reproductive performance. BCS, and changes in BCS, appear to be more reliable indicators of nutritional status than is body weight or changes in body weight, which can vary with gut fill and pregnancy status. In addition, BCS can often be assessed more conveniently than body weight can be measured. BCS is both repeatable and accurate in experienced hands. It is best done through visual appraisal, reinforced by palpation of body regions most likely to demonstrate fat deposits. Group observations of BCS made from a distance when animals are in the pasture or paddock are less accurate than those made when animals are nearby in the pen or chute.

BCS varies throughout the year and should be monitored regularly. In the 1–9 BCS system widely used in North America, the reference standard for beef females is a BCS of 5, which represents an average, moderately fleshed cow that is neither fat nor thin. However, the BCS for optimal female efficiency varies with breed and operation and may be higher or lower. In general, cows should calve when they are between condition scores 5–6 (heifers 6–7) and then regain the weight lost at calving and gain slightly until breeding. It generally takes ~2 mo to gain 1 score (75–100 lb [34.1–45.5 kg]) for nonlactating cows under pasture conditions. Care should be taken not to rely on averages, because these can mask variations that might adversely affect herd fertility.

Whereas BCS at calving has been long proved to impact reproductive success, recent studies have demonstrated that an increasing BCS from after calving to breeding is just as important or can be more important than precalving BCS in terms of herd fertility. The concept of increasing BCS just before breeding is especially true of yearling heifers. These heifers are often developed on more of a feedlot type ration during the winter and then turned out to pasture at breeding time. This causes a decrease in available energy, which can significantly decrease first-service conception rate. Solutions to this are to feed a lower energy ration during the development stage and to add additional energy to the diet after pasture turn-out.

The BCS of females at calving can provide much information about their rebreeding prospects. However, assessment of BCS at this time provides a relatively short length of time in which to meet targets if cows are too thin. Assessment of BCS in females at

breeding should provide the most accurate prediction of herd fertility, because it is done just before the predictive event. The disadvantage is that there is no opportunity to correct significant shortfalls in time to affect the current breeding season. Assessment of BCS at the time of pregnancy checking has the advantage of not requiring a separate animal handling. It also allows considerable time to remedy obvious deficiencies before calving and subsequent rebreeding. The disadvantage is that, although it can provide clues to explain current pregnancy patterns, it is again too late to remedy them. The ideal time to assign BCS to cows is ~2–3 mo precalving. This gives ample time to move cows to an optimal precalving BCS, because BCS at calving is highly correlated to herd fertility. It is best if someone other than the owner (eg, veterinarian, extension specialist, etc) does the BCS evaluation of the herd, because the owner sees the cows every day and is less likely to see changes.

HEALTH AND PRODUCTION MANAGEMENT PROGRAM

A cost-effective herd health and production management program is essential for the economic viability of cow-calf operations. Such programs vary by region, relative economics, perceptions, and opportunity. A good herd health program manages risk of disease and lowered productivity at a number of levels, including considerations of biosecurity, nutrition, and the judicious use of biologics and parasiticides.

One starting point for such a program is to identify current production losses by comparing the performance of the particular herd with relevant standards, eg, from regional or national surveys, which can also provide an economic estimate of losses.

The major disease risks for a given herd, along with appropriate preventive measures, should be established in consultation with herd owners. The best times for herd intervention must be identified. These often coincide with other managerial tasks and can be synchronized to minimize herd disruption and labor costs. One approach is to devise a herd-health “calendar” in which the health events are coordinated with major operational events. Interventions for a particular herd vary based on factors such as available labor, normal herd working dates, calf weaning dates, calf management practices, and previous disease problems.

VACCINATIONS

Prebreeding vaccinations should be completed ~4 wk before the start of breeding and should be based on local patterns of disease and state and national requirements. Replacement females should be vaccinated with the same vaccines given to mature females before breeding.

Precalving vaccinations are intended to protect the newborn calf through colostrum transfer. The most common immunizations are those that offer protection against some of the infectious causes of diarrhea in neonatal calves. Others are based on local patterns of disease. Many of these vaccines have variable results when used in field conditions and should not be used in substitution of excellent management practices.

Prewearing is an important intervention that can help prepare calves for the stress of weaning and reduce the possibility that such stress will compromise the efficacy of biologicals. Common vaccinations include those against the clostridials and bovine respiratory disease complex (BRD). A broad-spectrum anthelmintic should also be given at this time, because calves that have been on pasture have almost certainly been exposed to internal parasites. At weaning, a second vaccination should be given for those products recommending two injections. Modified-live virus (MLV) products should be given at this stage. Another clostridial vaccination is not indicated if calves were previously vaccinated at working and preweaning. For areas where brucellosis is under regulatory control, heifers should be vaccinated appropriately within the age ranges stipulated.

Bulls should receive the same vaccines as the cow-calf herd, with some exceptions. Bulls should not be vaccinated for brucellosis. Also, the trichomoniasis vaccine currently approved for use in the USA is not approved for bulls. Caution is advised with MLV infectious bovine rhinotracheitis vaccines, because this virus may recrudesce in bulls and be shed in semen; the manufacturer's technical services veterinarian should always be asked if this is a concern. Also, if MLV infectious bovine rhinotracheitis vaccine is used, semen shipment to other countries may be jeopardized.

CALF MANAGEMENT

Management of the calving season is critical to optimize the weaned calf crop. Research indicates that 57% of mortality is seen in the

first 24 hr and 75% within 7 days of birth. In addition, there are significant risk factors for increased calf morbidity at the time of calving that can lead to increased mortality and decreased calf performance. Factors to consider in calving management include dystocia management (of primary concern in first-calf heifers), calving environment (including ambient temperature), passive transfer, and cow-calf pair management. (See MANAGEMENT OF REPRODUCTION: CATTLE, p 2171.) A visit to the farm or ranch ~4 wk before the onset of the calving season provides the opportunity to evaluate the preparations made by the producer and to recommend any changes.

Keeping records on calving ease and morbidity and mortality incidence allows for analysis of risks and risk groups and detection of any increased incidence of disease. At least one additional visit should be made to the farm 2–3 wk after calving has begun to assess the management and environment. Morbidity and mortality incidence levels may be established; if these are exceeded, the herd health veterinarian should be called and an investigation begun.

The most common cause of calf morbidity in the neonatal period is diarrhea (see p 275). It is sometimes not possible and many times not important to differentiate diarrheas associated with different etiologic agents, especially when diarrhea occurs in the 7- to 14-day range. Control for pathogenic agents of neonatal diarrhea involves segregation of sick animals from the healthy nursery to decrease environmental contamination and transmission. In addition, *Escherichia coli* and *Salmonella* control involves biosecurity rules to prevent the purchase and introduction of new calves or cows during the calving season. Sick calves should be isolated quickly to prevent further environmental contamination. Once the environment is contaminated, moist, cool conditions allow survival of infectious agents for an extended period. Cryptosporidia are especially suited to survival in the environment, and prevention of contamination in the healthy nursery is critical. Commercial vaccines for rotavirus, coronavirus, *E. coli*, and *Clostridium perfringens* types B and C may be given to cows and heifers before calving to increase levels of specific immunoglobulins in colostrum. An initial vaccination and booster followed by a yearly booster is generally required. If a booster vaccination is needed, it should be given at least 2 wk and not more than 6 wk before calving. Clinical trial data are not consistent; some trials report no effect, whereas others report significant

decreases in morbidity. Vaccination may be a useful adjunct to proper management in controlling neonatal diarrhea, but the key is environmental control.

An excellent environmental control program is the “Sandhills calving system” developed at the University of Nebraska. In this system, pregnant cows are wintered in an area separate from the calving area. When the first cow calves or is about to calve, the entire herd is moved to the first calving pasture. Cows stay here for 2 wk; after this time, all cows with calves stay on pasture 1 while all cows yet to calve move to pasture 2. After 1 wk on pasture 2, all cows with calves stay and all pregnant cows move to pasture 3. This continues for the next 6 wk. Cow-calf pairs can be combined when the youngest calf in the group is 4 wk old and at low risk of diarrhea. This system assures that each calf is born into a clean environment, so disease transmission is minimal to nonexistent. Herds that had severe morbidity and mortality from scours before using the system may have almost no health concerns after its adoption.

In this and in all calving systems, heifers should be wintered and calved separately from adult cows, because heifers have lower immunity to pathogens than cows.

Castration and Dehorning: Castration of male calves in early life (before 3 mo of age) is less stressful to calves than castration performed later, when testicular size is dramatically increased. A number of methods may be used, including the open surgical technique, the use of rubber rings, and the Burdizzo method. Calves castrated surgically initially exhibit more agitation than calves castrated with rubber rings, but both groups resume normal behavior soon after the operation. Dehorning early in life is also less stressful than when performed later, when horns have increased in size. Horns are mostly a problem for the feeding period (ie, horned calves require more bunk space), and they may cause bruising in perimates. Such problems are best managed by polled breeding or early dehorning.

Identification: Individual identification of cows and calves allows for selection based on performance as well as for tracing the animal to its herd of origin to track or contain disease. Plastic ear tags are the most commonly used method of individual identification. Branding as a method of herd identification is coming under increasing

scrutiny for product quality and animal welfare reasons. Commercial products are currently on the market that allow individual electronic identification. Such initiatives may eventually replace current identification systems.

Vaccinations: Vaccines are available for viral and bacterial respiratory pathogens. Residual passive immunity in young calves may limit the detectable antibody response to vaccination at an early age, but use of MLV infectious bovine rhinotracheitis and bovine viral diarrhea vaccines stimulates a significant cell-mediated immune response in calves with residual passive immunity to these diseases. Specific age recommendations for initial vaccination are made by vaccine manufacturers. Calves vaccinated at branding time or pasture turn-out may be sensitized to the antigens and respond with an anamnestic response when given another vaccine at arrival in the feedlot. Recommended vaccination programs include clostridial and viral respiratory vaccination at the time of branding. A number of “value-added” calf programs have been initiated, some of which require a vaccination program at branding time. Pneumonia incidence is typically low during the summer grazing periods, making clinical effectiveness of a vaccination program against respiratory disease difficult to demonstrate. Primary sensitization to increase subsequent vaccination response before weaning may be the major benefit of such a vaccination program. A repeat vaccination against viral respiratory agents is often administered to calves before weaning. Vaccination for *Mannheimia* has been recommended for inclusion in some preweaning or weaning vaccination programs as well.

Infectious keratoconjunctivitis (see p 512) can be a significant problem in suckling calves, and control can be difficult. Vaccination has shown variable results. Challenge with a homologous strain after vaccination may provide some level of control, but challenge with a heterologous strain creates little protection.

Implant Strategies: Use of hormonal implants as a management practice for suckling calves may increase weaning weights by 3%–5%. Optimal response is seen in healthy calves with adequate nutrition. Heifers kept for breeding should not be implanted if <45 days old, and bulls should never be implanted. (See p 2758.)

Parasite Control: Egg burdens of calves are typically low at spring branding but may rise significantly by midsummer. Deworming of cows in late spring may lead to increased weaning weights in calves. Studies examining the effects of deworming calves only at branding have been few, and results were inconsistent—some showed positive effects, whereas others found no effect. Deworming of calves in addition to cows in late spring appears to confer minimal additional benefit. External parasites of cattle are estimated to be an important cause of economic loss as well. Studies have generally shown a weight gain of 10–20 lb in suckling calves when fly control is provided. The most common method of fly control is the use of insecticide-impregnated ear tags. With the widespread use of pyrethroid insecticides in ear tags, emerging resistance has become a problem, so rotating to organophosphate or endosulfan tags can be helpful. Insecticide sprays and back rubbers can also be effective (and less expensive), but cattle must be forced to use them.

Nutrition: Suckling beef calves are generally not supplemented during the summer grazing period, when milk and an increasing intake of forage provide their diet. Deficiency of trace minerals may be a concern in some areas. Proper nutrition of the herd before calving should provide the calf with adequate reserves at birth. Subsequent supplementation is difficult, however, because trace mineral mix intake in calves is sporadic at best. Creep feeding may increase the reliability of intake, but it is an expensive substitute for available forage, and the response is highly variable. Creep feeding for 3–4 wk before weaning may be an effective way to reduce stress and disease at weaning. (See *also* NUTRITIONAL REQUIREMENTS OF BEEF CATTLE, p 2248.)

Weaning: Weaning is stressful because the calf is removed from its dam and has to adjust to a different diet and environment; population density is increased, leading to potential for increased disease exposure and transmission. Management procedures should aim to minimize stress to calves while ensuring they are in sound condition nutritionally and immunologically. Castration and dehorning should be performed well before weaning. Completion of vaccination, deworming, and implant procedures before weaning allows calves to be weaned without handling.

Early weaning of beef calves at 90–150 days of age may create more efficient use of feed resources by directly supplementing calves to maintain weight gain rather than supplementing cows to produce milk. Weaning times as early as 30–60 days can increase reproductive performance of cows and heifers. Cows and heifers cycle and rebreed earlier in the calving season, and pregnancy rates are higher in a limited breeding season after early weaning. Nutritional needs of the weaned calves must be met carefully to ensure acceptable health and performance. Weaning this early should be done only in an emergency situation to salvage the reproductive future of cows in extremely thin (BCS <4) condition at calving. The goal is to prevent this situation through strategies that improve precalving BCS (see p 2120). Weaning at 150–170 days of age decreases lactational stress on cows when forage resources are limited and improves cow condition. Reproductive performance in the breeding season is not affected by weaning at this time. When forage resources are limited, weaning calves to decrease the nutritional requirements of the cows allows them to regain condition before winter with less or no supplementation. It is more efficient to wean the calves and feed them directly than to feed the cows more to increase milk production late in lactation.

REPLACEMENT HEIFERS

Replacement heifer development programs generally begin at weaning as the heifers begin preparation for their initial breeding season. However, decisions relating to use of hormonal growth-promoting implant programs (see p 2758) for replacements must be made beginning at the working of calves at 2–3 mo of age. Reimplanting heifers intended for breeding at weaning, or after 6 mo of age, is not recommended. Heifers that calve at 22–24 mo of age have increased lifetime production compared with heifers that calve first at 30–36 mo of age.

Heifer Selection: Selection of replacement heifer prospects begins at weaning, when heifers are typically 6–8 mo old, and is based on birth date, genetics, frame score, disposition, weaning weight and ratio, and dam production records. Selection of heifers born early in the calving season leads to replacement heifers that are older and heavier at the start of the breeding season. Heifers should be evaluated for structural soundness, and unacceptable conformation should disqualify a heifer as a

replacement prospect. Age-adjusted frame scores can be used to estimate the mature size of prospects. These scores provide an objective method of selecting replacements to maintain a consistent cow size suitable for the environment and feed resources.

Once potential replacement heifers are selected, a nutrition and vaccination program should be instituted in preparation for breeding. If heifers are to calve at 22–23 mo of age, they must be bred at 13–14 mo of age. For optimal fertility, heifers should weigh ~53%–65% of their mature body weight by this time. The ration must be balanced to provide the required rate of gain to meet the target goal of 53%–65% of mature body weight in the time available. Specific requirements vary with the weight and breed of the heifers and the amount of time available before breeding. (See also NUTRITION: CATTLE, p 2248.)

Considerable research on the most cost-effective target weight for breeding heifers has shown that it is almost always below the previous recommendation of 65% of mature body weight. Instead of a goal of the maximum number of heifers conceiving, a better goal may be to have a slightly lower percentage of heifers bred at a cost that is significantly lower than developing heifers to breed at 65% of mature body weight.

Vaccination: The vaccination program for replacement heifers should provide optimal protection from reproductive diseases and should include vaccination for infectious bovine rhinotracheitis (IBR) and bovine viral diarrhoea (BVD) types 1 and 2. Depending on the local disease risk, vaccinations for *Brucella*, *Leptospira*, *Trichomonas*, and *Campylobacter* may also be indicated. *Brucella* vaccination is performed according to state or regional regulations. Modified-live vaccines for IBR and BVD give the broadest immunity to strain differences and should be given twice to ensure a high level of immunity. Some evidence suggests that modified-live BVD and IBR vaccines may transiently infect the ovary and cause decreased fertility. For this reason, vaccination should be done ≥1 mo before breeding. Vaccination of heifers with *Trichomonas* vaccine increases calving rate and decreases duration of infection in infected herds but does not prevent infection. A vaccine for trichomoniasis may be useful in infected herds or in herds at high risk of infection, but it may not be economic in low-risk herds.

Management: Heifers should be adequately developed at the time of first

breeding, and their management during gestation must ensure their continued growth. Pregnant heifers should be separated from the main cow herd at the time of pregnancy testing and maintained separately until reentry into the breeding herd as animals move to pasture. Undernutrition during pregnancy in first-calf heifers can lead to an increased incidence of dystocia because of lack of weight and size, weakness at the time of parturition, insufficient colostrum, weak calves at birth, and a high incidence of prolonged postpartum anestrus, which leads to a high percentage of nonpregnant animals that will need to be culled. Thus, pregnant heifers should be fed and managed separately from cows and should be on a higher plane of nutrition than cows. Such management may slightly increase calf birth weight but will not increase dystocia scores if heifers calve in BCS 6–7. Heifers are ideally bred 2–3 wk before cows, and they should always be bred for a shorter period of time (~42 days) to ensure that those with the highest inherent fertility are retained in the herd. This also ensures that any increase in the postpartum anestrus period after their first, perhaps difficult, calving does not compromise their chances for cycling and rebreeding with the main cow herd.

GENERAL HEALTH MANAGEMENT CONSIDERATIONS

The greatest risk for initial introduction of many infectious diseases into a herd is the addition of subclinically infected animals, although some risk is also attributable to wildlife carriers. Potential sources of infection may be seen with herd additions, or through intentional or inadvertent movements and contacts. Herds may be classified as “closed” or “open,” based on their potential for pathogen exposure. (See also BIOSECURITY, p 2068.) Closed herds restrict the introduction of animals and vehicles from livestock sources as well as contact with other herds and animals. Open herds have a higher risk of introducing pathogens through such practices as introduction of purchased replacements (especially from commingled sale groups), purchase of bulls, direct introduction of high-risk stocker calves (especially into high population densities), and mingling of animals of different backgrounds, through either cooperative breeding programs or poor herd biosecurity.

In general, all purchased or introduced animals should be separated from the home

herd for a reasonable observation period (eg, 4 wk); these animals should undergo the same health procedures as the home herd. It is prudent to obtain animals from herds in which the herd health history is known and to have a record of vaccinations and treatments. Before purchasing animals, buyers should be sure that herds have tested negative for paratuberculosis and are free of persistently infected BVD, tuberculosis, and brucellosis. If the herd is free of diseases such as bovine leukosis and anaplasmosis, purchasing only animals from other herds negative for these diseases is vitally important. Pubertal bulls should be tested for trichomoniasis and vibriosis when indicated. For artificial insemination (AI) programs, semen should be used only if it was processed by an approved AI center with a comprehensive health program for minimizing the risk of transmission of venereal (and other) diseases through frozen semen.

BEEF FEEDLOTS

In beef feedlots, young growing cattle are fed a high-energy diet to produce marketable beef at a low cost of gain. Depending on the starting body weight and age of the cattle, the period of feeding varies from 60 days to 12 mo. The success of a modern feedlot depends on excellent management, a favorable economic climate, and relative freedom from unfortunate events such as disease epidemics or unexpected increases in costs (eg, feed) or decreases in the price received for the final product. The concept of disease should include all of the identifiable factors that cause suboptimal performance: inadequacies in feeds and feeding systems, the purchase of undesirable types of cattle, and clinical and subclinical disease.

The feedlot veterinarian is responsible for maintaining optimal animal health through the following activities: 1) Making regularly scheduled visits to the feedlot. The frequency of visits depends on the size of the feedlot, the time of year, the expertise of the feedlot personnel, whether animals have recently arrived, and the degree to which the veterinarian is contractually responsible for the total animal health program. 2) Being available for emergency visits to the feedlot when disease epidemics are seen. 3) Performing necropsies during visits and training feedlot personnel to do necropsies at other times. 4) Examining sick animals to ensure that reasonably accurate diagnoses are being made and rational therapy is being given according to established treatment protocol. 5) Regularly examining, analyzing,

and interpreting animal health and production data and making recommendations in a written report. The effectiveness of detection of sick animals, based on response and relapse rates and case fatality rates, should be determined, and the effectiveness of the processing program for new arrivals, which includes the vaccines used and the medications given, should be examined and analyzed regularly. 6) Selecting and prescribing all drugs used in the feedlot, giving specific advice about the use of drugs, and establishing a drug residue-avoidance program. 7) Discussing overall animal health and production performance with the feedlot manager and other consultants, setting animal health and production goals, and monitoring achievement. 8) Comparing the feedlot with other operations. The veterinarian should produce a monthly report that compares processing costs, treatment costs, and death loss by arrival weight and days on feed.

When the consulting veterinarian is not readily available, a local practitioner can serve as a valuable resource for the feedlot. Serving as part of the feedlot's health care team, the local veterinarian can make significant contributions to the animal health program.

ECONOMIC IMPACT OF DISEASE

Disease may cause economic loss in feedlots through mortality, treatment cost, or effects on productivity. The impact of clinical and subclinical disease on production efficiency and economic returns may be greater than the losses associated with mortality. A thorough understanding of the impact of disease on animal performance and economic loss is essential to make cost-effective recommendations to feedlot managers. The costs associated with death loss, chronically ill cattle marketed prematurely at a discount, and treatment are obvious and easy to calculate. Hidden costs, such as reduced performance and lower carcass quality, are often overlooked.

Treatment costs are another source of economic loss. Factors influencing the average cost include the morbidity rate, retreatment rate, cost of the drug(s), combination versus single antimicrobial therapy, whether adjunct therapy is used, labor, and feedlot markup on the products used. The morbidity rate has the strongest influence on the average treatment cost for all cattle in the pen. When metaphylaxis is used to manage bovine respiratory tract disease, it must be added to the total medical cost for the pen.

IMPLEMENTING A FEEDLOT MEDICINE PROGRAM

Regular Inspection: Regular inspection of all areas of the feedlot should be included in a feedlot health service. Credit for keen observation and a job well done along with recommendations for improvement in animal husbandry should be noted and recorded for discussion with personnel. Attention should be given particularly to the delivery of feed and water, the general well-being of cattle, and any unusual characteristics of each feeding pen. Many feedlot health problems can be prevented with excellent management.

Disease Surveillance: Continued disease surveillance through regular necropsy examination of all dead cattle and regular observations of sick cattle are necessary. In colder climates, carcasses may freeze solid before the veterinarian is available. Conversely, in warmer climates, carcasses may decompose beyond usefulness. When distance prevents the consulting veterinarian from performing a necropsy on every animal that dies, a more accessible veterinarian may be employed. In many cases, feedlot personnel can be trained to recognize common postmortem lesions, take digital photographs of such lesions and send them to the consulting veterinarian, and collect tissues for potential analysis.

A key to management of disease in feedlots is a fast and accurate diagnosis. This requires a good surveillance system, a systematic plan to search for sick animals, appropriate facilities for examination and treatment, accurate identification of animals, and appropriate laboratory facilities, especially a necropsy service. Emphasis is placed on training and supervising feedlot employees in the detection and early treatment of sick cattle. Employees, particularly any personnel responsible for checking the cattle pens for sick cattle, should be given regular instruction in the clinical signs of common diseases. These include anorexia, depression, lameness or abnormal gait, stiff movement, coughing, nasal and ocular discharge, increased breathing rate, crusted muzzle, sunken eyes, rough hair coat, loose or very firm feces, abnormal abdominal fill, and straining. Cattle with these or other signs of illness are examined more closely in the hospital area and, if necessary, treated. In some feedlots, treated cattle are immediately returned to their original pens,

whereas in others cattle are kept in hospital pens until they recover. Most animals that do not recover or that relapse after the first treatment are re-treated, although this decision depends on the nature of the disease and the economics involved. If an animal becomes chronically ill and chances of recovery are slim, it should be sold for slaughter if this is a viable option (after the appropriate withdrawal time) or, in the case of a calf, euthanized.

Pens from which sick animals are taken should be closely observed. A potential epidemic must be identified early so that pen-level intervention can be considered.

Despite its importance, pen surveillance is not highly reliable for the detection of sick feedlot animals, particularly calves in the first week after arrival. It is difficult to distinguish tired, gaunt calves that may have been weaned a few days earlier from calves in the early stage of acute, undifferentiated respiratory disease. As many as 50% of animals pulled from a pen of recently arrived calves will not show clinical signs of respiratory disease based on measurement of body temperature and a cursory clinical examination.

Treatment Protocols: The veterinarian must specify procedures for the clinical management of sick cattle and provide a standard protocol that outlines specific treatments for disease syndromes, including drug dosages, treatment intervals, routes of administration, and withdrawal times. The protocol should be followed strictly by all personnel so that the success or failure of therapy can be evaluated accurately and that chances of creating food safety hazards are zero. The effectiveness of the treatment protocol should be evaluated regularly by determination of the response rates for the various treatment regimens. Failure to develop and implement appropriate treatment protocols often leads to the use of many different drugs indiscriminately, which then leads to excessive treatment costs and often an increase in the case fatality rate.

FEEDLOT RECORDS

Records are essential to monitor the incidence of disease, response to treatment, and production performance, and they should be analyzed regularly by the veterinarian, nutritionist, and feedlot manager. They can be maintained by hand or by using commercially available computer software. The necessary input records include the lot description, processing record, lot update, sale

information, animal identification, and feed and animal health product purchases. The necessary output records include the numbers of animals pulled from each pen daily, from which an epidemic curve can be drawn; the treatment response report according to pen or drug used; the percentage of pulled animals that had a fever, which is an indication of how many are probably affected with an acute respiratory disease rather than a noninfectious disease such as grain overload; the daily mortality report, which should include the list of animals that died, along with their arrival dates, the dates of treatment, and the causes of death; a case abstract of the treatment history of each individual animal; and a close-out summary, which includes all production costs, the health and production performance of the lot or pen of cattle (including morbidity, mortality, ratio of feed conversion to body weight gain, average daily gain), the costs of gain per unit of gain, the number of days on feed, and the profit or loss.

Individual Treatment Record: Each animal treated should be individually identified, if this was not done on entry, and the information recorded on the treatment report. Treatment personnel should record the feeding pen, lot number, body temperature, body weight, disease suspected, treatment given, and location of the animal after treatment (eg, which hospital pen). The severity of the illness should be assessed to properly evaluate response to treatment. Late treatment in advanced stages of disease, particularly respiratory disease, is a major cause of failure to respond, even when the treatment of choice is instituted.

A report is filled out for each animal treated, and all subsequent treatments are recorded. The updated reports are retrieved for animals that relapse or die. The cumulative information on the report can be used to decide whether an animal should be culled for chronic or recurring illnesses that are refractory to treatment, to decide on alternative treatments, to explain reasons for death, and to evaluate the effectiveness of the treatments recommended. Some feedlots record animals that are removed from the pen but sent back untreated because they did not meet the temperature criterion in the case definition for a given disease. This information can be of value if the animal is removed again or dies.

Daily Morbidity and Mortality

Record: This record contains the number

of treated cattle by pen and lot number, the disease diagnosed, and the date. It provides both the manager and the veterinarian with a rapid assessment of the location of disease problems in the feedlot. It contains information on the number of animals removed and the number not treated and then classifies those treated according to diagnosis and whether they are a relapse or new case. By using this report in conjunction with an inventory report showing filling dates and numbers added to the pen on those dates, it is possible to generate epidemic curves.

Morbidity and Treatment Analysis

Record: This aggregation of data summarizes the morbidity rate, the relapse rate, and the death rate for a lot or pen of cattle. It is especially important as a tool to evaluate the overall effectiveness of the treatment program for various diseases; the relapse rates and death rates are compared with goals set for the feedlot and with standards published in the literature. The disposition summary alerts the feedlot manager and consulting veterinarian when the results are highly positive, so this feedback can be relayed to all employees to acknowledge their hard work, and when the chronic or culling rates are abnormally high, so that appropriate changes can be made.

Mortality Analysis: The causes of death as determined by necropsy should be summarized on a regular basis. A mortality analysis includes the number of days the animal was in the feedlot, any observed premonitory signs, and treatment (diagnosis, drug used, and when treated). The pen location of the animal in the feedlot at the time of death should also be considered.

Feedlot Performance Summary: Most feedlots complete a close-out summary for each group of cattle that have been finished and marketed. The performance record and feeding summary sections include average daily gain, total feed consumption, feed conversion ratios and cost per unit of body weight gain, mortality rates, culling rate, and medical costs. The financial summary provides the profit or loss on an individual and lot basis. If cattle are marketed on a grid basis with rewards for certain carcass characteristics, this information is also included.

VACCINATION PROTOCOLS

An important component of feedlot health programs is the planning of vaccination programs. Vaccination schedules vary

depending on the prevalence of disease both in the feedlot area and in the area from which the cattle originated. The vaccines used and the vaccination schedule should be based on the expected incidence of the disease, the cost of the disease when it is seen, the cost of the preventive procedure (vaccine plus labor), the field efficacy of the vaccine, and other available control procedures.

NUTRITIONAL ADVICE

Feedlots frequently consult a qualified nutritionist to assist in the formulation of cost-effective diets. The veterinarian should communicate with the nutritionist regarding the composition of the diets and any changes being planned. Most of the emphasis in feedlot nutrition has been on the development of cost-effective diets that support an optimal growth rate without any deleterious effects. Considerable information is available on the nutrient requirements for feedlot cattle and on the feeds and feeding systems used. (See also NUTRITION: BEEF CATTLE, p 2248.)

Nutritional deficiency diseases are uncommon in feedlot cattle, because cattle usually receive a diet that contains the nutrients required for maintenance and promotion of rapid growth. Diets prepared according to published standards should meet all the requirements under most conditions. Specific nutrient deficiencies are extremely rare; however, such a situation may be seen in a small farm feedlot that prepares its own diet with little or no attention to the necessity for supplementation of homegrown feeds. Although only a few nutritional diseases may affect a well-managed feedlot, these diseases may cause large economic losses when they develop. They include carbohydrate engorgement (grain overload or D-lactic acidosis), feedlot bloat or ruminal tympany, and feeding errors (ie, accidental incorporation of an excessive amount of a feed additive, such as monensin or urea, or sudden unintended changes in the ingredient composition of the diet).

DISEASE EPIDEMICS

In spite of good management, unexpected disease epidemics are seen in feedlot cattle. When feeding accidents occur, many animals can be affected suddenly, ie, within 1–2 days. In outbreaks of acute infectious diseases, such as infectious bovine rhinotracheitis, pneumonic pasteurellosis, or *Histophilus* meningoencephalitis, the

first few cases are followed by a steady increase in the morbidity rate for several days and then a decline as the outbreak subsides 10–14 days after the index case.

In some cases, the diagnosis may be obvious (eg, carbohydrate engorgement caused by a feeding error). In other cases (eg, infectious diseases of the respiratory tract), the diagnosis may not be readily obvious, and a detailed epidemiologic, clinical, and laboratory investigation may be required. A complete investigation may require specialists from several disciplines. Every effort should be made to determine the specific source of the disease. The investigation should include a general description of the problem, a complete history of the disease outbreak (including details and date of index case, total number of sick animals, treatments, case fatality rate, population mortality rate, and vaccination history), and clinical examination of several affected animals (with appropriate samples) as well as necropsies. After the diagnosis is determined, the rationale for treatment is outlined. When outbreaks of infectious disease are encountered, the intensity of surveillance must be increased to detect new cases in the early stages of disease when response to treatment is usually good.

All of the details of the outbreak should be listed in chronologic order and then analyzed. Correlations can be made between exposure factors and the development of new cases during the course of the outbreak. Often, epidemiologic determinants that explain disease occurrence can be identified and the information used to control future episodes. A detailed report of the outbreak, outlining the conclusion and recommendations, should be prepared by the veterinarian and nutritionist and submitted to the owner.

CONTROL AND PREVENTION OF DISEASE IN FEEDLOT CATTLE

Control and prevention of disease in feedlot cattle depends on purchasing healthy animals; providing a transportation system that minimizes stress, a comfortable feedlot pen environment, and an adequate feeding system; establishing a good surveillance system; and judiciously using vaccines and, when necessary, antimicrobial agents.

Feedlot Facilities

One of the most important considerations in the construction of a feedlot is good

drainage. The pens and alleyways should be well drained and easily accessible for scraping the ground surface as necessary. Good drainage requires a 6% slope. To avoid overstocking, each animal should be provided with 18 m² of space in well-drained land and with 9 m² in a paved lot.

Cattle need protection from wind, rain, snow, excessive heat, and excessive sunshine. Trees are planted as windbreaks, and buildings and fences are placed so the wind is not deflected into feeding areas or sheds. An open-front shed provides protection from winter storms and hot summer sun. Each animal needs ~1–1.5 m² of cover. The shed should be open to the south or southeast, and the front should be high enough so the sun strikes the ground at the back on the shortest day of the winter. The back of the shed should be ≥2.5 m high. A covered feed bunk protects feed from weather damage and affords cattle added comfort when eating. Feed remains dry and palatable, and waste is reduced. Shades to provide relief from extreme summer heat are useful in feedlots where this is a major concern during the year.

Environmental concerns about feedlot operations have greatly increased in recent years. Stricter environmental laws require that all feedlot waste and run-off be contained in approved lagoon systems. Pollution prevention plans must be on file with the appropriate government agency. Monitoring, testing, and record-keeping requirements vary from country to country as well as regionally. In addition, foodborne illnesses, particularly those caused by *Escherichia coli* O157:H7 and *Salmonella*, have forced the meat-packing industry to change the way beef carcasses are processed. The packing industry has placed pressure on feedlots to provide animals that are as clean as possible.

Transportation of Cattle

Transportation or shipping of cattle has long been associated with increased bovine respiratory disease (BRD) in the feedlot, hence the term “shipping fever.” With current improvements in transportation, however, there is no correlation between the distance cattle are shipped and the risk of fatal fibrinous pneumonia in the feedlot. Factors such as weaning, level of immunity, commingling, and other stressors appear more important in the risk of BRD than distance shipped.

Cattle can lose considerable weight within the first 24–48 hr after weaning, during shipment, and after deprivation of

feed and water. This loss in body weight (known as shrink) varies from a minimum of 4% in cattle deprived of feed and water for 24 hr to up to 9% in animals transported long distances over a period of 2–4 days or in unweaned, high-risk, lightweight calves. Most of the fluid and electrolyte loss can be restored within a few days if the animals begin to eat and drink normally, but some studies show as few as 35% of high-risk calves consume an appreciable amount of feed the first 24 hr in the lot. Shrink >7% has been associated with increased health problems. The total loss in body weight may not be restored for as long as 3 wk in some highly stressed calves.

Transportation equipment and facilities should meet local standards and be able to transport cattle comfortably regardless of the season of the year. Some countries prohibit the transport of cattle over a certain length of time without unloading for rest, feed, and water. On arrival at their destination, cattle should be examined carefully for evidence of clinical disease or injury. Provision of fresh hay, a small amount of starter feed, and water can help detect those that are anorectic and require closer examination. This is particularly important if unexpected delays in transportation have occurred that increase the level of stress in the animals.

Cattle Purchase and Introduction to a Feedlot

Infectious diseases of the respiratory tract are major causes of morbidity and mortality during the first 30–45 days after arrival in the feedlot. Digestive diseases, especially carbohydrate engorgement, in cattle placed on a high-energy diet within 30 days after arrival in the feedlot are a major potential threat but can be controlled. The acute respiratory disease complex (see p 1431) is more difficult to control in feedlot cattle, even under good management conditions.

The major objective on arrival at the feedlot is to get the cattle onto a high-energy diet—which will result in rapid growth—as soon as possible, usually within 21 days, while minimizing the morbidity and mortality associated with acute respiratory disease, other common infections, and digestive diseases associated with adjustments to high-energy diets.

Preimmunization and Preconditioning

Preconditioning is the preparation of feeder calves for marketing, shipment, and the

feedlot environment; it may include vaccinations, castration, and training calves to eat and drink in pens. The concept of preconditioning is based in part on immunologic and nutritional principles. Preimmunization, or vaccination of calves 2–3 wk before shipment from the ranch to the feedlot, was the basis of preconditioning. In addition to vaccination, more recent efforts have been directed toward increasing the number of days weaned before movement and improving management procedures on the ranch, such as genetic selection and nutrition, that assist calves in making an easier transition to the feedlot.

In the USA, preconditioning has been defined by the following elements:

- 1) weaning at least 30 days before sale,
 - 2) training to eat from a feed bunk and to drink from a tank,
 - 3) parasite treatment,
 - 4) vaccination for blackleg, malignant edema, parainfluenza 3, infectious bovine rhinotracheitis, bovine viral diarrhea (some programs also call for vaccination against *Mannheimia haemolytica*, *Pasteurella multocida*, and/or *Histophilus somni*),
 - 5) castration and dehorning with wounds healed,
 - 6) identification with an ear tag, and
 - 7) sale through special auctions.
- When preconditioned calves are placed in a feedlot, they usually begin to eat and drink on arrival; if they have not been subjected to unusual stressors, the incidence of disease is minimal. However, daily surveillance is still necessary to identify cases of illness. Because these cattle generally go onto feed more easily than calves that have not been preconditioned, care must be taken not to increase intake too quickly and cause digestive concerns.

When preconditioning is examined on a partial budget basis, the cost effectiveness for the cow-calf producer is generally quite favorable. Calves can gain 2–3 lb/day at a very low cost of gain while not getting fat. The health program “bonus” can add \$3–\$8/100 lb to the price when calves are sold at large, special preconditioned sales, but the primary financial reward to the cow-calf producer is in the form of added weight sold at a low cost of gain.

Backgrounding is a variation of preconditioning in which recently weaned calves are grown to heavier weights, usually in a smaller feedlot. The principal objective is to prepare these cattle to adjust to a high-energy finishing ration in a feedlot with minimal problems. This is achieved by feeding the calves a growth diet that yields rapid, efficient body weight gains without fattening. The spectrum of diseases seen in backgrounding operations during the first

45 days after arrival of the calves depends on whether the calves were preimmunized, preconditioned, or obtained from several different sources with no preconditioning. Infectious diseases of the respiratory tract (eg, BRD) and of the digestive tract (coccidiosis) account for most of the losses.

Recently arrived cattle of unknown backgrounds (eg, those from auction markets) require extra surveillance and care. After a 24-hr rest, these cattle should be vaccinated and some need to be castrated, dehorned, and treated for internal and external parasites. Nonpreconditioned, stressed cattle of unknown backgrounds should be watched closely for signs of BRD for ≥3 wk after arrival. On their starter ration, the cattle are limited fed good-quality roughage along with a quantity of a highly palatable, nutrient-dense concentrate ration. They are checked carefully at least twice daily for evidence of illness, and sick cattle are identified and treated. Once the animals are determined to be healthy and the common infectious diseases are not a problem, they can be moved up to finishing diets.

Vaccination against certain respiratory diseases at 24 hr after arrival is standard practice for most feedlot and backgrounding operations. Vaccination should be limited to those products that actually reduce losses resulting from respiratory disease. The use of metaphylactic antimicrobials against respiratory disease may be necessary in high-risk, nonpreconditioned calves. Numerous studies show a financial benefit to using metaphylactic antibiotics on high-risk calves, because BRD morbidity and mortality can be greatly reduced.

Regardless of the system used, soon after arrival the cattle should be weighed, examined for evidence of illness, and treated if necessary. Some feedlots administer antimicrobials to all calves considered to be at high risk of acute respiratory disease. If the illness appears different from the usual case of respiratory disease, diagnosis by a veterinarian should be sought at the earliest possible time. Close examination and surveillance are desirable for groups of cattle with a history of unusual stress. The youngest and smallest cattle often need special attention, and it may be necessary to separate them from older cattle. A reliable history of vaccination, vitamin injections, implants, and anthelmintic administration would be useful but is usually not available. The major objective during the first few days is to avoid unnecessary stress and get most cattle consuming the starter ration.

Depending on the condition of the cattle, it may be difficult during the first few days after arrival to easily distinguish sick cattle from healthy cattle, and careful clinical surveillance every few hours may be necessary. Observations at the time of feeding often reveal anorectic animals that should be pulled from the pen and examined.

Processing Procedures

Identification: Each animal must be identified immediately, preferably with a color-coded and numbered plastic ear tag that is easily visible from a distance. In many feedlots, each animal is not identified individually but instead receives a tag with a lot number (group) or pen number. Systems are now in place that individually identify animals with tags that can be read electronically from a distance of 8–10 in. Information maintained on individual animals through this technology may include performance, vaccination, and treatment history. These tags remain on the animal until slaughter, at which time the identification from the ear tag can be transferred to the overhead trolley system.

Measurement of Body Temperature: On arrival, some animals may be affected with acute disease but show no obvious clinical signs. Others may appear fatigued and gaunt but are not affected with clinical disease. Identifying animals with acute infectious disease that should be treated early to minimize mortality can be difficult. The body temperature of high-risk cattle (eg, unweaned calves, calves from auctions, or calves transported long distances over several days) is often measured at processing. Animals with a body temperature > 104°F (40°C) may be treated with an antimicrobial. Treated animals may be tagged and noted in the individual animal database, or the total number of animals treated (total amount of drug administered) in a group or pen may be recorded.

Vaccination: The value of vaccinating feedlot cattle for common infectious diseases, particularly those of the respiratory tract, has been controversial since the vaccines were introduced. Nevertheless, a wide variety of vaccines are used in feedlot health programs.

Vaccines are available for the following diseases or infections of feedlot cattle: infectious bovine rhinotracheitis, pneu-

monic pasteurellosis, parainfluenza 3 virus infection, bovine respiratory syncytial virus infection, *Histophilus somni* disease complex, bovine viral diarrhea types 1 and 2, and clostridial disease. The vaccines available for clostridial diseases are highly effective. The number of clostridial antigens to be used (2- to 8-way) depends on local prevalence of clostridial diseases, including blackleg (*Clostridium chauvoei*), malignant edema (*C. septicum*), bacillary hemoglobinuria (*C. novyi*, type D [*haemolyticum*]), infectious hepatitis (*C. novyi*, type B), tetanus (*C. tetani*), and enterotoxemia (*C. perfringens* types B, C, and D). Leptospirosis (*Leptospira* serovars Hardjo, Pomona, Grippotyphosa, Canicola, and Icterohaemorrhagiae) bacterins are also used in some situations.

A basic vaccination schedule for receiving calves should include a viral respiratory vaccine plus a clostridial vaccine. Additional vaccines should be included only if two criteria can be met: the disease is enough of a risk that prevention is necessary (eg, leptospirosis in some areas), and data are available to support the use of vaccines to prevent disease.

Castration and Dehorning: These surgical procedures are best performed well ahead of entry to the feedlot, but invariably there will be bulls and horned cattle offered for sale. When to castrate and dehorn these mismanaged cattle is quite controversial, with studies showing that performing surgery at initial processing 24 hr after arrival was superior to delaying these procedures.

Anthelmintics and Insecticides: Anthelmintics and insecticides are administered according to local conditions. Most incoming cattle will have been exposed to internal parasites, and appropriate deworming methods should be implemented. Young cattle raised on small farms in which the stocking rate on pasture is high may harbor helminths. Young cattle may also be affected by chronic verminous pneumonia caused by *Dictyocaulus viviparus*. Most young cattle will be infected with coccidia, and having an appropriate anticoccidial agent in the feed is necessary.

Growth-promoting Agents: Growth-promoting agents (see p 2758) increase growth rate of animals without being used themselves to provide nutrients for growth. They are generally administered in small amounts—often via implants or in feed—to

alter metabolism so the animal increases body tissues and grows more rapidly. They include antibacterials, antimicrobials, steroids (eg, estrogens, androgens), and ionophores. They promote changes in composition, conformation, mature weight, or efficiency of growth, along with changes in the rate of live weight gain.

BEEF QUALITY ASSURANCE AND BEEF SAFETY PROGRAMS

The purpose of a beef quality assurance (BQA) program is to identify and avoid areas in the feedlot where quality or safety defects can be seen. The goal of the BQA program is to assure the consumer that all cattle shipped from a feedlot are healthy, wholesome, and safe and that their management has met all government and industry standards.

The feedlot must be able to document all steps of production. Critical points in production must be monitored to ensure no residue violations or carcass defects. These critical points include, but are not limited to, incoming cattle, product and commodities, cattle handling, and evaluation of outgoing cattle. There is a built-in margin of safety for withdrawal times in the feedlot industry, because most withdrawal times for animal health products are shorter than the feeding periods. Feedlot personnel must be aware of situations that create high risk of residues. Nonperforming cattle could have organ damage, which could prevent normal clearance of a drug product, causing violative residues even after the preslaughter withdrawal time has elapsed.

The BQA program is based on the principles of the Hazard Analysis of Critical Control Points (HACCP) system. Each production step should be evaluated for potential quality or safety defects, including bacterial contamination, which can cause infectious disease in cattle or employees; chemical usage/contamination, which can lead to violative residues; and physical damage, such as injection site damage, bruising, or broken needles in animal tissues. The analysis should include sanitation standard operating procedures (eg, finding ways to prevent or minimize fecal-oral contamination).

All relevant government regulations on feedstuffs, feed additives, and medications (including route of administration and withdrawal times) must be closely followed. Extra-label drug use must be prescribed only by the herd health veterinarian. All owners of cattle treated with medications adminis-

tered extra-label must comply with prescribed, extended withdrawal times that have been set by the herd health veterinarian under the guidelines of a valid veterinarian-client-patient relationship. The Food Animal Residue Avoidance Databank is the primary resource to determine the preslaughter withdrawal time when an animal has been treated in an extra-label manner.

Record Keeping: All records should be kept for ≥ 2 yr after cattle have been shipped from the feedlot. If a violative residue is found in any cattle shipped for slaughter, the feedlot must make applicable records available to the appropriate government agencies. The source and cause of violative residue should be determined and corrective action taken to prevent reoccurrence.

Individual Records: Treatment records should be maintained for all cattle treated individually. This can be done using handwritten records or a computerized record system. Essential information includes the individual animal identification, treatment date(s), diagnosis, drug administered, serial/lot number, dosage used, approximate weight of animal, route and location of administration, and earliest date the animal could clear the preslaughter withdrawal period. The treatment history of cattle with chronic medical problems, or of those that have a poor, unexplained growth rate, should be scrutinized carefully. In many cases, residue screening, such as the live animal swab test, is advisable. Residue screening should be performed under the supervision of the herd health veterinarian. The results of such testing determine whether an animal can be released for shipment.

Group Records: All animals treated as part of a group (processing or mass medication) should be identified by group or lot, and the treatment information should be recorded. Records should include the animal lot or group identification, product used, serial/lot number of the product, date treated, dosage used, route and location of administration, and withdrawal information. A preslaughter withdrawal time is assigned to the entire pen. Recording treatments under this system assumes that every animal in the lot or group received the treatment. The health records of cattle shipped to slaughter should be checked by feedlot personnel to ensure that treated animals have cleared the appropriate withdrawal times. All pesticides should be used in accordance with label directions, and their use and withdrawal time should be recorded.

Treatment Protocol Book: The herd health veterinarian should provide a treatment protocol book specific to the feedlot operation. It should be reviewed regularly and updated at least every 90 days. One copy should be kept at the treatment facility and another copy should be maintained in the feedlot office. A written treatment protocol and current prescriptions are important documents the feedlot must have if there is a government inspection of the feedlot facilities, drug usage procedures, and residue avoidance plans. It also provides written guidelines for animal health programs, thus minimizing chances of mistakes or misunderstandings.

Culling of Feedlot Cattle

Culling may be done at any point between examination of the cattle on arrival and a few weeks later, before the cattle are placed on a high-energy diet. Diseases that justify culling include chronic unthriftiness and inappetence of undetermined etiology, chronic laminitis, chronic lameness caused by footrot, chronic bloat, chronic pneumonia, acute and chronic pulmonary abscess, and bovine viral diarrhea. Each of these diseases leads to unthriftiness, and a clinical examination is necessary for diagnosis.

Animal Welfare in Feedlots

Good feedlot design is important to ensure animal comfort. Handling facilities must be modern and efficient and must not induce animal attendants to be cruel to animals when they are being moved from one location to another; excessive force should not be used to get the animals to move. The feedlot personnel must be educated in the techniques of low-stress cattle handling and recognition of signs of pain and discomfort associated with certain illnesses.

The veterinarian should emphasize good feedlot design and equipment that will ensure comfort for the animals and minimize pain and stress associated with handling procedures. The veterinarian must also be a vigilant guardian, denouncing inhumane practices and encouraging sound animal welfare management. (See also ANIMAL WELFARE, p 1579.)

DEVELOPMENT OF ANTIMICROBIAL-RESISTANT BACTERIA IN FEEDLOT CATTLE

The use of antimicrobials in feedlot cattle, as in all food animal species, has come under increased scrutiny because of

concerns about the potential transfer of resistant zoonotic pathogens to people and also transfer of resistant genetic determinants to human pathogens. A pathogen of concern related to resistance in cattle is *Salmonella* spp. Transfer of *Escherichia coli* O157:H7 through the food chain, while

a valid zoonotic disease concern, is not related to an issue of resistance. The American Association of Bovine Practitioners publishes *Prudent Drug Usage Guidelines*, which provides guidelines for antimicrobial usage in cattle feedlot operations.

HEALTH-MANAGEMENT INTERACTION: DAIRY CATTLE

The dairy industry is in a period of economic volatility of historic proportions. An era of modest fluctuation in milk and feed pricing in the late 1990s to the early 2000s was followed by increases in milk prices not seen before. The period of high dairy profitability in early 2008 was soon dampened because of substantial increases in production costs as a result of high fuel and feed costs as the USA government encouraged crop farmers to produce corn for ethanol distillation. Since then, milk prices have rebounded and dropped several times, although not to the same extent. USA dairy product exports have also fluctuated widely, contributing significantly to milk price volatility and overall profitability. As of early 2014, some 15% of USA dairy products are exported, milk prices are at an all-time high, and feed prices are somewhat lower.

THE MODERN DAIRY INDUSTRY

The structure of the dairy industry in developed countries has continued to evolve as production efficiency has risen. Industry consolidation is the norm, with reduced herd numbers, increased herd sizes, and adoption of specialized management practices that encourage higher productivity.

In the past, most dairy cows were housed in stall-barn facilities designed to maximize operator comfort. Today, free-stall facilities are built to maximize natural ventilation and cow comfort. Historically, barns were often placed in sheltered locations, whereas today they are usually located in open fields or on hilltops to ensure adequate airflow. The type of milking facility is also evolving; whereas in 2007, 49.2% of operations reported using tie-stall or stanchion milking facilities, almost 75% of cows are

now milked in parlors, reflecting the fact that most large herds are housed in free-stall or open facilities (and milked in parlors). Most parlors are highly mechanized and designed to minimize the amount of labor required, and economics dictate that milking proceed nearly around the clock to maximize the return on investment.

Milk quality is traditionally defined by the somatic cell count (SCC) and bacterial count in prepasteurized bulk tank milk. In all developed nations, regulatory officials set allowable maximums for SCC. Since 1986, limits for SCC and bacteria have been gradually lowered. The current upper limit for the bulk tank SCC is 750,000 in the USA and 500,000 cells/mL in Canada. The SCC maximum in the EU is 400,000 cells/mL using geometric means as the basis for calculation.

Artificial insemination (through the commercial distribution of frozen semen) is the preferred method of reproductive management in most dairy operations. In fact, 45% of USA dairy operators in 1996 reported that no breeding bulls were present on their farms. The use of genetically elite sires has contributed to increases of >150 kg/yr in genetic merit for milk production. Declining fertility has accompanied advancements in genetic merit. Dairy farms commonly record herd conception rates of <40%. Technologies such as embryo transfer, rapid hormonal assays, controlled breeding programs that use reproductive hormones, and ultrasonography are used increasingly on modern dairy farms.

Nutritional research also has advanced rapidly, especially in areas such as rumen physiology and lipid metabolism (see NUTRITION: DAIRY CATTLE, p 2265). Lactating dairy cows are generally fed either a component-

based ration (forages and grain are fed separately) or a total mixed ration (TMR, forages and grain are mixed and fed together). The basis of a successful nutritional program is the determination of nutrient content of the ration ingredients through laboratory testing, formulation of nutritionally sound diets, and assurance of adequate intake of required nutrients through feed bunk management. Maintaining a stable, healthy rumen environment is difficult with component-based feeding systems. TMR diets are generally based on mixing stored forages (in North America, usually alfalfa hay or haylage and corn silage) with grains (such as high-moisture corn or soybeans) and byproducts such as cottonseed or locally available commodities such as citrus pulp, brewers grains, or bakery waste. On larger farms, cows are often grouped and fed diets specifically formulated to meet their production and metabolic needs. Many farms use professional nutritionists to formulate rations.

Most producers raise their own replacement animals, but an increasing number of large dairy farms contract with specialized heifer growing operations. In the USA, >60% of newborn heifer calves are hand-fed colostrum within the first 24 hr of life to ensure adequate intake of immunoglobulins. The feeding of waste milk from cows undergoing antibiotic treatment or with mastitis is economical but may transmit infectious diseases to the calf. To decrease the potential for disease transmission, some producers pasteurize waste milk (15% of all calves in 2007) or feed milk replacer (>70% of calves in 2007). The amount of milk fed to heifers (typically 8%–10% of body wt at birth) has typically been restricted to encourage consumption of high-protein calf starters, with a goal of early rumen development and weaning by 8–10 wk of age. However, calf health was found to improve when calves were fed more milk than this, and current practice recommends that calves be fed an increasing amount of milk—up to 12%–15% of body wt after the first week of age (10–11 L/day). Holstein heifers are now heavier and taller at the withers than in published standards recommended from years past. The goal of efficient Holstein heifer-raising programs in North America is for heifers to calve at a weight of 550 kg at 22.5–25 mo of age. Various health management programs are used to reach this goal, including deworming and the use of oral coccidiostats, supplemental selenium, and ionophores.

ANIMAL AND HERD PRODUCTIVITY

The productivity of an individual cow is the sum of the value of the milk she produces, the value of her offspring, and her individual market value when she leaves the herd. Many factors influence individual cow productivity, which is also based on longevity and the proportion of the cow's lifetime spent producing milk. Nonproductive periods include the period from birth until first parturition and dry periods before subsequent calvings. Heifers must be managed to reach appropriate breeding size by 13–15 mo of age to maximize lifetime production.

Milk yield is related to stage of lactation. Milk yield increases rapidly after calving, reaches a plateau 40–60 days after calving, and then declines at a rate of 5%–10%/mo. The rate of decline is lower in first-parity animals than in older cows. Good reproductive management ensures that the largest proportion of a cow's total lifetime production is spent during early high-producing stages of lactation rather than late, lower-producing periods. Milk yield increases with age and parity until about the sixth lactation; these cows may produce up to 25% more milk volume than first lactation cows. Health disorders or other management problems that reduce longevity have a negative impact on productivity.

Nutritional Management

In most dairy herds, nutritional management is the most important determinant of herd productivity. The relationship between nutrition and productivity begins at birth. The feeding system must deliver the necessary nutrients to each cow at the correct stage of lactation to maintain optimal productivity.

Research has documented the importance of the ration fed to cows in the transition during the 2–3 wk before calving. Dry cows are fed a diet relatively low in carbohydrates and protein and high in fiber, reflecting the low nutrient demands of the nonlactating cow. The transition period ration must allow the rumen to adapt to the lower-forage, more nutrient-dense lactating ration. Further, the stresses associated with moving animals to the transition pen and of calving itself tend to reduce feed consumption at this critical time. Reduced feed intake in the transition period is associated with excessive weight loss, reduced peak milk production, and an increased incidence of postpartum diseases such as metritis, retained placenta, ketosis,

displaced abomasum, and fatty liver.

Research has documented the benefits of monitoring postpartum cattle for excessive energy mobilization by measuring blood β -hydroxybutyric acid, one of the ketone bodies.

⦿ Rations for lactating cows must strike a balance between providing high levels of energy and protein to support high milk production and maintaining optimal rumen health and motility. Subacute rumen acidosis (SARA) is a common condition resulting from excessive fermentable carbohydrates, inadequate fiber of adequate length, or a combination of the two. Health effects of SARA include digestive upsets and diarrhea, reduced feed consumption and milk production, reduced butterfat content of milk, ulceration of rumen epithelium, liver abscessation, and a series of foot problems related to subclinical laminitis.

The choice of a feeding system is associated with herd size and production level. Three general types of feeding systems are used currently by dairy farmers: total mixed ration (TMR), component feeding, and management-intensive grazing. Each of these systems, when implemented correctly, can deliver adequate nutrients for a highly productive dairy herd. Each system has its own inherent challenges in achieving optimal productivity.

The use of TMR feeding systems has increased as more herds have adopted free-stall or dry-lot housing. TMR diets have several advantages: cows consume the desired proportion of forages, risk of digestive upset is reduced, feed efficiency is increased, byproduct feeds may be used, accuracy of diet formulation is higher, and labor needs are reduced. The performance of herds using TMR diets can be lowered by errors in ration formulation and feed delivery. An oft-quoted statement illustrates the challenges of TMR feeding. There are three rations for a dairy herd: the ration on paper as formulated by the nutritionist, the ration fed to the cows, and the ration the cows actually consume. Some common errors include inadequate or nonexistent forage testing, variation in forage dry matter, variation in dry-matter intakes, overmixing of diets that reduces effective fiber length, errors or imprecision in the mixing of the ration, and overfeeding or underfeeding energy to late-lactation cattle. When TMR are fed, feeding mistakes are often spread across the entire group or herd. Health management programs of herds that receive TMR diets should include systems to monitor the adequacy of the ration formulation and delivery.

Component-fed herds receive grain and forage separately. Advocates of component feeding emphasize the ability to meet the production and metabolic needs of individual cows throughout their production cycle. The primary disadvantage of component feeding systems is that the cow receives concentrates separate from forages, enabling ingestion of these concentrates in a single feeding, leading to rumen acidosis and indigestion.

Management-intensive grazing systems can be used to meet the needs of modern dairy cows. In some regions of the world (eg, New Zealand and Australia), pasture-based systems are the predominant method of feeding dairy cattle. In these truly pastoral systems, nutrition frequently limits productivity because of significant annual variation in growing conditions. However, the economic model in such a system emphasizes low costs of production rather than maximal productivity. In other areas such as Britain and the northeastern USA, rotational grazing is used to provide for the forage requirements of lactating cattle during the spring and summer months, and supplemental concentrates and corn silage are fed to achieve high milk production. In both situations, seasonal calving is practiced to match rainy or spring season pasture conditions with the energy needs of early lactation cows. Attention to reproductive management is therefore critical for herds that attempt to breed all cows within a defined period. Production management programs for herds using management-intensive grazing systems must include programs to control bloat, hypomagnesemia, and copper and selenium deficiency. Pastured cattle may walk considerable distances to harvest forages. Therefore, a system to monitor and minimize lameness must be included in the health delivery system.

Reproductive Management

Artificial insemination (AI) using semen from genetically superior sires is the most important factor leading to increased productivity in the dairy industry, accounting for at least 150 kg increased annual production since its inception. Even today, the genetic potential for milk production greatly exceeds the actual milk yield achieved on most farms. Reproductive disorders are the most common and costly reasons for premature culling of dairy cows (see MANAGEMENT OF REPRODUCTION: CATTLE, p 2171). In conventional dairy herds in which calving occurs throughout

the year, suboptimal reproductive management leads to the failure of cows to conceive in a timely fashion, or at all. Cows remaining open longer reduce productivity in the following ways: 1) Open cows spend more time in late lactation, with lower milk production. 2) Cows taking longer to conceive may dry off sooner, leading to longer dry periods. 3) Risk of culling increases greatly in cows remaining open >300 days after calving. 4) Fewer replacement heifers are available. 5) Higher labor and treatment costs are associated with prolonged efforts to synchronize and breed open cows.

Successful AI requires that cows be inseminated during estrus in a narrow range of optimal fertility, and that the semen be thawed properly, transported quickly to the cow, and deposited in the appropriate area of the reproductive tract. The most important factor affecting the success of an AI program is the detection of estrus: recent data from the USA indicate that fewer than 40% of estrus periods were detected in lactating dairy cattle. Efforts to improve heat detection using estrus synchronization and artificial detection aids have been largely unsuccessful and are hampered by the reduced duration and intensity of estrus exhibited by modern USA Holsteins, and by the increasing size of farms making estrus observation more difficult. Because heat detection rates are so low, some dairy managers have returned to extensive use of natural service sires to ensure that cows conceive promptly. In these herds, breeding soundness examinations and bull management programs should be included to ensure continued herd productivity. (*See also BREEDING SOUNDNESS EXAMINATION OF BULLS*, p 2231.) However, the problems associated with natural service include reduced genetic improvement of offspring; costs associated with purchase, raising, and feeding bulls; damage to facilities; and danger to people.

Researchers in Wisconsin and Florida have developed hormonal synchronization protocols that allow timed insemination to be performed with acceptable conception rates. These programs have been widely adopted and have enabled herds to dramatically increase the number of pregnant cows throughout defined time periods. Many of the injections and the inseminations can be scheduled on a weekly basis, leading to more efficient use of labor.

Replacement Management

Herd productivity can be profoundly affected by the success of the replacement

program. The cost of raising heifers is a significant proportion of the overall cost of production; a replacement animal does not begin to earn a profit until midway through her second lactation. A wide range of mortality rates (5%–25%) is reported for replacement animals. The highest morbidity and mortality rates on dairy farms generally are seen before weaning. The most significant causes of preweaning death are infectious diseases of the digestive and respiratory systems. These disorders can be controlled by well-designed health management procedures that define the care and housing of the dam during the periparturient period, the calving process, feeding adequate quantities of high-quality colostrum, and the application of proper preventive measures (including sound nutritional programs) for newborn calves.

Delayed age at first calving reduces dairy productivity by increasing the need for replacement animals and increasing the costs of raising the replacements because of longer feeding periods. Heifers should be 23–25 mo old at first calving, which means they should conceive when 14–16 mo old. Adequate nutrition is important to ensure that heifers are fertile and cycling at this stage and that continued growth occurs so that heifers are large enough at calving to limit dystocia and maximize mammary development and lactation.

Herd Size, Composition, and Culling

There is a well-demonstrated relationship between productivity and herd size. One reason for this is the greater willingness for larger operations to adopt production-enhancing technologies. Government policies can also substantially influence herd size (eg, countries with supply management systems effectively limit the annual income a farm can achieve from the sale of milk). The amount and productivity of pasture can influence the size of herds that use grazing. In these herds, productivity is determined by balancing the ability of the pasture to produce nutrients against the ability of the cows to produce milk. The size of both grazing and confinement herds are increasingly affected by competing demands for land.

The proportion of the herd producing milk versus the nonproductive stock (dry cows, calves, heifers, and bulls) has an effect on total herd productivity. Herd composition is the result of a number of interrelated management decisions, such as culling policy, rate of reproductive success, rate of disease, replacement management,

and longterm goals regarding herd size. The ability of a herd manager to cull animals can have a significant impact on herd composition. When numerous replacement heifers are available, culling may intensify, leading to a younger herd with improved genetic potential for future milk production. In countries such as the USA, where herd production is not limited, longterm plans regarding expansion often influence herd composition. In some growing or start-up herds, only nonlactating cattle are purchased to reduce the risk of purchasing animals with infectious diseases such as contagious mastitis or bovine viral diarrhoea. These herds often consist of a high proportion of first-lactation animals.

Decisions regarding cow removal can significantly impact productivity of the dairy herd. Culling rates vary between herds and may be related to disease rates or disease control programs. Fertility, mastitis, and lameness are common reasons for cow removal. Culling is an important aspect of controlling other diseases such as bovine tuberculosis, brucellosis, paratuberculosis, and chronic mastitis caused by some contagious mastitis pathogens.

Environmental Conditions

Even with optimal housing situations, herd productivity can be affected by environmental conditions. High-producing cows have higher dry-matter intake, generate more internal heat, and are less tolerant of high ambient temperature. Weather conditions that combine high ambient temperature and high humidity without periods of cooling generally depress dry-matter intake and reduce milk yield. The increased concentration of dairy farming in regions that experience considerable periods of high temperatures (eg, southwestern USA) has resulted in more seasonal variation in milk output.

Farmers have adopted a variety of systems to combat heat stress. New facilities are constructed with large, open sides and ends (often >4.3 m high) and use fans and sprinkler systems to keep cows comfortable. Older, enclosed facilities can be retrofitted with tunnel ventilation systems to provide adequate air movement. (See also VENTILATION, p 2116.)

Drying Off and Dry Cow Management

Risk factors for most postpartum diseases of dairy cows are present during the dry period, with clinical signs of disease

becoming evident after calving. Diseases such as hypocalcemia (milk fever), hypomagnesemia, udder edema, ketosis, displaced abomasum, and mastitis often begin during the dry period. Dairy health management programs focus on many preventive practices such as vaccination, hoof care, and nutritional monitoring during this period.

The length of the dry period influences milk yield in the subsequent lactation. The recommended dry period is 6–8 wk. Dry periods of <40 days reduce milk yield in the following lactation. Dry periods that are too long may lead to excessive weight gain and reduced production efficiency. Both short and long dry periods are most common when breeding dates are uncertain because of either bull breeding or inaccurate (or missing) reproductive records.

INTERACTIONS BETWEEN HEALTH AND PRODUCTION

An important factor that influences dairy herd productivity is the amount and type of disease in the herd. The basis of disease control programs includes knowledge of the frequency of disease, information about the biologic effect of disease, and information on the effectiveness of control procedures.

Most studies report incidence rates of only common, easily diagnosed clinical diseases such as mastitis, lameness, milk fever, retained placenta, or displaced abomasum. The frequency of subclinical disease is much more difficult to discern. The cost to obtain subclinical disease information is inflated by the need to use screening tests (eg, culture or somatic cell counts [SCC] for mastitis, fecal culture or ELISA for paratuberculosis) for diagnosis. The lack of repeated testing leads to the reporting of prevalence rather than incidence for many subclinical diseases. Estimates of the frequency of sporadic or endemic infectious diseases (such as listeriosis, infectious bovine rhinotracheitis, or leptospirosis) are also sparse. There is zero tolerance for some diseases that have serious consequences for public health. The diagnosis of even one case of bovine spongiform encephalopathy, brucellosis, rabies, or tuberculosis in areas thought to be free of those conditions is cause for immediate action.

Influence of Disease on Productivity

Increased culling, reduced milk or protein yield, increased adult cow mortality, and

reduced reproductive efficiency are all potential results of disease in adult cows. Milk production is often profoundly reduced in cows with clinical disease. The duration of acute clinical syndromes is often short, but the effects of the disease may persist throughout the entire lactation. Early lactation is the highest risk period for many diseases. Disease during early lactation may reduce peak milk yields and therefore contribute to lower total lactational yields. Through advances in animal husbandry and health management programs, many farms have minimized clinical syndromes associated with infectious and metabolic disease.

Although epidemics of clinical syndromes still are seen, the nature of disease has changed on many dairy farms. The trend toward larger units and shrinking profit margins has encouraged a shift toward optimizing herd or group productivity through reduction of subclinical diseases, such as ketosis, mastitis, acidosis, and laminitis, which can have a major impact on productivity.

Infectious disease still represents a major source of loss to dairy industries worldwide. In Britain, outbreaks of foot and mouth disease (as well as bovine spongiform encephalopathy) are dramatic examples of the disastrous effects of infectious diseases on productivity. Other serious infectious diseases such as tuberculosis, brucellosis, bluetongue, and vesicular stomatitis continue to affect livestock around the world. In North America, more common infectious diseases that must be actively controlled include the contagious mastitis pathogens *Mycoplasma bovis*, *Staphylococcus aureus*, and *Streptococcus agalactiae*; bovine viral diarrhoea; salmonellosis; paratuberculosis; and pneumonia. Excellent control programs have been developed for most of these diseases, but their adoption is quite variable.

The effects of disease on productivity can be direct (such as mastitis causing a profound reduction in milk yield) or indirect (lameness leading to reduced feed intake, thus causing reduced milk yield). Diseases occurring in early lactation can also cause cascading effects that ultimately reduce productivity. For example, periparturient disorders often are seen as a complex, and cows diagnosed with parturient paresis are at increased risk of retained placenta, complicated ketosis, and mastitis. Cows with dystocia and retained placenta are at increased risk of metritis. Subclinical ketosis leads to increased risk of displaced abomasum and reduced milk production. The

best documented direct effect is the effect of mastitis on milk yield. A single case of clinical mastitis can result in a milk yield loss of 300–400 kg/lactation, with variations ranging from negligible to 1,050 kg. Mastitis during early lactation is associated with higher losses (450–550 kg) than cases seen later in lactation. (See also MASTITIS IN CATTLE, p 1358.)

Losses resulting from subclinical disease are often considerable. The best described relationship between subclinical disease and productivity is the effect of subclinical mastitis on milk yield. Each 2-fold increase in SCC >50,000 cells/mL caused a loss of 0.4 kg milk/day in primiparous cows and 0.6 kg milk/day in multiparous cows. Total lactational milk yields were estimated to be reduced by 80 kg for primiparous cows and 120 kg for multiparous cows for each 2-fold increase in the geometric mean SCC >50,000 cells/mL. Other subclinical diseases (eg, paratuberculosis) have also been related to reduced productivity.

Diseases that delay or prohibit conception have a negative effect on herd productivity by prolonging the time cows spend in lower-producing stages of lactation, by reducing the number of offspring for replacements or for sale, and by increasing the likelihood the animal will be culled prematurely. Several diseases have been associated with decreased conception rates. The likelihood of conception was reduced by 14%, 15%, and 21% for cows that experienced retained placenta, metritis, or ovarian cysts, respectively. Mastitis, metritis, and ovarian cysts reduced the likelihood of cattle being bred for the first time. Postpartum diseases that prolong negative energy balance in early lactation also have a negative effect on reproductive performance through alterations in hormonal activities.

The effect of disease on longevity has been investigated. A large proportion of cow culling is considered involuntary (driven by disease, injury, or death) rather than for reasons of low production. The premature removal of a cow from the herd reduces lifetime milk yield. Reproductive failure and mastitis are consistently recorded as the top two reasons for culling.

THE HEALTH MANAGEMENT PROGRAM

The goal of health management programs is to ensure the optimal care and well-being of dairy cattle and to reduce losses in productivity caused by disease and

management errors. The health management program is generally developed cooperatively by the herd veterinarian and the dairy producer based on comparisons of herd performance with predetermined performance goals. The structure of health management programs is unique to each farm but is typically keyed to the scheduled veterinary herd visits that combine routine reproductive examinations, review of selected herd performance records, and decisions and actions related to specific herd management issues.

Scheduled Farm Visits

The frequency of scheduled veterinarian visits is somewhat dependent on herd size. In herds of <100 cows, one or two cows calve every week and a single, scheduled monthly visit is probably appropriate. These herds may have more unscheduled visits for examination of sick cows than herds visited more regularly. Larger herds in which cows are calving daily warrant more frequent visits, and weekly scheduled visits are not uncommon for herds of >200 cows. A trend on extremely large dairy farms (>2,000 cows) is employment of a full-time staff veterinarian to oversee and direct day-to-day issues regarding health and performance. The frequency of scheduled herd visits for grass-based seasonal dairy operations varies depending on the herd's stage of lactation. More frequent visits are necessary in early lactation and during the breeding period.

Activities at herd visits fall into four general categories: provision of individual animal health care and emergency services, scheduled technical activities, scheduled analytic and training activities, and provision of quality control programs. The frequency of individual activities varies.

Individual Health Care and Emergency Services:

The examination and treatment of individual animals is an important activity during scheduled dairy visits. Frequent herd visits allow practitioners to examine cows early in the course of disease when the likelihood of successful treatment is higher. Routine visits also allow veterinarians to monitor the outcome of treatments and modify treatment protocols as needed. Ideally, monitoring programs include a system to detect cows not performing as expected. Special attention should be paid to the highest-risk cows, including frequent observation of animals during the periparturient period. Some

farms have adopted a system that includes routine daily monitoring of body temperature and rumen activity of cows during the first 7 days after calving. Animals that fall outside normal limits are treated according to predefined criteria or detained for examination by the herd veterinarian. All treatments administered to dairy cows should be recorded in treatment logs (either computerized or handwritten) to ensure adherence to proper meat and milk withholding periods. The frequency of unscheduled visits for emergency medical services usually diminishes in herds that have adopted a health and production management program.

Scheduled, Traditional, and Technical Activities:

Routine reproductive examinations account for much of the veterinarian's time during scheduled herd visits. Attaining reproductive success is an essential determinant of herd productivity. For a description of reproductive programs, see p 2171. The end point of reproductive examinations should be to identify nonpregnant cows that can be returned to the breeding program and to generate data that can be used to determine the success or failure of breeding programs. The implementation, success, and cost-effectiveness of scheduled breeding programs should be reviewed frequently.

On smaller farms, it is often customary for the veterinarian to perform routine individual animal treatments (such as IV injections), prophylactic activities (such as vaccinations), and some technical tasks (such as dehorning calves) during scheduled herd visits. It is appropriate for the veterinarian, or a technician under the veterinarian's supervision, to perform these tasks, because the farm staff may not perform them often enough to become technically proficient. On larger farms, these tasks must often be performed on a daily basis; in this case, farm employees should be trained to accomplish these tasks.

Scheduled Analytic and Training Activities:

Conducting scheduled or unscheduled technical activities will not be effective unless a system exists to capture the results of the activities and allow for analysis and ongoing revision. The structure of the health and production management program must include time for the farmer and the herd veterinarian to analyze and discuss herd management issues. In herds that depend on hired personnel to implement designated tasks, time must be

scheduled to observe and effectively train personnel ultimately responsible for performing the activities. Development of standard operating procedures is one method to ensure that agreed-on practices are implemented.

Treatment protocols are used to define standard treatments for common diseases on dairy farms and should be used when multiple people have responsibility for administering antibiotic treatments to dairy cattle or when extra-label drug use is prescribed. They also provide a mechanism for increased communication about treatment plans between the veterinarian and producer.

The avoidance of residues in food products is a major responsibility of dairy practitioners. Increased scrutiny regarding antimicrobial use in food-producing animals has arisen because of concern about the development of antimicrobial resistance in foodborne pathogens. Although the level of detected antibiotic residues in meat and milk products is extremely low, antibiotic residues in bulk milk and carcasses are seen occasionally. In the USA, contamination of bulk milk is rare because of an effective surveillance system based on rapid testing for selected antimicrobial agents of every load of raw milk. Milk contaminated with antibiotics is discarded, and the producer is fined.

The requirements for extra-label drug use in the USA have been defined by regulatory officials under the Animal Medicinal Drug Use Clarification Act and should be closely followed. The American Association of Bovine Practitioners has responded to societal and regulatory concerns about the use of antimicrobial agents by adopting recommendations for the prudent and judicious use of antimicrobial agents in dairy cattle. In response to concerns about the development of antimicrobial resistance in human medicine, the FDA is requesting that drug manufacturers begin the process of eliminating the labeling and use of certain antimicrobials for production purposes (to increase feed efficiency or weight gain). Specifically, antimicrobials of importance to human medicine will no longer be permitted to be provided in feed or water solely for production purposes, and no new antimicrobials will be approved for production purposes, although they can be approved for use in feed or water for treatment or prevention of disease. For producers to use an antimicrobial in feed or water, they must receive a feed directive from their veterinarian (essentially a prescription);

over-the-counter sales of antimicrobials for use in feed or water will no longer be allowed. *See also* THE VETERINARY FEED DIRECTIVE, p 2634.

Some dairy practitioners function as the nutritional specialists for the dairy farms they serve. They may collect feed samples for nutrient analysis, formulate rations, and advise the farmer regarding crop and harvesting conditions. These veterinarians often devote a considerable amount of their professional time to nutritional management. Other farms employ a professional nutritionist or use a nutritionist employed by a feed company or local cooperative to formulate the rations and submit feed samples for nutrient analysis. Regardless of the source of the dairy's nutrition program, the veterinarian can perform an essential oversight function simply by observing body condition and general health in cows in certain high-risk areas (periparturient and high milk production), monitoring the incidence of nutrition-related diseases such as parturient hypocalcemia and displaced abomasum, and ensuring that the diet described on paper is adequately formulated and delivered to the cows. Assessing pasture conditions by periodic inspection of pasture is an important component of managing the nutritional program of herds that use management-intensive grazing. These quality control activities should be conducted routinely as part of the health and production management program.

Quality Control Programs

Quality control refers to activities that ensure consistency in performing key management processes. Vital management areas for most herds include nutritional management, milking management, and young-stock programs. Some farms may also develop quality control processes for environment and housing and farm-specific management of breeding bulls.

Milking management should be a standard element of quality control programs. Tasks such as observing the milking routine and scoring the condition of teats should be performed at least quarterly. A scheduled system of routine screening for mastitis pathogens can be implemented as part of the milking management program. The veterinarian can teach farm personnel how to perform the California Mastitis Test as part of a surveillance program. Animals routinely screened may include cows at dry off, fresh cows and heifers, and newly purchased cows. Milk samples can be

collected and submitted for culture from quarters that show positive reactions.

Newborn calves and replacement heifers are often housed separately from lactating cows and may not be observed routinely by the herd veterinarian. However, routine surveillance of critical management issues such as adequate delivery of colostrum to calves and growth rates of replacement heifers can be done as part of scheduled herd visits. The environment of dairy cattle can have considerable influence on health and productivity. Some veterinarians routinely schedule "walkabouts" through the housing areas to assess factors related to animal comfort and hygiene. Udder cleanliness, hoof and hock lesions, and respiratory disease are often determined by housing conditions. Herd walkabouts should include areas often ignored, such as dry-cow and heifer housing.

Performance Targets

Performance targets reflect herd standards of performance that are perceived as indicators of successful herd management. They are useful as comparison values for herd performance and as a starting point to initiate discussions about potential areas for improvement. To use a performance target, it is necessary for a herd to have a record system that allows for generation of

comparable herd indices. In many instances, performance targets have been calculated as arithmetic averages, which are useful indicators of herd performance when the contributing data (such as milk, fat, and protein yields) are normally distributed and have a reasonable degree of variation. However, many reproductive indices and values such as SCCs are not distributed normally, and erroneous conclusions about herd performance may be made if averages alone are used to make management decisions. Appropriate frequency distributions are more useful for these types of data.

Key indicators for performance targets should be defined. The monitoring system should specify the indices used, the animals included, and the time interval to reassess progress made toward reaching each target. Typical performance indicators include milk production, reproductive performance, milk quality, replacement management, cow removal, animal health, and special reports (see TABLE 4). Performance targets should be reviewed at appropriate intervals with realistic expectations regarding the amount of time it takes to effect change in an index. For example, management actions taken to reduce days to first calving would require 29–10 mo to become apparent. A more timely value such as age at conception would more rapidly reflect current management changes.

TABLE 4 EXAMPLES OF ACTIVITIES FOR ROUTINE MONITORING^a

Cow Monitoring	Environment Monitoring	Records Monitoring
Body condition	Stalls and bedding	Milk production
Rumen fill	Barn climate	Milk quality features
Feces consistency	Milking method	Roughage analysis
Undigested fraction in feces	Milking parlor condition	Drinking water quality
Teat end callosity	Pasture management	Sire evaluations
Lesions of udder/teat/skin	Grass harvesting (silage)	Soil analysis
Clinical disease cases	Maize harvesting (silage)	Artificial insemination records
Reproductive examinations	Floor design and maintenance	Disease and drug records
Ectoparasites	Ration formulation	Farm economics report
Locomotion and claw score	Feeding management	Slaughter findings
Young stock growth	Hygiene practices	Laboratory findings

Record Keeping

A system of unique individual cow identification is a prerequisite for a successful health management program. The most common methods of animal identification are ear tags, collars, and branding. Increasingly, farms are using electronic identification via transponders on ankle bands or neck straps. At a minimum, data must be recorded on birth, breeding, and calving dates and periodic milk yield. Under ideal circumstances, summarized data should be available for the nutritional program, disease occurrence, and financial performance.

Record analysis is a necessary component of the health management cycle. Most or all dairy herd improvement (DHI) systems allow for electronic access to performance data, and various computerized systems for herd management are used throughout the industry. Most monitoring systems can be characterized broadly as one of the following: 1) manual (handwritten) card systems, 2) on-farm computer programs, 3) DHI, or 4) DHI and on-farm computer. Regardless of the type of system used, it should be easy to use and relevant to the day-to-day operations of the dairy.

One important function of record systems is the generation of "action" lists (due to calve, due to dry, etc). This function is critical in large herds in which cattle are not individually known by the animal handlers

and can be overlooked easily. Most systems also provide for a minimal level of herd analysis, such as the generation of timely performance reports for production, reproduction, and disease. Some programs can also generate statistics. The record-keeping system should allow the producer and veterinarian to understand and modify the formulas used to generate herd performance indices. For parameters and values used to monitor herd health and production, see TABLE 5.

The veterinarian should ensure that collected data are used in a timely manner. Accurate data collection is most likely when the producer is using the data frequently and understands its value. The validity of data generated from both manual and automated data collection systems should be reviewed and critically assessed. Unusual results and deviations from normal performance targets should be challenged. The producer and the veterinarian should agree on defined actions based on the herd status and goals. Actions are generally diagnostic, preventive, or treatment oriented. Typical activities might include listing animals for routine herd fertility or illness examinations, or selecting cows to obtain milk samples for culture, to vaccinate, to consider culling, to breed, to receive body condition scoring, or to receive treatments.

TABLE 5 PARAMETERS USEFUL TO MONITOR HEALTH AND PRODUCTION OF DAIRY HERDS

Parameter	Goal
Adult Cow Disease	
Average percent of herd lame	<25%
Metritis/endometritis incidence	<5%-25%
Subclinical ketosis (>1.2 mmol/L)	<10%
Clinical ketosis	<2%
Left displaced abomasum	<3%-5%
Milk fever	<3% of adult cows calving per month
Retained fetal membranes	<3% of cows calving per month
Cut point for ruminal acidosis	pH <5.5
Clinical mastitis monthly incidence	<3% of lactating herd
Culling and Death Loss	
Annual average overall cull rate	35%
Annual average selective cull rate	>15%

(continued)

TABLE 5

PARAMETERS USEFUL TO MONITOR HEALTH AND PRODUCTION OF DAIRY HERDS (continued)

Parameter	Goal
Annual death loss	<10%
Annual disease and injury culling	<5%
Annual reproductive cull rate	5%–10%
% Removed <60 days in milk (lactation = 1)	<4%
% Removed <60 days in milk (lactation > 1)	<6%
Udder Health and Milk Quality	
SCC legal limit	750,000 cells/mL
SCC farm goal	<150,000 cells/mL (or adjust for a dairy)
Standard plate count legal limit	100,000 CFU/mL
Standard plate count farm goal	2,000–4,000 CFU/mL
Preliminary incubation count	2,000–6,000 CFU/mL
Bulk Tank Cultures - Bacterium	
<i>Streptococcus agalactiae</i>	0 CFU/mL
<i>Staphylococcus aureus</i>	<50 CFU/mL
<i>Staphylococcus</i> spp	<1,000 CFU/mL
<i>Mycoplasma</i> spp	0 CFU/mL
Environmental streptococci	<1,000 CFU/mL
Coliforms	<500 CFU/mL
General Reproductive Standard	
Average days open	100–110 (ideally low 100's to achieve 12-mo calving)
Average gestation	283 days
Calving interval	13.5 mo
Average days in milk	200
Percentage of cows <90 days in milk	25%
Percentage of cows 90–180 days in milk	25%
Voluntary waiting period (VWP)	50–60 days for cows; 80–90 days for heifers
Days in milk at first breeding	Goal: VWP + 11 days
First service conception rate	40%
Heat detection	Goal overall >50% (national average <40%)
Intervals between breedings	18–24 days for 65% of cows
Length of estrous cycle	18–24 days
Overall conception rate	>35%
Services per conception	2
Definition of pregnancy rate	Heat detection rate × conception rate (21-day interval)

(continued)

TABLE 5

PARAMETERS USEFUL TO MONITOR HEALTH AND PRODUCTION OF DAIRY HERDS (continued)

Parameter	Goal
First cycle pregnancy rate	>30%
Percent pregnant by three cycles	>50%
Overall pregnancy rate	>20%
Percent of herd pregnant	50%
Pregnancy Diagnosis	
When to do pregnancy checks	>40 days after being bred
Ability to locate amnion	42–65 days
“Membrane slip”	Day 30 to term
Ability to locate fetus	65–95 days
Placentomes present	After 3 mo of gestation
Ability to sex fetus	After 60–70 days of gestation
“Placentomes”	Day 70 to term
By amnion size (days)	
35	7 mm (½ finger)
42	15 mm (1 finger)
48	35 mm (2 fingers)
53	55 mm (3 fingers)
58	75 mm (4 fingers)
62	90 mm (palm)
65	105 mm (hand)
By fetal crown-nose length (days)	
70	1.5 cm (1 finger)
80	3.5 cm (2 fingers)
90	5.5 cm (3 fingers)
100	7.5 cm (4 fingers)
110	9 cm (palm)
120	10.5 cm (hand)
Postpartum Involution	
Lochia (normal)	
Day 1–2	Bright red blood, thick mucus, little smell
Day 3–7	Dark red, thin, odor not foul but objectionable
Day 7–14	Progressively less red to white to translucent, thicker, smell improves
Entire uterus palpable	2 wk
Full reduction in size	40–45 days
Epithelialization complete	40–45 days

(continued)

TABLE 5

PARAMETERS USEFUL TO MONITOR HEALTH AND PRODUCTION OF DAIRY HERDS (continued)

Parameter	Goal
Occurrence of endometritis	>26 days after calving
Full uterine involution	40–45 days postpartum
Abortion	
Normal embryonic loss (<50 days)	<10%
Average rate of early embryonic loss	15%
Normal rate of abortion	3%
Major infectious abortion agents	Bovine viral diarrhea, mycotic, leptospirosis, <i>Neospora</i>
Noninfectious causes	
Heat stress	>90°C, 80% relative humidity
Toxins	Nitrates: methemoglobinemia
Plants	Locoweed, snakeweed, pine needles, lupine
Urea	Excess rumen degradable protein or nonprotein nitrogen; milk urea nitrogen 10–14 mg/dL

Investigations of Health and Production Problems

Even on the best managed farms, unexpected health and production problems arise. Surveillance programs incorporated in health and production management

programs should detect problems early, before considerable financial damage has occurred. Systems to investigate herd outbreaks have been described. Epidemiologic concepts of disease investigation are useful to identify risk factors and to stimulate corrective action.

HEALTH-MANAGEMENT INTERACTION: GOATS

Management of goats depends on the type (eg, dairy, pygmy, meat, mohair, or cashmere) and the reasons for which they are kept (eg, companionship or commercial enterprise). However, all are ruminants, and the basic principles of livestock husbandry are applicable. Dairy goats and pygmies are often raised intensively, with most of the feed being brought to the animals. Meat goats and fiber goats are usually raised extensively, with most of the diet coming from browse and occasionally from high-quality pasture at times of highest nutritional need, such as the last 6 wk of gestation and the first 18 mo of life. A

pregnant Angora doe without adequate energy and protein continues to grow mohair, even if stressed until she aborts.

Of all farm animals, goats have the strongest social hierarchy; thus, adequate feeder space or pasture should be provided so the dominant animals cannot guard feed and prevent others from eating. The amount of floor space available per doe affects the amount of aggressive behavior. A goat can become so subordinated to its penmates that it does not eat and loses condition. This behavioral component must be considered in cases of wasting goats. To maximize longevity and to avoid fighting injuries, adult

males should be fed and housed individually, especially during the breeding season when fighting increases. If group penned, bucks should be kept together and given time to get to know each other before breeding season begins. Introducing a new buck to a pen of existing bucks during breeding season may result in injury or death.

Goats are adventurous and are natural climbers, and efforts to control them are necessary. The ultimate control would be high-tensile, electric fences; goats stand and push on other fences and can be very destructive. Hazards that might contribute to broken legs and strangulations should be removed. Tethering goats is potentially dangerous, because they are vulnerable to dog attacks; also, if two goats are chained too close to each other, one might strangle. Chafing of ropes too tight on the neck can lead to deep abrasions and tetanus. Because goats chew on painted surfaces, lead poisoning is a potential hazard in old barns. An efficient layout of pens, easy access to well-designed feeders, and effective control of movement minimize management-related problems.

It is extremely difficult to keep goats' feet, urine, and feces out of many types of grain feeders, hay racks, and waterers. Goats often refuse to eat soiled feed or water, hay that has fallen on the floor, and grain contaminated with urine or feces. Design of hay feeders is critical to reduce feed wastage. Many dairy and pygmy goats are bedded on wasted hay, but this practice may lead to an increase in parasitism. Wet bedding contributes to development of coccidiosis in kids and staphylococcal impetigo on the udder, commonly but erroneously known as "goatpox." Under similar conditions, joint-ill (*see p 1094*) and navel infections of the newborn are likely. Separate, dry, well-bedded pens should be maintained for kidding. In certain areas, kids are susceptible to white muscle disease (*see p 1095*), which can be controlled by dietary selenium supplementation or by injection of vitamin E/selenium to the pregnant doe and/or newborn. Concerns about abortions associated with vitamin E/selenium injection in ewes have prompted caution about parenteral injection in pregnant does, and oral supplementation may be preferred.

Housing of goats affects disease patterns. Angoras in the southern and western USA are usually given access to shelter only during severe storms or for a few weeks after the twice-yearly shearing, without which they may die of cold weather stress. Goats in the northern USA are housed in the

winter, perhaps more for the owners' comfort than for optimal health of the goats. Combinations of manure packs, overhead hay-mows, or noninsulated ceilings lead to dampness and ammonia buildup, especially if the barn is closed tightly. Warm, wet, poorly ventilated barns are conducive to development of neonatal navel infections, mastitis, enteritis, pneumonia, and coccidiosis. Caseous lymphadenitis (the disease known as "abscesses"), caused by *Corynebacterium pseudotuberculosis* (*ovis*), spreads rapidly in closely confined goats (*see p 63*). The slow-growing, nonpainful lymph node abscesses eventually rupture and contaminate the feeders, walls, and other animals. Keyhole-style feeders and head catches on milking stands are prime sources of transmission, because they promote rupture of abscesses on the head and neck. The infection is spread by contact with the pus, and the organism can penetrate intact skin. Isolating affected goats, preferably culling them, and preventing environmental contamination is important. A commercial vaccine approved for goats is available, and autogenous bacterins have been used to decrease the incidence of these abscesses. Intensive management of adult goats may promote horizontal transmission of the virus that causes caprine arthritis and encephalitis (CAE, *see p 747*).

Mature bucks develop a powerful, characteristic odor that is most intense in the breeding season, and personnel are reluctant to handle them. This often leads to neglect of feet, failure to recognize heavy parasite loads, or loss of body condition. The sebaceous glands on top of the head can be removed surgically at any age or can be cauterized at the time of disbudding; however, this does not render the buck totally odorless. Does are attracted by this smell and may refuse to be bred by a descended buck if there is an odoriferous one nearby; therefore, the glands should not be removed inadvertently at the time of disbudding if male kids are to be kept for breeding. The habit of urinating on the face, beard, and forelegs also contributes to buck odor and often leads to ulcerating sores in cold weather. During the breeding season, most bucks lose weight, although this is not necessarily due to breeding too many does. Many bucks lose weight when housed close to does in heat, even when breeding is not allowed. One management strategy is to ensure that bucks are in prime physical condition before the breeding season.

In the European dairy breeds, the genetically homozygous polled doe usually

is anatomically an intersex and, therefore, infertile. Aberrations vary from a slightly enlarged clitoris visible only after puberty, to a buck-like conformation with a scrotum, penis (often shortened), and ovotestes. Some phenotypically male pseudohermaphrodites show male libido with breeding activity. Because these animals are infertile, early recognition and culling is advisable. Some homozygous polled males may be able to sire kids, but these bucks are likely to develop sperm granulomas as they mature and should be culled rather than used for breeding. Most owners reduce the incidence of homozygous polled animals by never mating two polled animals. While most intersex goats are polled, similar anatomic aberrations are seen occasionally in horned goats. These would most probably be chimeras (freemartins), the result of anastomoses developing in utero between males and females. Such chimeras in goats are rare (considering the high frequency of twins) when compared with cattle.

For foot care, *see* p 1092.

PERINATAL MANAGEMENT

Common problems in does are extra teats, double teats, and fish-tail teats with double orifices. In cattle, extra teats can be removed with impunity, but in dairy goats there is often a functional milk gland behind the spare teat, and removal of abnormal teats is discouraged.

Newborn goats must be fed colostrum, and if caprine arthritis and encephalitis (CAE) is a problem, heat treatment is essential for control. Later, kids can be fed (in decreasing order of desirability) goat's milk, goat-milk replacer, lamb-milk replacer, or cow's milk. Any fresh milk fed should be pasteurized or from stock known to be free of CAE virus, mycoplasmas, and paratuberculosis. Newborn goats should be fed at 10%–12% of their body wt per day. Kids should be provided sufficient milk or replacer at regular intervals to achieve normal growth.

Kids should have access to hay and a grain-based creep feed as early as 1 wk of age. They can be weaned when they are readily eating solid feed as most of the diet; this varies from early weaning at 6 wk of age until weaning as late as 12 wk of age. Weaning may be delayed in some goat operations because there is no commercial outlet for doe's milk, so it is fed to kids.

Dairy goat doe kids of European breeds should be disbudded at 5–7 days of age. Bucks of the European breeds should be

disbudded 2 days earlier to maximally inhibit horn growth or subsequent development of abnormal regrowth (scurs). Horns may develop more slowly in Nubian, Nigerian Dwarf, and Pygmy does, but disbudding before 2 wk of age is preferred to decrease pain during the procedure and to prevent scur development. Hot-iron disbudding is the method of choice, using either a restraint box and nerve block, or general anesthesia. Excessive applications of the hot iron can lead to brain damage or subsequent death. Disbudding kids with caustic paste is not recommended.

Angora goats in range operations are not disbudded because the horns are thought to be helpful against predators, and because owners handle the goats by their horns. When goats are housed in winter, disbudding is advantageous, because it reduces trauma and prevents accidents in which goats are trapped by their horns in feeders and fence lines. Pygmies can be disbudded according to the owner's preference; it is not a cause for disqualification or discrimination in the show ring in the USA. Dairy goats generally are disbudded, and horned animals usually are barred from the show ring in the USA. Tetanus can be seen after disbudding or castration and, as a precaution, antitoxin can be administered at disbudding.

Dairy goats and pygmy bucks are castrated in the first few weeks; Angoras are castrated later, after they have attained good horn growth. In males to be kept as pets, castration should be delayed to allow maximal urethral development, which reduces the likelihood of urolithiasis (*see* p 1502). To improve their desirability as pets, wethers should have the scent glands, located caudomedially to the horn base, removed during disbudding.

NUTRITION

Dairy goats should be fed similarly to dairy cattle (*see* p 2308 and *see* p 2265). A good-quality hay, preferably alfalfa, should be the basis of the ration, and a 14%–16% protein concentrate should be fed as a supplement during lactation. Silage is not commonly fed to goats because of the lack of mechanical equipment. Overfeeding grain to pregnant does in late lactation is a common problem that may lead to increased levels of internal fat deposition in the abdomen and result in pregnancy toxemia and dystocia.

To increase salt consumption, loose trace mineral salt (TMS) should be fed rather than block salt. The choice of salt should be

based on the mineral content of available feeds in that specific area. Goats are highly susceptible to copper deficiency and, unlike sheep, fairly resistant to copper toxicity. Therefore, cattle TMS, rather than sheep salt with no copper, should be offered unless the soils or water source are known to have high levels of copper. Goats raised for fiber may require supplementation of sulfur for proper fiber production.

Pet wethers fed substantial amounts of grain are prone to develop urinary calculi. Management practices that decrease the incidence of urolithiasis include reducing grain consumption, adding ammonium chloride to the diet, keeping the calcium:phosphorus ratio $\sim 2:1$, and keeping the magnesium level low. Perineal urethrostomy can be used as a salvage operation for commercial goats with urolithiasis but is not recommended for pet goats, because recurrences of obstruction and urethral scarring necessitate euthanasia for many. The surgical interventions of choice for pet goats are surgical tube cystotomy or bladder marsupialization. To encourage water consumption, clean, loose TMS should be fed, and clean, fresh water available ad lib. To increase water consumption, especially for high-yielding does, water should be fresh and warm in winter, and fresh and cool in summer.

COMMON DISEASES

Goats harbor several species of **coccidia** but not all exhibit clinical coccidiosis (see p 207). Adult goats shed coccidia in feces, contaminate the environment, and infect the newborn. As infection pressure builds up in the pens, morbidity in kids born later increases. Signs include diarrhea or pasty feces, loss of condition, general frailness, and failure to grow. In peracute cases, kids may die without clinical signs. Rotating all the kids through one or two pens is dangerous. To help prevent coccidiosis in artificially reared dairy goats, the kids should be put in small, age-matched groups in outside, portable pens that are moved to clean ground periodically. Eradication is not feasible, but infection can be controlled through good management practices. Coccidiostats added to the water or feed are adjuncts to a management control program and not substitutes. Chronic coccidiosis is one of the main causes of poor growth in kids and is responsible for the uneconomical practice of delaying breeding for a year until the goat has reached adequate size (70 lb [32 kg] for dairy breeds). In Angora

goats kept extensively, the problem is seen at weaning, when the kids are kept in smaller lots and fed supplement on the ground.

In pastured and free-ranging goats, **helminthiasis** can assume great clinical significance. GI nematodiasis, liver fluke infestation, and lungworm infections all may be seen. Age-related resistance to parasitism in goats is weak relative to that in other ruminants. Although most common in yearlings during their first season on pasture, clinical parasitism may be seen in adults as well. Poor growth, weight loss, diarrhea, a scruffy hair coat, signs of anemia, and intermandibular edema (bottle jaw) may be seen with GI parasitism or liver fluke disease. *Haemonchus contortus* infection has emerged as a major constraint in the expanding meat goat industry in the southeastern USA. Persistent coughing in late summer and autumn is the usual presentation of lungworms; secondary bacterial pneumonia with fever is a common sequela. Parasitism is insidious on hobby farms, where the problem may not exist for several years and then suddenly explodes as goat numbers continue to increase and facilities become overstocked. Tapeworm proglottids are often noted in goat feces by owners. Although tapeworms are not generally considered to be of clinical importance, their discovery can be used to review the subject of helminthiasis with owners and develop an overall parasite control program (see p 312).

Clostridium perfringens type D can be fatal, and it is not always associated with the classic "change in quality and quantity of feed." In problem herds, vaccination every 4–6 mo may be necessary, because goats may not maintain protective immunity as long as sheep or cattle when given the same commercial vaccines. Vaccination prevents the acute death syndrome, but occasionally even vaccinated goats may develop acute enteritis. Affected goats develop severe diarrhea and profound depression; milk yield drops abruptly. Death may result in 24 hr. Treatment involves administration of antitoxin, analgesics, fluid therapy, correction of acidosis, and antibiotics.

Vaccination for **contagious ecthyma** (sore mouth, see p 866) is not indicated unless the disease exists on the premises. The main problems with infected kids are difficulty in nursing, spreading lesions to the does' udders or the assistants' hands, and attendance at goat shows being disallowed. Live virus vaccine is used by scarifying the skin (eg, inside the thighs or under the tail) and painting on the vaccine. Both natural

lesions and those resulting from vaccination may last as long as 4 wk, but after the scabs have dropped off, the goats can go to shows.

Chronic wasting is seen quite frequently; it is not a single disease but a syndrome. Generally, if a goat is well fed, kept in a stress-free environment, and has good teeth and a low parasite load, it should thrive and produce. If it does not, and begins "wasting," it should be culled immediately. The major causes of chronic wasting include poor nutrition, parasitism, dental problems, paratuberculosis, internal visceral abscesses due to *Corynebacterium pseudotuberculosis* (*ovis*) or *Trueperella pyogenes*, locomotor problems (particularly arthritis due to retrovirus infection [CAE virus]), and chronic hidden infections such as metritis, peritonitis, or pneumonia. Tumors are occasionally diagnosed in older goats. These diseases are rarely treatable, and many are contagious; this is the basis for the strict culling policy, which is vital to the overall productivity of a herd.

Paratuberculosis in goats differs from that in cattle (*see p 762*); gross postmortem lesions are less pronounced, and profuse diarrhea occurs less commonly in goats until right before death. Consequently, many cases may go undiagnosed until necropsy. The ileocecal node is the most rewarding tissue for bacteriologic culture and histopathology. Diagnostic testing for

caprine paratuberculosis includes agar gel immunodiffusion, pooled liquid fecal culture, direct fecal PCR, and ELISA. The control program for paratuberculosis in goats is similar to that in cattle.

Caprine arthritis and encephalitis (CAE, *see p 747*) virus has emerged as an important infectious agent of intensively raised dairy goats, but all breeds of goats are susceptible to this retrovirus. CAE infection in goats can manifest in numerous ways: subclinical, persistent infection; a progressive paresis of young goats 2–12 mo old; agalactia with a firm, noninflamed udder at parturition in bred females; or an arthritic condition with pain and swollen joints in adults. A chronic, progressive interstitial pneumonia or a wasting syndrome may also be seen in adults. CAE infection has been considered primarily to be spread from dam to offspring through virus-laden colostrum and milk, and control programs have been aimed at separating the newborns from the adult population and feeding heat-treated colostrum and pasteurized milk. Infection may persist in herds in which this is practiced due to horizontal transmission between adults. Regular testing and rigorous culling of all seropositive goats, or strict segregation of seropositive and seronegative goats, must be practiced if disease eradication is the goal.

For mastitis in goats, *see p 1367*.

HEALTH-MANAGEMENT INTERACTION: HORSES

Proper management can reduce the incidence of many disease conditions in horses. Informed management of the environment and diet, routine foot and dental care, and adherence to an appropriate deworming and vaccination program form the basis of a preventive health program. Client education is important for compliance; owners are more likely to follow recommended changes in husbandry programs once they appreciate the advantages. Diet manipulation reduces the incidence of certain types of colic and exercise-induced myopathies, good dental care improves feed utilization, minimizing exposure to barn dusts and molds reduces the risk of recurrent airway obstruction (chronic obstructive pulmonary disease), and individually designed deworming and

vaccination programs reduce morbidity and mortality due to parasitism and infectious disease. Owners should be aware of the normal vital signs and proper movement of a healthy horse, so that they will be better able to recognize when a health problem such as pneumonia, colic, or lameness develops. New modalities for prevention and treatment are always evolving. In addition, the use of complementary or alternative medicine such as acupuncture, acupressure, chiropractic procedures, photomodulation, and massage has grown in equine care (*see COMPLEMENTARY AND ALTERNATIVE VETERINARY MEDICINE, p 2078*). Knowledgeable owners working with a veterinarian and a farrier can result in a productive and pleasant life for every horse.

HOUSING

Stabled horses are exposed to numerous respiratory and GI pathogens, including viruses, bacteria, mold spores, dust mites, and parasites. Stable environments affect disease transmission in terms of air quality and ventilation, population density, and general cleanliness. Barns should be constructed to optimize ventilation and light, minimize exposure to dust and molds, provide temperature regulation, facilitate cleaning and disinfection, and provide ample space for each horse. Windows and skylights provide sunlight and natural ventilation. Sunlight is a potent killer of many bacteria and viruses; it also promotes coat shedding and regular estrous cycles. Eight air changes per hour is considered adequate ventilation for temperate climates and average humidity. (See also VENTILATION, p 2116.) Ceiling or wall-mounted fans can be used to increase air circulation on hot, humid days. Stall doors open at the top or made of heavy mesh screening provide better ventilation. Stalls should have nonslip flooring and walls or partitions that prevent direct contact between horses in adjacent stalls. Suggested stall dimensions for adult horses and for mares with foals are 3.6 × 3.6 m and 5 × 5 m, respectively. Doorways should be at least 2.4 m high × 1.2 m wide.

Recurrent airway obstruction (chronic obstructive pulmonary disease [see p 1455]), and noninfectious inflammatory airway disease are associated with airway hypersensitivity to environmental allergens and irritants and exposure to organic dust. The most commonly incriminated allergens are fungal spores and pollens, but barn dust is also rich in dust from shavings, sawdust, manure, hay, animal hair and dander, silica from dirt in indoor arenas, and endotoxin. The amount of air contaminants increases with the dustiness of the barn, bedding, and forage. Management techniques that help prevent this condition include substituting wood chips, peat moss, or shredded paper for dusty straw bedding; avoiding dusty concentrates; using shallow rather than deep feed containers; and soaking hay before feeding at ground level. Air quality can be improved further if bedding and feed are not stored above the stalls. Riding areas and the dust they generate should be situated away from stalls to reduce exposure to dust.

Feeds should be stored in dry containers to reduce contamination with molds and animal excreta. Moldy hay and silage feeding have been associated with cases of equine

botulism. Opossum feces can transmit infective sporocysts of *Sarcocystis neurona*, the causative agent of equine protozoal myeloencephalitis (see p 1309). Contamination of feeds by deer urine has been incriminated in the spread of certain strains of *Leptospira* (see p 652).

Regular disinfection of stables and feed and water buckets helps reduce persistence of infectious agents in the environment. Organic debris inactivates most chemical disinfectants; therefore, disinfection should begin with physical cleaning (ie, hosing, scrubbing) of all surfaces followed by chemical disinfection. Phenols, quaternary ammonium compounds, and chlorine are the most commonly used disinfectants. (See also ANTISEPTICS AND DISINFECTANTS, p 2738.)

To further reduce spread of infectious disease, stalls should have walls or partitions to prevent direct contact between horses in adjacent stalls. Pregnant mares, mares with foals, and weanlings should be kept separate from yearlings and adult horses. Ideally, new arrivals should be isolated from the resident horse population for 30 days to reduce introduction of contagious respiratory diseases, including respiratory viruses (eg, equine influenza virus and equine herpesviruses 1 and 4) and bacterial infections (eg, *Streptococcus equi*). Alcohol-based hand sanitizer gels are very effective against most infectious respiratory viruses and bacteria. Wall-mounted hand gel dispensers can be placed strategically throughout barns and tack rooms to improve hand hygiene and to reduce transfer of infectious diseases.

PASTURE

Horses should have ample time on good quality pasture. The opportunity to graze and exercise improves condition, prevents boredom-related behaviors (eg, cribbing and weaving), and reduces the risk of large-intestinal impactions. Grazing on grass also helps reduce the incidence of gastric ulcers. Reducing the time spent in poorly ventilated barns reduces exposure to many inhalant allergens incriminated in development of recurrent airway obstruction. Access to good forage provides a natural source of vitamins and fiber. If horses are fed in groups, sufficient space should be allowed to minimize competition and to ensure that even the most submissive horse has access to an adequate diet. Feeding hay and grain in elevated feeders off the ground reduces ingestion of sand, infective parasite eggs, and animal excreta.

Safe, durable fencing should be used for pastures and paddocks to reduce the risk of self-trauma. Double fencing between paddocks minimizes transmission of contagious disease between horses. Overcrowding should be avoided. Overgrazed pastures, which result from overstocking, lead to extremes in ground conditions (eg, dust or mud), contribute to increased parasite burdens, and favor overgrowth of potentially toxic plants.

Excessive dust increases the risk of respiratory infections among young horses by inhalation of soil saprophytes, such as *Rhodococcus equi* (see p 1451). The risk of this potentially fatal bacterial pneumonia on farms where the disease is enzootic can be reduced by minimizing exposure of young (<4 mo old), susceptible foals to aerosolized *R equi* using environmental control strategies such as decreasing dust formation on pastures and paddocks, housing foals in well-ventilated areas, rotating pastures, reducing the size of mare-foal bands, irrigating and planting dirt areas with grass, and removing feces frequently from stalls, paddocks, indoor arenas, and pastures. Breeding mares earlier in the season to ensure foaling during colder weather may reduce the number of susceptible foals exposed to dry, dusty summer conditions. On farms where *R equi* is endemic and foal morbidity and mortality rates are high despite attempts at pasture management, the incidence of disease can be reduced with preventive administration of 1 L of hyperimmune plasma containing high concentrations of antibodies against *R equi* to newborn foals within the first week of life, followed by a second dose 25 days later.

Overstocking in barns and pastures favors outbreaks of other contagious respiratory infections caused by viral and bacterial pathogens spread between horses via aerosolization of respiratory tract secretions. Enteric infections with *Clostridium difficile* and *C perfringens* can become endemic on some farms. An increased incidence of *Clostridium* diarrhea in newborn foals has been associated with foaling on dirt, gravel, or sand surfaces, and with stall confinement or limited turnout on dry lots during the first 3 days of life.

Whenever possible, horses should not be pastured on sandy soils, because sand ingestion during grazing predisposes to colonic and rectal sand impaction, chronic diarrhea, and weight loss. If sandy pastures are unavoidable, the risk of sand colic can be reduced by feeding psyllium at regular intervals and by providing trace mineralized salt with equal parts of bone meal.

Horses grazing on pastures near water may be at increased risk of contracting certain diseases such as Potomac horse fever, caused by *Neorickettsia risticii* and disseminated by aquatic insects and snails (see p 283). Pastures and paddocks should be kept free of standing or stagnant water to reduce the breeding grounds for mosquitoes carrying infectious equine viral pathogens, including West Nile virus and Eastern and Western equine encephalomyelitis viruses (see p 1291).

NUTRITION

During the last 20–30 yr, there has been an increased awareness of equine nutrition and its importance to the health of the horse. (See also NUTRITION: HORSES, p 2312). In every stage of life, nutrition is the foundation for equine health and longevity. The dietary needs of a horse change as it goes through each life stage. The great varieties of commercial feeds on the market attest to the recognition of different diets for different life stages. Horses must be provided with an adequate supply of energy, protein, vitamins, and minerals and have access to fresh, clean water.

Adequate fresh water intake is essential for every horse. Storage tanks, troughs, or pails should be placed so the horse can reach in comfortably. Because most horses are reluctant to put their head in a trough or pail below eye level, the water level should be kept high. If water levels get too low, many horses will refuse to drink. The optimal temperature for drinking water is 68°–78°F (20°–26°C). Horses will reduce water intake if the water temperature is too cold or too warm. When daytime temperatures exceed 100°F (38°C), water in exposed pipes or hoses will be dangerously hot and should not be used for drinking or bathing.

The nutrient energy requirement of the horse depends on its level of activity, the energy content of the diet, and the capacity of the animal's digestive system. The size and weight of the newborn foal is influenced by the nutrition of the pregnant mare. Horses fed for rapid body and skeletal growth may develop bone abnormalities or be more prone to lameness conditions. A balanced diet should be fed according to the desired rate of gain within the sound parameters of good health. The best measure of growth in a young horse is weight, and the best description of size of a horse is a combination of height and weight. A high correlation between the measure of the heart girth and body weight in the horse

has been reported. In young, growing horses, monthly measurements are helpful to monitor growth changes.

There are several reasons to know the weight of horses. Many feeding requirements are based on percentages of the horse's weight. Most feed recommendations are stated in the amount of feed (in pounds or kilograms) the horse should receive based on body weight. In young horses, "developmental orthopedic disease," although a multifactorial condition, can be related to rapid growth or imbalances in energy, protein, and minerals (see p 1148). The proper balance of protein, calcium, phosphorus, zinc, and copper is important in supporting healthy endochondral ossification and in stabilizing bone collagen and elastin synthesis. The amount of nutrients required in the diet for normal bone development are dictated by rate of growth. Excessive energy intake contributes to osteochondrosis by decreasing bone density and cortical thickness.

Deficiency of protein must be severe to interfere with endochondral ossification. Rapidly increasing protein intake may produce faster bone growth; however, if the diet lacks adequate minerals to support this increased growth, altered endochondral ossification can be seen. Calcium and phosphorus balance affect bone density, rate of growth, and cartilage thickness. Inadequate amounts of copper and zinc have been associated with an increased incidence of osteochondrosis and osteomyelogenesis.

Some of the most common mistakes made when feeding young horses include feeding excessive grain and leafy legumes (eg, alfalfa, which results in too high an energy intake), feeding a diet with too little zinc or copper to support rate of growth, and feeding a diet with an improper calcium:phosphorus ratio. Cereal grains and grass forages are low in calcium, phosphorus, protein, and lysine. Excess energy from cereal grains may be more detrimental than excess energy from grass forages; one reason may be that energy from grain is derived from starch, whereas energy from grass forage comes from microbial production of volatile fatty acids. Starch, but not volatile fatty acids, stimulates insulin secretion, which has been implicated in stimulating hormone changes that contribute to osteochondrosis.

Older horses often have dental problems that compromise feed intake and mastication. Extruded or soft pelleted feeds are ideal. Hay should be good quality, leafy, and easy to chew. The most variable dietary

requirement for any horse is energy. A certain amount of energy is required for maintenance and daily activity. Metabolic demands are increased for such activities as growing, performance activity, or lactation. In some activities, such as racing, jumping, or polo, the energy requirement may be increased by as much as 100%.

Diet manipulation can help treat, control, and prevent other disease conditions. Horses with recurrent airway obstruction should be fed as dust-free a feed as possible. Adding water or oil to grains decreases dust. Hay should be thoroughly soaked and fed close to the ground. If complete pelleted feeds are fed, hay can be removed completely from the diet. On sandy soils, hay should be fed off the ground to reduce sand ingestion. Dietary management can be used to reduce the risk of gastric ulcers. Alfalfa hay, with its high calcium and protein concentration, acts as a buffering antacid and has a protective effect on the nonglandular squamous mucosa. Small hay meals fed frequently or access to pasture also reduces the risk of gastric ulceration.

Nutritional management for Quarter horses with hyperkalemic periodic paralysis (see p 1047) is focused on decreasing dietary intake of potassium and increasing renal potassium losses. Dietary manipulation includes avoiding high-potassium feeds such as alfalfa hay, brome grass, canola oil, soybean meal or oil, and sugar or beet molasses and replacing them with timothy or bermuda grass, beet pulp, and grains such as oats, corn, wheat, or barley. Affected horses should be exercised regularly and have access to pasture.

Heavily muscled breeds of horses, including Quarter horses, draft horses, and Warmbloods, are prone to myopathies associated with increased muscle glycogen stores and polysaccharide storage inclusions in type II muscle fibers. Successful management of this condition, known as polysaccharide storage myopathy, focuses on increasing the fat content of the diet and eliminating or reducing grain intake. (See also MYOPATHIES IN HORSES, p 1176.)

Management practices to reduce the risk of impaction include ad lib access to fresh water, adequate exercise, good quality feed, and good dental care. If impaction has been a problem, poorly digestible feeds (eg, mature forages) should be replaced with low-fiber, highly digestible forages (eg, growing grass or legume hays). A complete pelleted or extruded feed helps maintain soft feces.

Grazing lush pastures or consuming large amounts of legume hay and the develop-

ment of laminitis have long been associated. Anecdotal observations indicate that pasture-associated laminitis occurs at times of rapid grass growth (eg, spring and early summer and in the fall after rainfall) that favor accumulation of certain carbohydrates such as fructans, starches, and sugars. Some horses and ponies may be more susceptible to pasture-associated laminitis because of genetic predisposition and other metabolic factors, including obesity, peripheral insulin resistance, and hyperinsulinemia. Strategies to reduce the risk of laminitis focus on limiting the intake of nonstructural carbohydrates such as fructans from pasture and other feedstuffs.

Horses and ponies with a history of recurrent laminitis should have limited pasture access during periods of rapid grass growth, such as spring and early summer. Nonstructural carbohydrate content also tends to increase during the morning, reaches maximal values in the afternoon, and then declines overnight. Therefore, a popular recommendation is to turn "susceptible" individuals out on pasture overnight or during the early morning and to remove them from pasture by mid-morning. Stenmy, mature pastures should be avoided, because mature grasses may contain more fructans. Turning susceptible individuals onto pasture that has been exposed to low temperatures in conjunction with bright sunlight (eg, as in the fall after a flush of growth followed by cool sunny days) should be avoided, because colder temperatures reduce grass growth and result in concentration of the fructan.

If feeding forage, lush legume hays should be avoided, because they tend to have higher nonstructural carbohydrate content. Soaking hay before feeding may help reduce the amount of fructans being fed. Grain and sweet feeds should be avoided.

The terms mature, senior, and geriatric refer to horses that have completed their growth cycle. However, because aging is a continuous process, there is no discrete age range for each category. Improved methods of overall care, management, and diet have enabled horses to live into their 20s or 30s. This increased longevity means they are used in a variety of leisure or competitive activities well into their teens or 20s. Good management of still-active older horses means recognition and evaluation of conditions that occur with age (eg, arthritis, hyperadrenocorticism, gastric ulcers, laminitis, navicular disease, kidney or liver dysfunction), followed by therapeutic management and special dietary considerations. Horses with arthritis require a

balanced diet with adequate minerals. In horses prone to hyperadrenocorticism, the use of fat-supplemented feeds with highly digestible fiber and reduced starch and sugar intake is important. Horses with liver or kidney conditions should not be fed legume hays and fat-supplemented feeds. Horses confined to stalls most of the time are more prone to intestinal problems and development of undesirable behaviors.

FOOT CARE

Hoof care is essential for good mobility and comfort of the horse. "No hoof, no horse" is a common expression as true today as it was 200 yr ago. Proper trimming at regular intervals will result in good hoof and leg balance. Conditions such as hoof cracks, thrush, and white line disease can be recognized early and treated properly. All horse owners should learn to recognize the initial signs of laminitis so that treatment can be started as soon as possible. In young foals, weanlings, and yearlings, frequent hoof trimming will assure proper weight bearing and bone alignment. A balanced foot early in a horse's life will also help to avoid potential lameness and alleviate injuries later in life. For a horse to perform to the best of its ability, it must be sound (free from pain). Soundness is an aspect of health and is more than the absence of lameness. A sound horse can better meet the demands of physical and mental activity. (See also LAMENESS IN HORSES, p 1096.)

DENTAL CARE

Regular dental care is essential for the comfort and longevity of the horse. The upper jaw of the horse is wider than the lower jaw, which results in very efficient crushing of food particles. The chewing surface of the teeth are at an angle of 10–15 degrees to each other. The grinding action of the molar teeth tend to produce sharp points on the outside of the upper molars and on the lingual aspect of the lower molars. Floating to balance the arcade is required for general maintenance of the horse's teeth. Irregularities are most common in the incisor and molar teeth of mature and geriatric horses. The mouth of the horse changes throughout life, but the greatest changes occur from ages 2–5; therefore, semiannual or annual treatment is important. Sharp points and uneven wear can cause problems not initially considered to be tooth related; eg, the horse may be prone to mouth ulcers, choke, gastric ulcers, back pain, or erratic head carriage when the bit is

in the mouth. Behavior problems may be a result of long, sharp teeth, an uneven arcade, or abscesses in the teeth or gums. Complete oral examination, including visualization of the premolars and molars, requires sedation, a speculum, and good lighting. Motorized dental instruments and carbide float blades have made equine dental care more precise as well as more comfortable for the horse. Age determination of horses has traditionally been done by examining the incisor arcade. Although not an exact science, it is a useful tool for those with experience. (See also DENTISTRY IN LARGE ANIMALS, p 175.)

PARASITE CONTROL

Control of internal parasites is a cornerstone of equine management and a continual endeavor. Control programs should be tailored to each farm situation and require a cooperative program between the horse owner and the veterinarian. The principal internal parasites of horses are nematodes. Unfortunately, many species of adult cyathostomes have developed resistance to standard doses of the benzimidazoles and the tetrahydropyrimidines. Among intensively managed horse populations, treatment with macrocyclic lactones (eg, ivermectin, moxidectin) does not suppress strongyle egg counts for as long as previously expected. Among foals, weanlings, and even yearlings, there are increasing reports of ascarids becoming resistant to ivermectin and moxidectin. (See also GASTROINTESTINAL PARASITES OF HORSES, p 315, and ANTHELMINTICS, p 2637.)

A program of anthelmintic resistance involves multiple parasites and multiple drug classes, and must consider horses of all ages. No single parasite control program is ideal for all horses. Age of the horse, population density, region of the country, climate, method of confinement (eg, stall or pasture), and pasture size and quality can affect the choice of parasite control programs. As horses age, they develop resistance to reinfection with certain parasites, such as *Strongyloides westeri* and *Parascaris equorum*. Resistance to most strongyles is incomplete. Although anthelmintics are the primary method of parasite control, other factors such as pasture management and stable environment are also important.

The parasites of greatest concern in horses are large strongyles, small strongyles, roundworms, pinworms, stomach bots, and tapeworms. GI parasites can cause acute medical problems as well as chronic debilitation. They may be responsi-

ble for diarrhea, intestinal impactions or irritation (colic), and poor performance. The result can be slow growth in young horses, poor performance, acute bouts of colic, and death in severe instances. The migrating ascarids (*Parascaris equorum*) are the primary cause of pulmonary inflammation and intestinal rupture in foals and weanlings. The control of large strongyles with improved anthelmintics has allowed the small strongyles (cyathostomes) to become a greater problem. Reports of tapeworms have also increased.

The three methods of diagnosis of parasites are direct examination of feces, concentrations of worm eggs by flotation, and culture of feces for infective larva. The direct examination method is quick but not always accurate. The flotation method for parasite egg concentration is more accurate to determine the type and number of parasites. The culture method is more suitable for laboratory use and research purposes. The effectiveness of any parasite control program can be evaluated by fecal examination. The fecal examination should be done before administration of a particular dewormer and then again 14 days later. The amount of decreases in egg population will determine the effectiveness of the dewormer. Parasite egg counts that remain high after use of a particular dewormer indicate the presence of resistance and a need to change the control program.

The three major classes of anthelmintics available for parasite control in horses are the avermectins, benzimidazoles, and pyrantels. The avermectins have a broad range of activity, are safe and effective at low doses, and control adult and migrating larval nematodes. Deworming of mares immediately after foaling lessens the foal's exposure to parasites in the mare's manure. Avermectins are not effective against tapeworms; however, the combination of ivermectin with praziquantel is effective against tapeworms as well as large and small strongyles, ascarids, pinworms, and bots. The benzimidazoles (oxibendazole, fenbendazole, and oxfendazole) are effective against most nematodes but not against encysted small strongyles or tapeworms. The pyrantels are effective against large and small strongyles, ascarids, and pinworms. Pyrantels kill nematode parasites slowly. Pyrantel is available as a paste (single dose), and as a tartrate salt that can be used as a daily dewormer mixed in the feed; it is effective against tapeworms but not bots. The avermectins are effective against bot larva and are recommended in the fall after the botfly season.

A fourth class of anthelmintics, the isoquinolines, contains praziquantel, a narrow-spectrum drug approved for horses as a cestocide. Praziquantel is available in combination with either ivermectin or moxidectin.

To slow the development of drug-resistant parasites, the focus of most parasite control programs is to reduce selection pressure for resistance by customizing deworming protocols for the farm and individual horses. This strategy includes identifying horses most susceptible to parasites (ie, the high egg shredders) and maximizing refugia (those parasites not exposed to drug selection pressure) by reducing the overall number of anthelmintic treatments administered and by monitoring the efficacy of different classes of dewormers using the fecal egg count reduction test. An effective deworming protocol for horses should incorporate a cestocide (eg, a praziquantel-containing product or a double dose of pyrantel pamoate) and a boticide (eg, ivermectin or moxidectin) once or twice a year to control tapeworms and bots, respectively, and a larvicidal dose of anthelmintic effective against encysted cyathostomes (eg, fenbendazole 10 mg/kg/day, PO, for 5 days, or a single dose of moxidectin) during early winter months in northern climates or during early summer in warmer climates. Foals should be maintained on a regular deworming schedule every 60 days that includes anthelmintics safe and effective against ascarids. Treatments effective against other nematodes (including encysted cyathostomes) and cestodes should be included in the deworming protocols for foals during the first year of life.

Effective deworming programs should also include one or more of the following nonchemical methods of parasite control:

- 1) Avoid overstocking and overgrazing pastures.
- 2) Keep pasture roughs mowed to a height of 3–8 in.
- 3) During hot, dry weather, harrow or rake pastures to disperse manure piles and expose larvae to sun. Rest the pasture at least 3–4 wk after harrowing.
- 4) Cross-graze pastures with other species. Cattle, sheep, and goats serve as biological vacuums for equine parasites.
- 5) Make at least one cutting of hay off some pastures to help reduce the parasite burden.
- 6) Plant an annual crop such as winter wheat.
- 7) Feed hay and grain in raised containers and not directly on the ground.
- 8) Remove manure from stalls, paddocks, and pastures every 24–72 hr before strongyle eggs have a chance to hatch and develop into infective larvae (5–7 days during optimal conditions).

- 9) Clean water sources regularly to prevent fecal contamination.
- 10) Quarantine new arrivals and perform fecal examinations. Use a larvicidal treatment before turning out new arrivals on pastures.
- 11) Use fecal egg counts, performed at the proper times, to identify and monitor high, medium, and low strongyle egg shedders, to monitor the efficacy of anthelmintics being used, and to evaluate new arrivals.
- 12) Compost manure. Properly composted manure will kill strongyle larvae and many ascarid eggs.

VACCINATION PROGRAM

The goal of vaccination is to develop and maintain both individual and herd immunity against infectious diseases. Commercial vaccines are available for rabies, encephalomyelitis (Eastern, Western, and Venezuelan), tetanus, influenza, equine herpesviruses 1 and 4, botulism, equine ehrlichiosis (Potomac horse fever), equine viral arteritis, rotavirus, West Nile virus, and *Streptococcus equi* (strangles). Vaccination programs are formulated based on the animal's age, use, and level of exposure. Broodmare vaccination is important to provide active immunity for the mare and passive immunity for the foal via transfer of colostral antibodies. Vaccination guidelines for foals have been modified because of the interference of maternal antibodies with the initial vaccination response. Sources such as the American Association of Equine Practitioners can provide the most current equine vaccination recommendations for horses in the USA.

The following vaccination recommendations assume that foals are born to vaccinated mares and have absorbed adequate colostral antibodies with IgG levels >800 mg/dL.

Foals with failure of passive antibody transfer (ie, IgG levels <200 mg/dL) and/or foals born to unvaccinated mares can receive their initial vaccination for equine herpesvirus 1 and 4, tetanus, and Eastern and Western equine encephalomyelitis beginning at 3–4 mo of age, followed by a second dose 4–6 wk later and a third dose at 10–12 mo of age. These foals can receive their first dose of rabies vaccine at 3–4 mo of age, followed by a booster at 12 mo. Influenza vaccination can be started at 6 mo of age. Foals born to mares that have never been exposed to or vaccinated against West Nile virus can receive their first vaccination at 3–5 mo of age.

Tetanus: *Clostridium tetani* is present in all parts of the world. Tetanus occurs most

commonly when wounds become contaminated with the organism from the soil. Vaccination is recommended for all horses and ponies on an annual basis. A horse with an unknown vaccination status that sustains an injury should receive a dose of tetanus antitoxin along with a dose of tetanus toxoid. A second dose of toxoid should be given 4 wk later. Foals from vaccinated mares should be given a three-dose series at 6, 7, and 9 mo of age. Foals from unvaccinated mares should receive tetanus toxoid at 3, 4, and 6 mo of age. Whenever a vaccinated horse experiences a serious wound, a tetanus booster may be indicated.

Equine Herpesvirus 1 and 4 (Rhino-pneumonitis): Two types of equine herpesviruses vaccine are available, EHV-1 and EHV-4. The EHV-1 virus is the primary cause of abortion and neurologic disease in horses. The EHV-4 virus is the primary cause of respiratory infections, especially in young horses. The control of rhinopneumonitis is by a combination of vaccination and good management practices. To prevent abortion, a killed EHV-1 vaccine should be administered to pregnant mares at 3, 5, 7, and 9 mo of gestation. Respiratory disease is best prevented using a combination vaccine of EHV-1 and EHV-4. There is no evidence that vaccination protects against the neurologic form of the disease. Vaccine recommendations for foals are three doses every 4 wk starting at 6 mo of age, and a booster at 1 yr of age. Pleasure and performance horses should be vaccinated every 3–6 mo, depending on the risk of exposure. Broodmares should have an EHV-4 vaccination 2–4 wk before foaling to ensure the availability of colostral immunity.

Encephalitis: Eastern equine encephalitis (EEE) virus has a wide distribution. This includes the eastern USA, Central and South America, and eastern Canada. In the USA, EEE is seen primarily in the southeastern states but has been reported in all states east of the Mississippi River. EEE in horses is nearly always fatal regardless of treatment. Infected horses usually become comatose, seizure, and die in 36–48 hr.

The virus of Western equine encephalitis (WEE) is primarily located in the western USA. In recent years, reports of WEE have not been common, probably as a result of adequate vaccination programs. The virus is not as pathogenic as EEE, and animals infected with WEE have a greater chance of survival. Mortality is usually 50%.

Venezuelan equine encephalitis (VEE) virus causes outbreaks of disease in horses in Mexico, Central and South America, and occasionally the southern USA. The VEE vaccine is a single vaccine or in combination with EEE and WEE. Its need is limited to those horses traveling to or located in endemic areas.

West Nile virus (WNV) disease is considered a zoonotic disease similar to the encephalitis viruses. The bird population allows for maintenance of the virus, which is then transmitted by mosquitoes to both people and horses. There is very little risk of disease from any infected horses. Vaccination protocols for broodmares, foals, and adult horses are the same as those for Eastern and Western encephalitis. Combination vaccines that include EEE, WEE, and WNV are available.

Influenza: Influenza is one of the most frequent causes of viral respiratory disease in horses and is highly contagious among susceptible horses. Therefore, vaccination is recommended for all foals, broodmares, and horses at risk of exposure, usually as a result of showing, racing, or shipping. Young foals from vaccinated mares, because of maternal antibodies, should be vaccinated at 9, 10, and 12 mo of age. Foals from unvaccinated mares should be vaccinated earlier. The intranasal vaccine can be used every 6 mo in young, susceptible performance horses 2–4 yr old. A vaccination is recommended every 6 mo for horses exposed to other horses at equine events.

Rabies: Signs of rabies include the inability to eat or drink, disorientation, and incoordination. Rabies is fatal, and also poses a health risk to those who handle infected horses. Prevention in horses is primarily via vaccination. Broodmares should be vaccinated 4–6 wk before foaling. Foals from vaccinated mares should be vaccinated at 6 and 7 mo of age and again at 12 mo of age. Foals from unvaccinated mares should be vaccinated at 3, 4, and 12 mo of age. All adult horses should be vaccinated annually.

Potomac Horse Fever: Potomac horse fever (equine monocytic ehrlichiosis, equine ehrlichial colitis) is caused by *Neorickettsia risticii*. Vaccination is recommended in endemic areas, such as near freshwater streams, rivers, ponds, and heavily irrigated pastures. Annual boosters in the spring are recommended. Pregnant mares should receive a booster before foaling. Although the vaccine may lessen the impact of the

disease, it appears not to prevent abortion in pregnant mares.

Botulism: Equine botulism is mostly seen in the Mid-Atlantic area of the United States, but the disease has also been reported worldwide. In the USA, the most common types are B and C botulism, although type A has been reported in the western USA. The spores of *Colostridium botulinum* are found in the soil and are resistant to light, drying, and heat. The Type B vaccine gives good protection in adult horses. Adult horses and broodmares in areas where botulism is a potential hazard should receive initially three doses at 30-day intervals and then annual boosters. Foals from vaccinated mares in endemic areas should be vaccinated at 2, 3, and 4 mo of age, because colostral immunity does not always occur. Foals from unvaccinated mares should be vaccinated at 2, 4, and 8 wk of age. The use of Type B vaccine in areas where Type C occurs has uncertain results.

Streptococcus equi Infection: *Streptococcus equi* infection (equine strangles, equine distemper) can be highly contagious. Use of the IM or intranasal vaccine is recommended only in those situations or on premises where the disease has been a problem. The IM vaccine involves three injections administered 2–4 wk apart, starting at 4 mo of age in foals, with a booster at 12 mo of age. If the intranasal vaccine is used, vaccination can begin at 6–9 mo of age, with a second dose given 3–4 wk later and a third dose administered at 12 mo of age. Adult horses, if in potential disease situations, should receive an annual vaccination. Broodmares on endemic farms should receive an annual booster using the IM vaccine 4–6 wk before foaling. Because of the increased risk of inducing immune-mediated purpura hemorrhagica, horses with titers to the SeM surface protein of *S. equi* in excess of 1:1,600 may not need to be vaccinated.

Rotavirus: Foal diarrhea as a result of rotavirus infection can be a severe problem on some breeding farms. Single cases or a farm outbreak can occur. Therefore, pregnant mares should be vaccinated IM at 8, 9, and 10 mo of gestation. This will increase the amount of colostral immunoglobulins. It is a vaccine for use in particular situations or areas of high endemicity.

Equine Infectious Anemia: In the acute state, equine infectious anemia (swamp fever) causes severe RBC destruction and

anemia. Once infected, a horse can become a carrier for life and is a threat to other horses. The virus is transmitted by bloodsucking insects. Currently, the disease is uncommon, and most horse owners are aware of its dire consequences. A simple blood test, the Coggins test, is available to detect infected horses. A horse that tests positive cannot cross state lines and is required to be maintained in strict isolation for life. For horses participating in equine activities or being transported across state lines, proof of a negative Coggins test is required. Annual testing of every horse is recommended. No vaccine is available.

PERINATAL MARE AND FOAL CARE

Pregnant mares need adequate daily exercise in a paddock or pasture, and any horses kept together should be compatible, which helps to reduce stress. Vaccinations and deworming should be done before the mare is bred, with no vaccinations given during the first 90 days of gestation. In general, except for rhinopneumonitis and possibly botulism, all vaccinations should be avoided until 30 days before foaling. Thirty days before foaling, the mare should receive vaccinations for Eastern, Western, and West Nile encephalitis, as well as for tetanus.

For the first 7 or 8 mo of gestation, the routine diet of pasture or hay and concentrate to maintain good body condition is all that is necessary. Mares too thin at foaling will not milk well, and mares too fat are subject to developing laminitis or have foaling difficulties. During the last 3 mo of gestation, the mare should be on a gradual, increasing plane of nutrition. The size of the fetus increases significantly during the last trimester, and the mare's weight can be expected to increase. During this time, the mare should be on good-quality legume or grass hay and a concentrate ration of 12%–14% protein. A mare weighing 1,000–1,200 pounds (454–544 kg) can be expected to gain 150–200 pounds during the last trimester with the proper diet. A body condition score of 6.5–7.5 is ideal for most pregnant mares at foaling.

The mare should be checked for the presence of a Caslick's operation of the vulva, which should be opened if present. The foaling process is continuous, with labor divided into three stages. Stage 1 may be 1–4 hr as uterine contractions increase in strength and frequency. Stage 2 is the actual delivery of the foal, which takes 5–15 min

unless there are complications. Stage 3 is the passage of the fetal membranes, which should occur within a 3-hr period. If the membranes are retained for >3 hr, then veterinary treatment is necessary because severe sepsis or laminitis can result. Some mares may exhibit abdominal pain after foaling, and low-dose analgesics may be helpful. The normal placenta will weigh ~10–12 pounds (4.5–5.4 kg) or ~10% of the foal's birth weight.

The mare should be dewormed within 48 hr after foaling to reduce exposure of the foal to parasites. In 90% of foalings, the newborn foal is usually sternal within 1 hr, stands within 2 hr, and nurses within 3 hr. The foaling stall should be at least 14 × 14 feet (4.3 × 4.3 m); a double stall 12 × 20 feet (3.7 × 6.1 m) is more satisfactory. The stall should be bedded with straw or short stem hay. Wood shavings are less desirable because of the possibility of the shavings entering the foal's nostrils or mouth and also contaminating the mare's birth canal. The newborn foal's umbilicus should be dipped in a dilute solution of chlorhexidine (0.5%) or povidone-iodine (1%) several times a day for 2–3 days.

The passage of meconium can be facilitated by use of an enema (warm soapy

water, or a commercial sodium-phosphate enema can be used once). Many foals will not nurse satisfactorily or with vigor until the meconium has passed.

Foals have no immunity at birth and acquire it through ingestion of colostrum. Absorption of colostral antibodies occurs within the first 24 hr of life. Ideally, when ~12 hr old, the foal should have a complete veterinary physical examination, including temperature, heart and lung auscultation, and examination for cleft palate, fractured ribs, or entropion. Evaluation of the foal's IgG level is most important. If the foal's serum level is <800 mg/dL, an IV transfusion of plasma is necessary.

Foals should be monitored closely during the first 7 days of life. A healthy foal can become critically ill in a matter of hours. The mare and foal should remain in the box stall for 24–48 hr until the foal is strong enough to follow the mare at a trot or gallop. Then the pair can be turned out in a small area for exercise, which is essential. Haltering and handling the foal during the first week of life will set the stage for the animal's behavior in the future. Mares that reject their foals usually do so right after birth. This is more common in primiparous mares and requires intense supervision.

HEALTH-MANAGEMENT INTERACTION: PIGS

Disease in pork production is generally caused by multiple factors. Microbial pathogens are rarely the sole cause of a health problem on a pig farm. Clinical disease is usually the interaction of a pathogen with errors in management and a variety of contributing influences such as environment and host factors. Many pathogens are endemic in the swine population and yet some farms suffer heavy losses from disease, whereas the impact on other farms is much less because of management differences.

Management and Economic Considerations: Economic considerations influence all decisions regarding health care on pig farms. Health management and disease prevention programs tend to be prioritized based on financial return, although other important considerations include animal welfare, food safety, and risk

management. Pigs are omnivores extremely well suited to convert low-cost feedstuffs (often including waste products) into meat. Pigs efficiently convert feed to muscle while growing at a rapid rate. In addition, their fecundity is remarkable. Female pigs reach sexual maturity, breed, and produce a litter of ≥10 piglets at ~1 year of age and then continue to produce litters 2.5 times per year.

Health management plays a key role in profitable farming enterprises. Profit is based on maximizing income and minimizing costs. Income is a function of the price received per kg of pork produced times the total amount of pork produced. Therefore, aspects of health management that ensure good reproductive performance and consistent pig numbers at all stages of production and rapid growth contribute to a steady, high income. Production parameters, such as pigs produced per sow per year and measures of throughput,

should be carefully monitored to ensure the farm is achieving a high level of productivity. At the same time, production costs must be evaluated to assess the health or profitability of a swine operation. Because feed costs are well over half the cost of production, health management initiatives to reduce feed costs or improve feed efficiency tend to be areas of high priority. Some of the most economically important swine diseases may present with little in the way of clinical signs. For example, porcine proliferative enteropathy (*Lawsonia intracellularis* infection, see p 299) might cause thickening of the bowel and reduced feed efficiency without signs of diarrhea or obvious illness, but the cost of the resulting increase in feed consumption likely makes this disease a high priority with regard to a health management program. Cost-benefit of programs should be evaluated to avoid spending so much to reduce the risk of the disease that it outweighs the benefits in improved performance. Therefore, a producer might choose to ignore a management protocol directed at disease control to save money longterm; however, this decision may change with time and circumstances, so medication and vaccine programs, for example, should be consistently assessed.

Production Records: The use of production records is an essential part of a herd health program. Records are used to assess performance and identify areas of concern. When a general issue is identified, records also can be used to help pinpoint the problem as well as assess whether the intervention strategy was successful. Records can be used to set targets and motivate staff to achieve these targets as well as help the veterinarian develop partial budget scenarios to justify health care expenses.

In breeding herds, the parameter most commonly used to assess overall herd performance is average number of pigs weaned per sow per year. On many North American farms, this number is ≥ 25 ; some producers achieve a number >30 . When this number is lower than the target, it is useful to examine the specific components of the parameter to determine the source of the problem. Pigs weaned per sow per year is a product of “pigs weaned per sow per litter” and “number of litters per sow per year.” With a 3-wk lactation, it is possible to achieve ~ 2.5 litters per sow per year. If the number of litters per sow per year is low, it may be because of a poor farrowing rate

(sows bred but failing to farrow; generally 80%–85% is achievable) or it may be because of prebreeding problems such as a long weaning-to-breeding interval (<7 days is typical). A low number of litters per sow per year will probably lead the herd veterinarian to investigate the breeding management; in contrast, if litters per sow per year is close to 2.5 but pigs weaned per sow per year is low, the veterinarian can begin to investigate the farrowing room to determine why litter size at weaning is low (10 pigs per litter is commonly achieved, but this number is increasing because of larger litter sizes being born). The cause of low numbers weaned may be because of small litters being born or a high preweaning mortality.

Record analysis can be used to focus attention so that resources can be concentrated on solving a specific problem. In the post-weaning until market period, the main production records include mortality, growth rate, and feed efficiency. Because feed cost contributes substantially to the cost of producing a market hog, measuring feed consumption and monitoring feed costs are extremely important. During the early growing period, pigs are extremely efficient in using feed to produce muscle. Feed:gain ratios of 1.5:1 or better are expected during the nursery phase (3–10 wk of age). As the pig approaches market age, metabolism changes and the pig begins to produce more fat, which shifts the feed:gain ratio so that >3 kg of feed is needed to produce 1 kg of gain. Overall through the grower-finisher phase, most herds achieve a feed:gain ratio of better than 3:1. Mortality records throughout the production stage are possibly the most useful parameter to identify a health problem. In general, preweaning mortality of $\geq 10\%$ can be achieved on most farms, with nursery mortality of 3%–4% and grower-finisher mortality of 2%–3% achievable.

Herd Size and Disease Challenge: As in most agricultural businesses, pig farming has an economy of scale; hence, pig farms have grown larger and larger over the past few decades, with a trend toward vertical integration in the industry. The management of health issues in large populations requires a major focus on biosecurity (see p 2068). Great efforts are warranted to keep new diseases from entering an immunologically naive population, in addition to programs to restrict the spread of endemic diseases within the herd and especially between one production stage and another. The general

strategy to prevent outbreaks of clinical disease is to minimize the level of pathogen challenge while maximizing herd and individual immunity. Poor management might result in a population of pigs with naive immune systems encountering novel pathogens, or in stress leading to a weakened immune system in vulnerable pigs. Alternatively, management errors might result in an overwhelming pathogen challenge in the case of an endemic disease or the entry of a new pathogen into a population of pigs without specific immunity.

One of the most effective management techniques to minimize the challenge from endemic diseases and possibly to eliminate a disease from a swine operation is the use of all-in/all-out pig flow through the various production stages. Commonly a group of sows are moved together into a clean and disinfected farrowing room, and later their piglets are weaned and the sows moved out as a group; all the weanling pigs enter a clean, empty nursery possibly on a separate site from the sow herd. Similarly, the pigs leave the nursery as a group and enter a clean, empty grower-finisher barn, possibly at a different site. This type of flow reduces the chance of endemic disease continuing to cycle in the population.

In summary, many pig diseases are controlled by this combined strategy of minimizing disease challenge and maximizing individual and herd immunity. For example, the common methods used to prevent neonatal diarrhea caused by enterotoxigenic *Escherichia coli* (ETEC) include all-in/all-out farrowing room management, the use of slatted flooring constructed of nonporous material that is easily cleaned, and washing and disinfection protocols to ensure minimal bacteria will be present in the environment to challenge the newborn piglets. At the same time, it is common practice to vaccinate the sows against ETEC before farrowing so they have high levels of specific immunoglobulins present in colostrum and milk to provide passive immunity to the piglets. In addition, it is necessary to ensure the piglets receive these immunoglobulins, so steps such as cross-fostering are important. Disease can occur if either the challenge becomes too great or the immune protection waivers, so both approaches are important and complementary.

Because herd size is often very large, ensuring that the population as a whole has immunity and that pockets of naive animals are not present within the herd can be a challenge. A subpopulation of susceptible

animals is likely to act as a reservoir for endemic diseases. This is particularly true for viral diseases for which vaccination is not very effective. For example, it is a common practice to purposely infect all sows in a herd with porcine reproductive and respiratory syndrome (PRRS) virus (see p 729) using a live field strain of the virus and at the same time closing the herd to new introduction if the herd is experiencing an outbreak of PRRS. The goal of such a program is to expose all the sows to the PRRS virus so that the entire herd develops immunity. When all the sows are immune, they will pass antibodies and not the virus in colostrum to the piglets. In this way, PRRS can be eliminated from the herd.

Health Strategies: Health strategies can be divided into three categories. First, there are strategies designed to live with endemic diseases. Generally, these are caused by pathogens that survive in the environment and are too difficult to eliminate, or they are ubiquitous organisms that generally cause little problem. The former are handled by maximizing immunity and minimizing the challenge, as outlined above. In the latter, disease flare-ups are often triggered by environmental-management deficiencies, which if corrected will restore the healthy state in the herd. Second, some pathogens can be eliminated. For example, *Sarcoptes scabiei* var *suis* can be eliminated from a herd using the strategic administration of agents such as ivermectin and doramectin. Alternatively, diseases such as transmissible gastroenteritis and PRRS can be eliminated from a herd by closing the herd to new introductions and purposely exposing all animals to the disease to create herd immunity. It is usually desirable in the longterm to eliminate the diseases, if possible and if it results in savings from reduced routine medication or vaccination. Third, there are strategies to prevent pathogens from entering the herd. As herd size has increased, the emphasis in maintaining the population of animals free of certain diseases has increased in importance. Some key components of a biosecurity program include careful management of replacement stock with quarantine and monitoring; preventing entry of rodents, birds, and other animals; precautions to prevent disease transfer from trucks and fomites; and the restricted entry of people (See also BIOSECURITY, 2068).

Vaccination and Disease Status:

Vaccination is a key health management tool to enhance individual and herd

immunity. Commercial vaccines are available for most of the important swine diseases, and when commercial vaccines are not available, autogenous vaccine may be a possibility. Generally, only a small number of vaccines are used in most herds. The decision to use a vaccine depends on a number of factors and needs to be assessed and frequently reassessed on an individual herd basis. To use all of the available vaccines would be cost prohibitive. Criteria used to decide which vaccines to incorporate into a herd vaccination program include cost (including labor) and efficacy of the vaccine, cost of the disease or possibly the risk of the disease occurring in the herd, and availability of alternative measures that might be more useful than vaccination. On many farms, gilts and sows are vaccinated before breeding to protect from reproductive failure caused by *Leptospira* sp, *Erysipelothrix rhusiopathiae*, and parvovirus infection. It is also common practice on many farms to vaccinate sows during gestation with an enterotoxigenic *E. coli* vaccine to boost antibodies in the colostrum and milk to protect piglets from diarrhea via passive immunity. Common vaccines given to weaned pigs include porcine circovirus and *Mycoplasma hyopneumoniae*. Several other vaccines warrant important consideration for most farms, including *L. intracellularis*, swine influenza virus, and PRRS virus.

The decision to vaccinate for a particular pathogen or develop specific control strategies sometimes depends on whether the disease is present on the farm. Knowing the disease status of a herd is an important consideration for a number of reasons. For example, it is critical if two sources of pigs need to be mixed or sources of replacement stock need to be chosen. To know what diseases are present in a herd, monitoring needs to be regularly performed and multiple sources of information incorporated into the assessment. On herd visits, animal inspection can identify clinical signs of disease. Pigs that are scratching may cast suspicion that mange is present in the herd.

The presence of coughing and sneezing might prompt further investigation of respiratory diseases. It is common practice to euthanize and conduct postmortem examinations on unthrifty pigs to screen for the presence of diseases such as enzootic pneumonia or ileitis. Analysis of blood or oral fluid from a representative sample of animals to monitor for disease is an important part of herd health evaluations. In addition, production records and drug use records can help to assess health status. Another information source may be abattoir reports, or if possible following pigs through the slaughterhouse floor and assessing lesions such as milk spots on liver that indicate roundworm migration.

Herd Visit and Facility Inspection:

The herd visit is also important to determine possible housing-environmental-management shortcomings. Animal inspection may reveal signs of stress or mismanagement affecting animal welfare and productivity. Behavioral vices such as tail biting may indicate underlying environmental problems such as crowding, or insufficient resources such as waterers or feeding space. A facility inspection should spot damaged penning and flooring that could lead to injury. Air quality, room temperature, and presence of drafts can all be assessed. Stocking density is possibly the most obvious potential stressor that should be investigated during a herd visit. Published guidelines for space requirements are being used more and more in animal welfare audits. Space requirements (see TABLE 6) vary according to age and weight of pigs as well as for flooring type and other considerations such as season, ventilation or cooling systems, and group size. Investigation of disease outbreaks may require a team approach, with a veterinarian interacting with experts in nutrition, building design or engineering, and other fields to determine the triggering factors. The longterm solution to a disease problem often depends on a change in management.

TABLE 6 SPACE RECOMMENDATIONS FOR GROWING PIGS

Production Stage	Body Weight	Space Allowance
Nursery	Weaning to 27 kg (30 lb)	0.16–0.23 m ² (1.7–2.5 ft ²)
Grower	27–68 kg (30–100 lb)	0.28–0.56 m ² (3–6 ft ²)
Finisher	68 kg (150 lb) to market wt	0.74–0.84 m ² (8–9 ft ²)

HEALTH-MANAGEMENT INTERACTION: SHEEP

Sheep and goats were first domesticated around 8,000 BC, making them the first of the domesticated food animals. Sheep are extremely adaptable and found all over the world, particularly in arid areas that do not support other types of livestock. Because sheep are raised in various environments, specific breeds have been developed to meet the needs of the environment and people. More than 100 breeds have been recorded. Different production systems are used in various areas of the world. Extensive year-round grazing, with large flocks (>1,000 sheep) and minimal sheep handling, is the typical system of sheep management where the climate and area to graze allow. Systems in New Zealand, South Africa, and Australia, where forage is available throughout the year, are prime examples of this type of management. Confinement and intensive feeding during the winter months, with access to range land pasture for the rest of the year, is a common system of large sheep flocks in parts of Europe, the UK, the western USA, and other countries that have snow and inclement weather seasonally.

Intensively managed smaller flocks can be found around the world, with sheep kept for milking, natural colored wool, purebred breeding stock, sale of lambs for home freezer trade, and hobby flocks on small acreages. Small flocks of breeding stock or hobby and pet flocks are common in the more developed areas of the world, particularly the USA and Canada.

Shepherding small flocks of sheep and goats along roadsides and common grazing areas is a typical management system in the Middle East, Asia, and Mexico.

EXTENSIVE GRAZING SYSTEMS

Veterinary services for sheep are typically not readily available in the poorer areas of the world unless provided by governments to satisfy exports to other countries. Where veterinary services are available, private practitioners are mostly called upon by extensive grazers that confine their sheep during the colder periods of the year for feeding. Veterinarians are often needed to manage lambing problems such as scours/diarrhea outbreaks, baby lamb mortalities, and other major disease outbreaks. Because

predation from coyotes, wild cats, bears, wild pigs, wolves, dingos, etc (depending on the country), usually accounts for the major losses during the rest of the year, private practitioners are generally not a part of flock health and management programs in these systems. However, extensive management systems often use government or university veterinary extension education and services where provided.

Veterinarians can use a request to solve a current problem from such a producer to also educate and advise on flock health. This is more common in extensive grazing units in which sheep are confined during the winter months and so are available for handling and examination. Abortion, still births, weak lambs, and open ewes require accurate diagnosis, and management of these problems can evolve into development of a vaccination program, breeding soundness examinations for rams, looking at mineral and protein supplementation programs, and other preventive programs.

Baby lamb deaths require formal diagnostic aid, which can be used to develop preventive programs for *Escherichia coli*, coccidia, *Mannheimia*, white muscle disease, and navel ill. Starvation deaths should lead to examining ewe body condition, preparturient supplementation, mastitis control, and lambing management in general.

Some knowledge of range land nutrition, including toxicities and deficiencies common to the area, feed costs, labor problems, and markets, in addition to knowledge of sheep diseases, is very helpful when giving advice and providing preventive programs and management changes to extensive grazing producers. The aim is to increase net farm income rather than just control disease. Although the diagnosis, treatment, and control of disease are important, an overall management change that will contribute to longterm profitability may be far more important. Net income per hectare/acre should be the major consideration of any recommended change.

A flock health plan, tailored to the specific needs of a large producer, should include: 1) a good mineral/nutritional supplementation program (after determining any deficiencies); 2) control of external parasites (internal parasites may not be a problem on arid ground

but that should be determined); 3) prevention of diseases for which cost-effective vaccines are available; 4) methods to prevent introduction of contagious diseases, such as sore mouth/scab, caseous lymphadenitis, footrot, epididymitis/brucellosis, and Johne disease; and 5) improvement of the number of lambs weaned per ewe bred, with enhanced ewe and ram fertility and reduced lamb mortalities (may be related to nutritional program).

In most sheep operations, wool is not the major source of income, so the economic outcome from an outbreak of disease or a serious nutritional problem is usually obvious. However, in operations in which wool is the predominant source of income, a moderate parasite burden or nutritional deficiencies can cause ill-thrift, reduced kilograms of wool shorn per head, and reduced fiber diameter. The latter outcome may result in a more valuable fleece and thus, no reduction of income. In this situation, reduced health of the ewes may not be obvious. A ewe that does not conceive or aborts in the first 3 mo of pregnancy will produce more wool than a ewe that rears a lamb, because a ewe rearing a lamb has a higher nutritional requirement and produces less wool than a dry ewe. However, in most places, the price of lamb, somewhat influenced by pelt price, is worth far more than that of the wool.

In some areas of the world, veterinarians may be able to go beyond a flock health program by developing a comprehensive flock management advisory service. This service would adopt a whole farm approach that considers the physical and financial resources of the farm/ranch and the interaction of livestock production with other activities such as cropping and pasture production. The stocking rate, type of stock run, timing of husbandry procedures, marketing strategies, and risk management should be reviewed as part of the program. A financial analysis of the farm as a business and preparation of farm budgets and gross margin analyses is a key part of most programs. However, this type of service has not been readily adopted by producers in most places, and most veterinarians do not have the expertise.

SUMMER GRAZING WITH WINTER CONFINEMENT (INTENSIVE MANAGEMENT)

These types of sheep enterprises tend to use veterinary services the most. Smaller backyard producers may use veterinarians

to perform procedures such as vaccinating, docking/tailing, castrating, and hoof trimming as well as to treat sick animals. However, larger producers in many countries often perform these routine procedures themselves, using veterinarians for such things as cesarean sections and help with disease control.

Wool production is usually a minor concern on the smaller production units; the number/pounds/kilos of lambs marketed per ewe joined/bred is the major determinant of economic return. The greatest potential loss is caused by neonatal lamb mortality, resulting from abortion, mismothering, starvation, and hypothermia. Second to that may be lack of growth weight due to internal and external parasites, protein deficiency, and lack of highly digestible and palatable feed for young lambs. Intensive management and good sanitation at lambing will reduce this loss. Labor-intensive lambing systems; intensive care of young lambs; and diagnosis, treatment, and occasional surgery of individual sheep may be justified by the value of the animals. However, preventive medicine programs are greatly needed in these management situations to prevent the numerous husbandry-related diseases associated with higher stocking rates. Attention to pastoral-related disease is important in the summer (ie, internal parasite control) and in the winter for problems related to closer confinement, winter nutrition, and lambing problems.

In these types of production situations, record keeping becomes critically important for improvement. Animals must be individually identified so that the production of each can be monitored. Some countries/regions, such as the UK, the European Union, Australia, Canada, and the USA mandate individual animal identification for disease tracking.

Lambs should be identified at birth, usually with a unique ear tag. The identification number, date of birth, dam, type of birth (single, twin, etc), sex, and remarks such as "weak," "required help birthing," etc, are recorded. Recording birth weight is also desirable. Thus, scales, one appropriate for baby lambs and another to weigh market-size lambs, are an important tool to determine productivity.

Lambs should be weighed again at 50–60 days and 100–120 days, which indicates some measure of the milking ability of the ewe (60-day weight) and genetics of the lamb (120-day weight). Comparisons of the lambs' rate of gain and twinning are two measures that can then be used to cull the

ewe flock. It often is the thinnest ewe that turns out to be the best producer, and the fattest ewe the poorest. This is a relatively basic record keeping system in which other criteria can be assessed if desired.

In Australia, computer-based programs are used to compare animals within a flock as well as to compare flocks with other flocks on the plan. The USA sheep industry offers a similar plan (the National Sheep Improvement Plan), to which any producer can subscribe.

Feed and labor are always the largest annual expense for livestock producers, particularly for winter-fed or intensively fed sheep and lambs. Producers and their families usually provide the labor for smaller flocks, making feed the largest out-of-pocket cost. Therefore, nutritional management is of major importance. Veterinarians with knowledge of nutrition and mineral management can be extremely helpful, because feed imbalances can be costly.

Feedlot lamb feeding and management is also an area in which veterinary services can be very useful, providing least cost rations and preventing major nutritional diseases such as acidosis, urolithiasis (see p 1502), rectal prolapse, type D enterotoxemia (pulpy kidney disease, see p 610), and polioencephalomalacia (see p 1281) and stress-related diseases such as pneumonia (see p 1472).

SHEPHERDING

Veterinary services to the small, shepherded sheep and goat flocks in the Middle East and Asia are primarily concerned with controlling clinical diseases and improving the survival rate of young lambs and kids. The restricted availability and low nutritional value of feed limit productivity. Sheep and goats are kept primarily as a source of meat and milk for the owner's family and for sale as a source of cash income. Veterinary care is often provided by government programs and is directed toward control of specific contagious and zoonotic diseases. Even though the value of animals in the flock is often high relative to the income of the owner, the funds available to invest in veterinary services are limited. Thus, private veterinary care is seldom used, even if available, despite the fact that the death or severe ill health of a few animals can have a major impact on both the productivity of the flock and the well-being of the owner.

In Asia, the system of land use is often complex, with sheep and goats integrated

with other grazing animals or grazing around the fringes of a more productive cropping or plantation enterprise. This may also be true in the Middle East, or sheep and goats may graze poorly productive arid areas that will support little else. In either case, opportunities for major changes to the management system are limited.

ORGANIC SHEEP PRODUCTION

Public demand is moving animal-based production toward organic systems. The standards required to allow an organic label for sheep products, although allegedly making the product safer for the consumer, do not tend to promote animal health. They prohibit the use of antibiotics, chemotherapeutics, and parasiticides ("chemicals"); therefore, organic producers cannot use preventive or therapeutic medications and rather must rely on "natural" or home remedies with questionable effects but no withdrawal times. This forces them to manage for disease prevention rather than use labeled medicines with known withdrawal times. These standards are often aspirational rather than practical and can lead to health issues and welfare concerns in organic flocks, even those that have excellent management systems dedicated to this approach. Veterinarians can be extremely helpful in this type of production system.

Organic flocks should be established from known health-status flocks that are free of testable and eradicable diseases such as orf/sore mouth, *Corynebacterium pseudotuberculosis* (cheesy gland, caseous lymphadenitis), *Brucella ovis* (ram epididymitis), footrot, maedi/ovine progressive pneumonia, scrapie, John's disease, and chlamydial and *Campylobacter* abortion. Flocks should be maintained as closed flocks as much as practical, and new genetic stock should be sourced from known health status flocks. New stock must be quarantined and thoroughly examined and tested before introduction to the flock and its pastures. Preventing entry of disease is critical, necessitating a high degree of biosecurity (see p 2068).

Parasitic gastroenteritis can be of particular concern in organic sheep production. In addition, although the regulations of some countries allow judicious use of anthelmintics and antiparasitics, others do not. Management plans must include methods to avoid or reduce parasitic larval intake. Grazing crop aftermaths, using mixed-species rotational grazing, attention to stocking

rates, drylotting, and using pastures for hay and grazing only after a good freeze for a season, can all be used to limit internal parasites. Other strategies that have been suggested include grazing plants that may reduce GI parasitism such as chicory, sanfoin, birdsfoot trefoil, and the use of copper oxide needles. Breeding and selecting for genetic resistance is definitely a viable option and not too difficult using the help of individual fecal egg counts.

DISORDERS ASSOCIATED WITH MANAGEMENT PRACTICES

Management practices, particularly feeding practices, can be the primary determinant of cases or outbreaks of infectious or metabolic disease in all flocks of sheep.

Pregnancy toxemia (see p 1021) may be seen in late-pregnant ewes bearing multiple fetuses subjected to a falling plane of nutrition, specifically energy. It is associated with simple starvation, ewes too fat in early pregnancy, ewes too fat in late pregnancy and that voluntarily reduce feed intake, poor quality feed, and ewes subjected to stress in late-pregnancy (eg, trailing or transport, or severe environmental changes). Ewes rarely survive after showing signs of pregnancy toxemia, even with excellent veterinary care, and it is difficult to stop losses even after interceding with adequate feed.

Hypocalcemia (see p 991) is seen in pregnant ewes or ewes in early lactation subjected to a period of temporary starvation or to feeds particularly low in calcium, especially ewes with multiple fetuses, as a result of decreased food intake in late pregnancy. It is also seen in feeder lambs on a grain-based ration without adequate mineral supplementation, and during drought conditions. Calcium deficiency can be confused with pregnancy toxemia and is often a part of the pregnancy toxemia syndrome. Fortunately, pure calcium deficiency can be easily treated and rectified, saving the ewe and her pregnancy.

Hypomagnesemia (see p 995) may be seen during a period of temporary starvation in late pregnancy or early lactation, and also after movement of lactating ewes to lush spring growth pasture (especially green cereal crops). As with hypocalcemia, this condition is easily treated and rectified if properly diagnosed.

Dermatophilosis (see p 858) is associated with poor shearing practices

leading to shearing cuts, particularly in areas that still use dipping vats for ectoparasite control (this practice has largely disappeared since the advent of the avermectin parasiticides). Sheep in long wool at times of high rainfall tend to be at higher risk of infection, and some sheep are also genetically predisposed.

Caseous lymphadenitis (see p 63) may be associated with shearing by not separating infected or discharging sheep before shearing, not shearing affected sheep last, not changing blades and disinfecting shears after cutting into an abscess, dipping in contaminated dip, and by close confinement of infected sheep with noninfected sheep after shearing and at other times.

Other means of spreading this very contagious disease is the use of feed bunks or working chutes where the organism (*Corynebacterium pseudotuberculosis*) has been smeared on slats or railings by sheep with draining abscesses. The organism can survive for up to a year in the environment. It can be controlled by vaccination.

This disease is responsible for huge economic losses in North America due to the rejection or trimming of large parts of carcasses of affected animals when slaughtered.

Enterotoxemia (*Clostridium perfringens* type D infection, see p 610) is seen in weaned, unvaccinated lambs on a rising plane of nutrition high in carbohydrates, as when moved to better pasture or following a "flush" in pasture growth, particularly cereal grains and in feeder lambs fed grain. It generally causes a "sudden death" syndrome and can be confused with acidosis. These animals are found dead and even if found alive can rarely be saved. There is an enterotoxemia antiserum, which if administered early, can be used for treatment. The vaccine is very effective.

Acidosis is seen in adults and lambs exposed suddenly to a higher carbohydrate diet than normal and is often confused with enterotoxemia. It is seen commonly when late-pregnancy ewes are started on grain, when feedlot self-feeders run out of feed for more than a few hours, and when children not properly instructed in correct feeding of animals perform feeding chores.

C perfringens type C infection is generally a suckling lamb disease seen in very young single lambs suckling ewes that produce an overabundance of milk or in a lamb after its twin dies. It is also seen in artificially reared orphan "bummer" lambs that have not had sufficient colostrum. The

disease can be prevented by vaccinating ewes close to parturition with enterotoxemia C and D vaccine to provide antibodies in their colostrum; saving frozen colostrum from vaccinated ewes, does, or cows for administration to lambs that received no colostrum; or giving those lambs injections of enterotoxemia antiserum.

Malignant edema (see p 604) and **blackleg** (see p 602) may follow wounds (eg, improper shearing, vaccination). However, these are clostridial diseases not commonly seen in sheep.

Tetanus (see p 611) may also be seen in unvaccinated sheep and lambs after a wound associated with procedures such as castration, docking (tailing), shearing, or vaccination performed in contaminated yards/corrals. Tetanus has been specifically associated with the use of elastrator (castrating) bands to remove tails and testicles of young lambs. Vaccinating ewes with a *C tetani*-containing vaccine shortly before lambing will prevent the disease for up to 60 days of age if the lambs receive their dams' colostrum.

Black disease (see p 603) is caused by *C novyi* type D. Sudden death is a hallmark of this disease seen among unvaccinated grazing sheep on pastures with wet areas that support the snail that is the intermediate host of *Fasciola hepatica*. The organism, which produces a potent toxin, colonizes the necrotic areas of the liver caused by the migrating flukes on their way to the gallbladder.

C novyi is also the cause of "big head" in rams, in which necrotic and anaerobic tissue on the head caused by the head butting of unvaccinated fighting rams becomes infected with the anaerobic clostridial organisms. Black disease and big head can be prevented by vaccinating.

Navel ill (*E coli* and *Erysipelas* arthritis) (see p 625) are associated with navel infections of lambs born in muddy or dirty areas and that have not had their navels dipped in 7% iodine at birth. These two infections are often confused with one another and are usually seen around 3 wk of age, although simmering infections can exacerbate later. Other causes may be contaminated dip or poor hygiene at docking/tailing or castration.

Poor lambing management and sanitation of the lambing area can result in significant economic loss due to varied problems ranging from baby lambs dying of hypothermia-related hypoglycemia, starvation due to misnothering or ewes with mastitis, and sudden death due to

overwhelming coccidial infection at 3 wk of age. Lambs that get little or no colostrum for whatever reason are at significant risk of succumbing to disease because of the lack of passive immunity even after weaning. Diseases particularly common to lambs lacking passive immunity are *E coli* scours, septicemias, navel ill, coccidia, pneumonia, tetanus, enterotoxemia, sore mouth, and arthritis.

Coccidiosis can cause a sudden death syndrome at 21 days of age if the infecting dose was large enough. Otherwise, the disease is characterized by the area around a young lamb's tail smeared with diarrhea. If not treated, the diarrhea can turn bloody after a time and the lamb can dehydrate and die. The lambs' environment or the dam's contaminated teats is the source of the infections; most adults carry small to moderate amounts with no signs. Lambs, too, can carry moderate infections and show only lack of vigor and weight gain. Coccidia is the most common cause of poor-doing lambs and significant loss to the producer.

Coccidiosis can be controlled by keeping the lambs' area clean and dry and by treating ewes before lambing with a coccidiostat. Feeding coccidiostats in feed accessible only to the lambs such as decoquinate, amprolium, lasalocid, or monesin further controls the disease. It is treated with sulfonamides.

Ovine posthitis (pizzle rot) is seen in merino wethers on high-protein pasture and in breeding rams kept in corrals or paddocks, particularly with moist areas where the animals prefer to lie during hot periods of the day. Ammonium salts in the urine are broken down by soil organisms contaminating the wool around the prepuce, and the resultant NH_3 causes erosions and scabbing of the preputial orifice. It can interfere with breeding because of pain and discomfort. Clipping wool around the preputial opening, keeping animals in dry paddocks, and reducing protein in the diet will help eliminate the problem.

Actinobacillosis (see p 589) is seen in sheep grazing on abrasive, thorny pasture.

For disease risks associated with **pasture or with specific plants** (eg, bloat, polioencephalomalacia, hemolytic anemia, esophageal obstruction, enterotoxemia in sheep, and goiter in the lambs born to ewes grazing *Brassica* spp), see POISONOUS PLANTS, p 3103. For the risk of nutritional deficiency or toxic disease associated with formulated feeds, see NUTRITION: SHEEP, p 2345.

HEALTH-MANAGEMENT INTERACTION: SMALL ANIMALS

Proper management to prevent and control disease has historically been a higher priority in production animal medicine than in small animal medicine. However, appropriate management is just as important for small animals, whether their environment is that of a single or multiple-pet household or a more intensive housing situation such as a kennel or cattery.

Responsible pet ownership must be emphasized to all those owning and considering owning pets. Areas of client education that should be emphasized include the following: 1) routine care and grooming, 2) preventive health care, 3) parasite control, 4) nutrition, 5) household hazards, and 6) housing requirements and environmental factors.

Routine care and grooming not only help maintain pet health but also allow identification of health problems early in the course of disease. Compared with disease in people, disease in animals is generally identified at a later stage. Close observation of pets allows for evaluation of changes in appetite, thirst, urination, defecation, ambulation, and general behavior. Any changes may suggest the need for a more thorough examination and possible intervention. Special attention should be given to hair coat, skin, ears, eyes, and teeth. Anal sac impaction and overgrowth of nails are common problems.

Preventive health care in small animals primarily involves vaccination and parasite prevention. Vaccines are available for a variety of infectious diseases in dogs, including distemper, parvovirus, hepatitis, leptospirosis, tracheobronchitis, rabies, Lyme disease, and coronavirus. Vaccines available against infectious diseases in cats include those for panleukopenia, rhinotracheitis, calicivirus, rabies, feline infectious peritonitis (FIP), and feline leukemia virus (FeLV).

Vaccination schedules vary but generally require an initial vaccination at 6–8 wk of age, followed by additional vaccinations at 3-wk intervals until the animal is 4–5 mo old. After this, most vaccines are given annually. Rabies vaccination is dictated by state law or local jurisdiction. First-time vaccination for diseases other than rabies in adult animals should include an initial vaccination followed by at least one booster.

In the past, there has been some question concerning the overvaccination or hyperimmunization of both dogs and cats. Vaccine-associated sarcomas, specifically fibrosarcoma, have been an increasing problem in cats (*see p 955*). The etiology of this tumor is not completely understood, but it appears at vaccination sites of rabies and FeLV vaccines. In dogs, there has been some correlation between vaccination and immune-mediated disorders such as immune-mediated hemolytic anemia.

Current canine vaccination guidelines, published in 2011 by the American Animal Hospital Association, identify core and noncore vaccines. Core vaccines include distemper, parvovirus, and adenovirus-2. A killed rabies vaccine is also core and is available as a 1-yr and 3-yr product. The specific vaccine schedule is 8 wk, 12 wk, and 16 wk of age. The first booster should be given no later than 1 yr after the final vaccine dose of the initial series. Subsequent boosters should be administered every 3 yr. Current feline vaccination guidelines, published in 2013 by the American Association of Feline Practitioners, suggest vaccination for panleukopenia, herpesvirus 1, calicivirus, and feline leukemia virus (FeLV). Additional vaccines may be suggested depending on risk of exposure, eg, indoor versus outdoor or cattery situations. Current recommendations for vaccination sites also follow the guidelines of the American Association for Feline Practitioners. This protocol can also be used for dogs. The guidelines suggest that cats be vaccinated in an area amenable to surgical resection, ie, distal limbs rather than torso. Vaccines for feline panleukopenia virus, feline herpesvirus 1, and feline calicivirus are administered below the right elbow. FeLV vaccines are given below the left stifle, and rabies vaccines below the right stifle. Vaccinating dogs and cats less frequently has also been suggested. A triannual vaccination protocol for vaccines other than rabies has been adopted at many institutions. It is also recommended to reserve vaccines for certain diseases such as FeLV, Lyme disease, leptospirosis, feline immunodeficiency virus, and FIP for at-risk animals.

Other preventive health care measures may include castration or ovariectomy.

tomy, and annual veterinary examinations. The current trend in preventive health care is to emphasize an annual examination separate from visits for vaccination. The preventive health visits allow the veterinarian to see the animal frequently and detect disease at an earlier stage.

Parasite control continues to be important. The primary endoparasites include GI parasites such as roundworms, whipworms, and tapeworms (*see* p 412, et seq). Heartworm disease (*see* p 127), an important clinical entity in both dogs and cats, is preventable with prophylactic therapy. Although a treatment is currently available for heartworm disease in dogs, no safe or acceptable treatment is available for cats. The American Heartworm Association provides treatment guidelines for canine and feline heartworm disease. The primary ectoparasites include fleas, ticks, and mites. Both oral and topical products are available for flea control in dogs and cats. Another important aspect of parasite control includes prevention of zoonotic diseases such as visceral larva migrans and toxoplasmosis. *Bartonella* may also be an important vector-borne disease affecting people.

Nutrition is an important and often overlooked aspect of pet ownership. Most pet foods on the market have been formulated based on significant research and development. Specialty diets are available (both over-the-counter and from veterinarians, including prescription diets) for young, growing, and geriatric pets, as well as for specific disease processes. Overfeeding and oversupplementation may lead to numerous problems, and feeding of table scraps should be kept to a minimum. (*See also* NUTRITION: SMALL ANIMALS, p 2354.)

Water quality should not be overlooked, especially in rural areas and in kennels and catteries. Fresh water should be available ad lib.

Household hazards provide a variety of dangers to dogs and cats. Potential hazards include electrical cords, lead-based paint, cleaning supplies, antifreeze (*see* p 3046), houseplants (*see* p 3103), insecticides (*see* p 3058), prescription drugs (*see* p 3032), illicit and abused drugs (*see* p 3038), alcoholic beverages, chocolate (*see* p 2966), artificial sweeteners (xylitol, *see* p 2698), sewing needles, fish hooks, and many others. (*See also* HOUSEHOLD HAZARDS, p 3000.) Elements of house design, such as steep stairs, slippery floors, open windows, etc, may also be hazardous.

Housing requirements and environmental factors are an important consideration for pets. For companion animals

sharing an owner's home, concerns are generally limited. However, outdoor housing must provide cover from direct sunlight, shelter from excessive wind and extreme temperatures, adequate ventilation, and an adequate supply of fresh water. These factors are critical in kennels and catteries. Drainage must be appropriate for proper sanitation, and surfaces must be suitable for cleaning and disinfection. Hazardous environmental conditions can result in hyperthermia, sunburn, dehydration, hypothermia, or frostbite. Housing must also be safe and keep pets away from dangers such as other animals, motor vehicles, and malicious mischief. If animals are restrained by a leash or a chain, care should be taken that self-trauma cannot be inflicted. Some municipalities have introduced chain laws to prevent this type of injury.

Miscellaneous considerations include obedience training, which may help reduce aggressive interactions with other animals and people.

Traveling with pets is another important consideration. If crossing state lines, a health certificate should be issued. When international travel is planned, owners should be advised to become familiar with the appropriate health, quarantine, agriculture, and customs requirements. Transport of animals by airlines is under the jurisdiction of the specific airline company, but a veterinarian should be consulted and a health certificate issued. Animals should not be allowed to ride unrestrained in motor vehicles and should never be allowed to ride in the back of open vehicles such as pick-up trucks. Motion sickness (*see* p 1267) and anxiety are common problems in dogs and cats when traveling. The phenothiazine tranquilizer acepromazine may be beneficial in this situation, and antihistamine therapy such as diphenhydramine may be useful. Maropitant citrate is also approved for treatment of motion sickness.

The potential disease-management interaction between pets and owners is important in prevention of **zoonotic diseases**, especially when pets are owned by immunocompromised people. Pet owners with human immunodeficiency virus or those being treated with chemotherapy or other immunosuppressive agents can safely own animals but should consult both their veterinarian and physician. Most animal-associated infections, including those due to *Toxoplasma gondii*, *Cryptosporidium*, *Salmonella*, and *Campylobacter*, appear to be acquired by

immunosuppressed individuals from sources other than exposure to animals. The possible exception may be *Bartonella* or cat scratch disease. Because the risk of zoonotic transmission is low, animals pose minimal risk to immunocompromised people if basic precautions are followed. Precautions include avoiding the cleaning

of litter boxes or using gloves when doing so, avoiding dog feces, avoiding young or unhealthy pets in favor of healthy or adult pets, having sick animals evaluated by a veterinarian, not allowing cats to hunt, not feeding pets undercooked meat, and preventing coprophagy or access to garbage.

MANAGEMENT OF REPRODUCTION: CATTLE

Dairy and beef producers should strive to increase reproductive efficiency as a key driver of economic efficiency in the sector. Reproductive efficiency, or “pregnancy rate,” is defined as the proportion of cows eligible to be bred that become pregnant during an estrous cycle (or approximately 21 days), and which determines the calving to conception interval at the end of the voluntary waiting period. As pregnancy rate increases in dairy herds, the calving to conception interval decreases, and the herd status becomes, on average, less “days in milk” (DIM). This has the effect of increasing the potential amount of milk produced per day of herd lifetime, because yield classically declines at 0.3% per day after peak lactation production. A major and realistic goal of every beef cow/calf operator should be to raise or market 85 calves per 100 cows every year. Greater reproductive efficiency also reduces the number of cows culled for reproductive failure; collectively, these changes increase herd income.

Reproductive performance in both beef cow/calf and dairy operations can be improved by the following: 1) properly identifying and managing animals to carry out reproductive programs; 2) keeping records that enable determination of important herd indices, such as percent calf crop, pregnancy rate, length of calving season, culling rates, calf morbidity and mortality, breeding efficiency of bulls, and performance and production information; 3) meeting the nutritional requirements of various classes of livestock in the herd, emphasizing nutritional needs and cost efficiencies; 4) establishing a breeding program for heifer replacements and cows; 5) practicing sire selection and reproductive management; 6) adopting a vaccination/immunization program for the cow/calf

herd, bulls, and calves; 7) evaluating reproductive failure and abortions; 8) providing adequate facilities; and 9) ensuring that the calf is well cared for at birth and receives adequate colostrum.

NUTRITION

Nutrition is one of the most important management factors in reaching calf crop goals and in attaining a short calving season every year in beef breeding herds. The limiting nutrient related to reproduction in beef and dairy cattle is usually energy; although dairy cattle are usually fed rations that supply adequate energy during lactation, genetic drivers for milk production inevitably lead to a period of some negative energy balance postpartum. The level of energy and body condition before calving primarily influences when a beef cow returns to estrus, whereas level of energy after calving primarily influences subsequent conception. Feed requirements vary during the reproductive cycle (see p 2248).

There are four periods of beef cow nutrient requirements, and generally three for dairy cows. **Period 1** is the interval from calving to breeding; it is ~70–90 days and is the period of greatest nutritional demand. The dairy cow is at maximal milk production and recovering from the stress of parturition. During this period, she is expected to be ready to breed.

Period 2 is the interval from rebreeding to weaning the beef calf; it is ~120–150 days in beef cows. Periods 2 and 3 overlap in dairy cows and are not as easily separated as in beef cattle. The beef cow should gain weight while still milking. Although some dairy cows maintain body weight, many high producers continue to lose weight during this period.

Period 3 is from weaning to 50 days before calving; it lasts ~100 days and is the period of least nutritional demand. The beef cow has only to maintain her condition and continue fetal development. The dairy cow should be managed to gain or lose body weight during the last months of lactation to achieve target body condition ready to enter the stable dry period.

Period 4 is a critical stage and is the 50 days before calving; it is during this time that 75% of fetal growth occurs. Cows are usually not lactating during this “dry period.” Cow condition at calving is critical to rebreeding; the onset of estrus after calving is delayed in cows that lose weight or are thin and not gaining during late pregnancy.

Dairy cows are usually fed (*see* p 2265) for optimal milk production throughout their 305-day lactation. It is assumed they will lose weight during heavy lactation (the early months) and regain the loss during the remainder of lactation. Dairy cows should not be overfed during the dry period because of a genetic predisposition to sacrifice body condition to maximize milk production through insulin resistance. This leads to the increased probability of metabolic diseases, eg, type II ketosis and fatty liver disease (*see* p 1024 and *see* p 1018), during early lactation as insulin resistance leads to excessive fat mobilization from adipose tissue storage and overwhelms the capacity of lipoprotein transport mechanisms in the bovine liver to transport and metabolize lipid. In addition, dairy cows should be fed to minimize the incidence of calving-related disorders (eg, dystocia, hypocalcemia, and retained fetal membranes), including control of dietary cation-anion balance (DCAB), which have a negative effect on fertility and health postpartum.

The amount of cow feed required per pound or kg of calf weaned is fairly constant, although larger cows require more feed for maintenance than smaller cows. Cows that give more milk require more feed, generally with a higher level of protein. Increased milk is produced at the expense of reproduction when feed is not adequate to meet all needs.

The protein requirement of young growing stock and heavy-milking cows is often a limiting factor, while mature dry cows are often overfed protein. Heifers must be fed adequately from weaning to breeding if they are to calve at 2 yr of age; this target is critical for herd economics, because before this point the absence of

beef calf or milk for sale represents significant investment and risk.

To provide the essential nutrient requirements during various stages of the reproductive cycle, major forages and homegrown cereals should be analyzed to monitor nutrient content and actual value. Variation in amounts of trace minerals is common between and within different geographic areas. Globally, different systems are used to determine energy levels of the ration, such as the metabolizable protein (MP) or “Feed into Milk” (FiM) models or the Total Digestible Nutrient System and the California Net Energy System. All are commonly used, and application should be tailored to fit the individual operation.

Even within nutritional need categories, cattle benefit from feeding and handling in subgroups: lightweight heifers at weaning need to gain more than heavier heifers to reach puberty by breeding season; first-calf heifers require special attention from both an energy and competition standpoint if they are expected to breed and conceive at the proper time. These heifers are still growing, as well as lactating, and they may not have the rumen capacity to meet postcalving energy needs on forage alone. Monitoring of growth rates is important to achieve successful rearing targets. Supplemental feeding of both high-energy and high-protein feeds to first-calf heifers may be required for optimal reproductive potential. Calves from first-calf beef heifers may be weaned 30–40 days earlier than calves from cows in the main herd to allow the heifer more time to grow and recover from demands associated with lactation.

Thin, old, and small cows may not compete favorably with heavier cows within the same herd and often benefit from being fed as a separate subgroup.

Lactating dairy cattle are usually fed according to milk production. They may be fed concentrate on an individual basis or divided into groups according to milk production and fed an appropriate total mixed ration.

BREEDING PROGRAM FOR HEIFER REPLACEMENTS AND COWS

If a cow is to calve consistently, she must deliver her first calf early. Puberty is a function of breed, age, and weight. Beef heifers that are bred at 13–15 mo and calve at 22–24 mo have two advantages: they get closer attention from herdspeople by

calving before the main herd starts to calve, and subsequently they have the extra time needed to rebreed with the mature cow herd. For heifers to breed at 14 mo, they should have attained at least 65%–75% of their projected mature weight; therefore, adequate nutrition is of major importance. The breeding season for virgin beef heifers should start 3 wk before that of the main cow herd. The above considerations do not apply to dairy cattle, which calve throughout the year; however, scheduling heifer calvings at the start of a seasonal calving dairy herd such as in New Zealand or Ireland represents an opportunity to “reset” the calving pattern. Lifetime profit of dairy replacement heifers is maximized when heifers calve at 23–25 mo of age. Thus, to maintain genetic progress and maximize profitability, heifer breeding strategies on dairy operations should include artificial insemination (AI) that results in attainment of pregnancy to allow calving at ~24 mo of age.

To compensate for the greater attrition rate usually seen with virgin heifers, a greater number should be bred than is needed to maintain or increase herd numbers, eg, 150%.

Irregularities of Estrus and Anestrus

Breeding will not occur if the cow is anestrus, or if estrus is undetected. Genuine anestrus is not common in dairy cows but is more common in postpartum beef cows in below target body condition. Anestrus, subestrus, or irregular estrous cycles in cows may result from a number of factors, including poor management or nutrition, disease, injury, or disturbances in endocrine functions. One of the most important management factors in artificially bred herds is failure to detect or observe estrus. The average duration of estrus is 18 hr, but in many cows it is appreciably shorter. A systematic program for detection of estrus is important if cows are to be bred at the right time. A producer must be familiar with signs of estrus. Aids in estrus detection that are valuable adjuncts to the heat-detection program include chalk marks on the tailhead, chemically or electronically activated devices attached to the tailhead of the cow that reveal when other cows have mounted, and a vaginal probe that measures the electrical conductivity of the vaginal mucus. Accidental access of bulls to cows and failure to keep proper breeding records often result in apparent anestrus because of pregnancy without a service history.

Although genuine anestrus is generally not common in dairy cows, “subestrus” with poor estrous expression or irregular estrous cycles in cows may result from a number of factors, including poor management or nutrition, disease, injury, or disturbances in endocrine functions. In many dairy herds, detection of estrus for AI is inefficient, because not all cows are identified in estrus because of human error, attenuated expression of estrus in high-producing cows, and adverse responses to heat stress. Systematic breeding programs for AI at a predetermined time (ie, timed AI [TAI]), without the need for estrus detection, coupled with early rebreeding of nonpregnant cows are successful options for reproductive management of lactating dairy cows. These systems optimize pregnancy rate by synchronizing follicle development, regression of the corpus luteum (CL), and precise induction of ovulation to provide a fixed TAI. Incorporation of TAI in dairy herd reproductive management programs reduces labor requirements for detection of estrus while improving overall reproductive performance and maximizing profit.

Silent heat refers to normal follicular development and ovulation without evident signs of estrus. Its frequency decreases as lactation progresses, so that incidence is low by 4 mo postpartum. Cows with true silent heats may be detected only through rectal palpation or ultrasound of the ovaries, via accelerometers/activity meters, or the use of progesterone assay in milk or plasma.

Cyclic changes occur in the ovary over 18–24 days. These changes generally can be recognized and the time of the cycle estimated, particularly in the 3–4 days before ovulation, at the time of ovulation, or 3–4 days after ovulation. The CL regresses 3–4 days before the onset of estrus; it becomes smaller in size and changes from a distended, liver-like consistency to one more fibrous. Estrus is evidenced by the presence of a palpable follicle, an absent or regressed CL, and firm uterine tone. The vaginal mucosa is edematous, the cervix is relaxed and hyperemic, and a variable amount of clear serous mucus is frequently seen at the vulva, which is puffy and swollen. The immediate postovulatory period is characterized by blood in the mucous discharge and an ovary with a corpus hemorrhagicum, which on palpation is recognized as a soft area (5–15 mm in diameter) in the ovary. The CL is detectable by day 4–5 as a small and somewhat softer structure than the mature CL, which reaches maximal size by day 7.

The examiner can sometimes predict the next estrus from previous observations around estrus, and the cow can be watched closely at the next anticipated estrus. The primary behavioral sign of estrus—standing to be mounted—is the accurate predictor of ovulation. In cows that are approaching ovulation, the appropriate time can be estimated, and the cow bred on secondary signs such as mounting other cows; however, breeding on secondary signs may be associated with wide variation in time to ovulation. Aged gametes (either semen or oocytes) are associated with reduced embryo viability.

Regimens have therefore been developed for administration of prostaglandins (PGs) and their analogues alongside other products to synchronize estrus and to reduce dependence on estrus detection. Prostaglandins are effective only if a cow has a functional CL. A range of synchronization options are in common use, including double prostaglandin regimens, GnRH and prostaglandin protocols, and regimens that use combinations of GnRH and prostaglandin alongside intravaginal progesterone-releasing devices. For estrus synchronization, the prostaglandin or its analogue is administered to all cows. In those in days 6–18 of the cycle, the CL will regress and estrus will occur in 2–7 days. The others may either have been in estrus recently or will be in a few days. Eleven days later, all cows will be between days 6 and 18 of their cycle, and prostaglandin is administered a second time. Most cows will be in estrus in 3–4 days and will ovulate in 4–5 days. Breeding is done either on signs of estrus or fixed time. Cystic ovary disease (see p 1354) may be responsible for irregularities of the estrous cycle, eg, follicular cysts (anestrus, nymphomania, and shortened cycles) and luteal cysts (anestrus).

Under certain circumstances, ovaries are nonfunctional. They can be recognized as smooth, small, bean-shaped structures on a single examination, or reveal no activity or change after several examinations over a period of 3 wk. The most common causes are low total energy intake during late winter or droughty summer pastures, and excessive loss of body weight in lactating dairy cows postpartum.

The stress of chronic or severe disease, injury, or ovarian tumors may interrupt ovarian activity and result in anestrus. Congenital defects, such as freemartinism and ovarian hypoplasia, result in estrual failure. Inactive ovaries are treated by correcting the basic cause; they usually do

not respond to gonadotropin or steroid hormone treatment.

BULL REPRODUCTIVE MANAGEMENT

A desirable goal for beef producers is a 95% calf crop delivered within 45–65 days, with an optimal weaning weight obtained at the most efficient cost. Bull selection, management, and evaluation of performance are integral aspects of beef improvement. The bull can affect calving percentage as well as quality of calves. The use of performance-tested bulls (beef and dairy) is recommended for both natural breeding and artificial insemination.

A disease control program for bulls should include the following procedures:

- 1) Before use, bulls should be checked for brucellosis, tuberculosis, trichomoniasis, and paratuberculosis (ie, from a herd free of paratuberculosis). Bulls previously used in other herds, particularly herds in which disease status is not known, may spread diseases, particularly campylobacteriosis and trichomoniasis. Prophylactic sheath-washing with antibiotics may reduce the risk of *Campylobacter* transmission.
- 2) Depending on prevailing health status and market requirements, bulls should be vaccinated against infectious bovine rhinotracheitis, bovine viral diarrhea, clostridia, *Haemophilus*, campylobacteriosis, and leptospirosis if available. Vaccines should be administered around puberty, at 6 mo and 1 yr of age, and then annually, 1 mo before the breeding season.
- 3) Breeding soundness examinations should be performed annually at the most economically advantageous time for the producer (usually 1 mo before the breeding season).

All bulls should be on the premises 2 mo before the breeding season to allow them to adapt to the environment. Isolation of all new additions to the herd (bulls or cows) is recommended for proper adaptation and preparation. A breeding soundness examination consisting of a thorough physical examination, including internal and external genitalia, measurement of scrotal circumference, and microscopic examination of semen for sperm motility and morphology, should be conducted ~1 mo before the breeding season. Opportunities are emerging for more objective methods of semen evaluation to be used alongside standard microscopy, such as computer-assisted semen analysis (CASA) for motility and flow cytometry to assess morphologic defects. (See also BREEDING SOUNDNESS EXAMINATION OF BULLS, p 2231.)

During the breeding season, the bull should be watched closely for mating behavior. The standard recommendation is 25 cows per bull. There are significant variations in this ratio, depending on the breeding soundness and libido of individual bulls, differences in terrain, and length of breeding season.

The weight loss that develops in bulls during the breeding season should be restored during the off-period, but overconditioning should be avoided.

BREEDING

The breeding program may use either artificial insemination (AI) or natural service. AI has been commercially available for >60 yr; it is widely used in dairy cattle but is used much less in beef cattle because of handling and labor costs. AI offers a selection of bulls with known genetic potential, such as measured by estimated breeding values (EBVs) for traits such as ease of calving or growth rates. When nutrition and heat detection are properly managed, satisfactory results are obtained. Failure to detect estrus is the major reason for unsuccessful AI. When cows are properly inseminated with good-quality semen at the proper time, 50%–60% may conceive on first service, the same percentage on second service.

Embryo transfer (*see* p 2239) is frequently used to increase the number of progeny from the most valuable beef and dairy cows. Sexing of semen has been adapted to commercial field usage and is increasingly used. Sexing of embryos is becoming more readily available and practical for field usage, and some cloning techniques are emerging in availability.

Heifers should be bred according to size and age at puberty; at first breeding they should be 65%–70% of their projected mature body weight, with dairy heifers achieving >125 cm withers height at this stage. Selection of bulls to be used for natural service should be based on likely size of the calf at birth; the bull's own birth weight (not his adult weight) is a useful guide, but genetic proofs such as EBVs are vital.

Heat synchronization of heifers and cows is possible, but such programs depend on adequate management and cooperation. Also, sufficient skilled labor to breed and assist during calving is essential.

Artificial Insemination (AI)

In cattle, AI is used primarily for genetic improvement of livestock and to facilitate

high health replacement strategies. The worldwide adoption of AI for genetic improvement in dairy cattle was made possible by development of a progeny test system and subsequent use of milk production records as an objective measure of performance on which to select superior bulls, techniques for freezing semen, and liquid nitrogen storage refrigerators.

The development of objective systems such as EBVs to measure economic traits in beef cattle (eg, growth rate, carcass conformation and composition, efficiency of feed conversion) and thus the more accurate selection of sires, as well as control of the estrous cycle, is leading to an increase in use of AI in beef cattle.

Processing of frozen semen is a highly specialized technique. Attention to detail at each step is important to maintain semen quality. The freezability of semen varies among bulls. However, semen of high motility and morphology quality generally freezes well. Best results are obtained when semen is processed in a properly equipped laboratory by experienced staff at an AI center.

Collection and Handling of the Semen

Sample: (*See also* BREEDING SOUNDNESS

EXAMINATION OF THE MALE, p 2230.) Semen is collected using an artificial vagina or by electroejaculation (electrical stimulation of the seminal vesicles and ampullae). As long as the sample is of high quality, freezability and fertility should be normal. These techniques should not be used if the bull is unable to naturally service a cow for reasons that could be genetic.

Most AI in cattle today is performed with frozen semen. Frozen semen may be maintained for years; extenders permit more insemination doses to be processed from one collection of semen, maintain the fertility of the semen longer, protect the spermatozoa from sudden temperature or pH change, and prolong viability. Semen is usually extended with citrate-buffered egg yolk or heat-treated skim milk plus glycerol, sugars, enzymes, and antibiotics. Final extension is designed to package 0.25 mL or 0.5 mL of semen containing 20–30 million spermatozoa at time of freezing.

Extenders are often divided into fraction A and fraction B. The initial extension of semen is done with fraction A at the same temperature, eg, 86°F (30°C). The extended semen is then cooled to 41°F (5°C) over 40–50 min, or more slowly. Holding the extended semen at this temperature for 3–4 hr enables the antibiotics in fraction A to complete their action before being inhibited

by the cryoprotectant glycerol. Fraction B contains a cryoprotectant such as ethylene glycol or glycerol (eg, 14%) and is added at 5°C in equal quantity to the extended semen. Each AI center has its own standard extenders and processing procedures. Glycerol (11%–13%) may be used with milk-based diluents. Before freezing, semen should be stored for 4–18 hr at 5°C.

For freezing, bull semen is usually packaged in appropriately identified plastic straws (0.25 or 0.5 mL). Optimal freezing rates are known for many cell types, and spermatozoa can withstand a wide range of rates. In practice, extended semen is frozen in liquid nitrogen vapor before being plunged into liquid nitrogen at –320°F (–196°C). Storage in liquid nitrogen tanks is safe for ≥20 yr, and semen is transported in such tanks. The level of liquid nitrogen in tanks must be monitored to avoid semen losses, which is seen when the tanks become defective or when liquid nitrogen gradually evaporates.

Because spermatozoa do not survive for long after thawing, the semen should be used immediately. Thawing is best done as quickly as possible without damaging the semen by overheating. In practice, straws may be thawed in warm water (95°–98°F [35°–36.5°C]) for ≥30 sec and immediately placed in the cow's reproductive tract. Recommendations by the AI center that processed the semen should be followed.

Insemination Technique: The rectovaginal method is used almost exclusively. After thoroughly cleaning the external genitalia with disposable toweling, one gloved hand is introduced into the rectum and grasps the cervix. The insemination pipette is introduced through the vulva and vagina to the external cervical os. By manipulating the cervix, along with light cranial pressure on the pipette, the pipette is advanced through the annular rings of the cervix to the junction of the internal cervical os and the body of the uterus. The semen should be expelled slowly (5 sec) to avoid sperm loss. If insemination records and consistency of the cervical mucus suggest possible pregnancy, the pipette should be advanced less than one-half of the way through the cervix, and the semen expelled. The optimal time to inseminate is between the last half of standing estrus and 6 hr thereafter, which is described as the "AM/PM rule," in that cows observed beginning standing heat in the morning should be inseminated that afternoon, etc.

If fertility problems arise when AI is being used, the semen should be investigated,

although many factors other than semen are involved in attaining high fertility. Motility after thawing is an important criterion. An adequate number of motile spermatozoa at the time of insemination is critical. Morphologic examination also helps assess the role of semen in infertility cases. Comparisons within herds of diagnosable pregnancies resulting from the suspect semen and from semen from other bulls may be useful. Estrus detection continues to be the most important factor that influences AI efficiency. This factor should be investigated first, and inseminator proficiency second. The latter includes an evaluation of thawing temperature, time of thawing in relation to actual insemination, temperature changes from thawing to insemination, site and speed of semen deposition, and sanitary procedures. If semen is purchased from a reputable supplier, it is unusual for the cause of the infertility to be poor-quality semen, although transport and storage factors should be considered.

PREGNANCY DETERMINATION

Pregnancy determination is recommended to maximize breeding efficiency. In beef herds, the breeding season (natural service or AI) is ideally fixed at a length of 60–70 days. This gives the average cow two or three services to conceive. Cows that are not pregnant or were bred late should be identified; if kept in the herd, they will calve later in the season. Maintenance costs are significant, although they vary widely by farm and by year.

Pregnancy determination of beef cows should be done shortly after the breeding season is over (eg, 45–60 days); if the breeding season starts June 1 and ends early in August, it can be done during late September while the cows still have plenty of flesh from summer pasture. It is then possible to profitably market nonpregnant cows before expensive winter feeding starts. When excessive returns are noted or bull performance issues are suspected, early pregnancy determination by ultrasound 50 days after the start of the breeding season can be invaluable. A target of 65% of cows should be pregnant to the first cycle in beef herds, and so by 50 days this can be measured as pregnancy determination success 30 days after breeding. Supplementary AI or new bull power can be implemented with poor success, alongside further investigation.

Dairy cows should be examined to determine their pregnancy status and if

found open can be synchronized into estrus with prostaglandin $F_{2\alpha}$, or timed AI. In cows that are open or that have not been detected in heat, the decision on which hormones to use to induce estrus is based on evaluating the ovaries for CL, follicles, and ovarian cysts. The most common method to determine pregnancy and evaluate ovaries is transrectal palpation and, increasingly, the use of ultrasonography. Ultrasonography may have the following advantages: 1) Nonpregnant cows can be found earlier (28–32 days after breeding), and diagnostic information on the status of the ovaries and uterus can be obtained. 2) The viability of the embryo or fetus can be assessed, eg, by visualization of a fetal heart beat. 3) Twins are more readily detected. 4) Sex of the fetus can be determined. 5) Age of the conceptus can be estimated more accurately. 6) The producer can be shown the conceptus, which could be reassuring in herd cases of embryonic losses.

Other herd health examinations should be considered while the cows are being checked for pregnancy. These include an accurate evaluation of body condition, the reproductive tract, teats and udder, feet and legs, teeth, and early neoplastic eye lesions. Vaccinations, internal and external parasite control, and processing of beef calves also can be done at this time.

EMBRYONIC DEATH, ABORTION, AND ABNORMAL FETAL DEVELOPMENT

Pregnancy may be terminated prematurely, resulting in abortion due to death of the conceptus or failure of the uterine environment to support the fetus. Abnormal fetal development may result in abortion or in a calf that dies soon after birth. Many cases of bovine abortion are not diagnosed. (See also ABORTION IN LARGE ANIMALS, p 1333.)

Etiology: Viruses, bacteria (including rickettsia and chlamydiae), molds, protozoa, or other infectious agents may attack the placenta or the fetus, or both. Some of these microorganisms reach the uterus hematogenously; others (such as venereal infections) are contracted during mating.

Infectious abortion may be sporadic or a herd problem. Herd problems usually are associated with significant losses and may be caused by infectious bovine rhinotracheitis, bovine viral diarrhea, brucellosis, leptospirosis (various serotypes), campylobacteriosis, trichomoniasis, anaplasmosis,

ureaplasmas, mycoplasmas, and others not yet identified.

Mycotic abortion usually is caused by *Aspergillus* or *Mucor* spp, which reach the uterus hematogenously and cause abortion in late gestation. In many of these fetuses, the skin is not affected; in others, ringworm-like lesions are seen. The placenta frequently is severely affected with necrosis of the cotyledons and thickening of the intercotyledonary areas. Diagnosis is based on identification of the fungus through culture of the fetal or placental tissues, histologic examination of these tissues, or direct examination of cotyledons after clearing with potassium hydroxide solution. These abortions are almost always sporadic, and the only means of control is to reduce exposure to the fungi.

Sporadic losses may result from *Listeria* sp (a bacterium occasionally present in silage when pH is >7); miscellaneous bacteria such as *Haemophilus* sp, *Trueperella pyogenes*, *Staphylococcus aureus*, *Bacillus cereus*, *Pasteurella multocida*, *Pseudomonas aeruginosa*, *Streptococcus bovis*, *Chlamydia* sp, and others; or viruses (eg, bluetongue).

Noninfectious causes of abortion are numerous; the most common include 1) recessive or lethal genes (or both) such as cervical vertebral malformation, hydrocephalus, osteopetrosis ("marble bone" disease), arthrogryposis ("crooked calf" syndrome), and several others, some not fully identified; 2) toxins (eg, excessive nitrates from feed or water, certain pine needles, poisonous plants (eg, lupine, locoweed), or mycotoxins (moldy feeds); 3) hormonal imbalances in the pregnant dam; 4) injuries affecting the pregnant cow; and 5) nutritional deficiencies, particularly of vitamin A, vitamin E or selenium (or both), iodine, and manganese.

Heat stress in cattle can cause early embryonic death and lower the herd pregnancy rate. The mechanism by which heat stress affects embryonic survival is complex. Heat stress can disrupt early embryonic development. Effects of heat stress on embryonic survival decrease as embryos advance in development. Heat stress at day 1 or days 1–3 after breeding reduces embryonic survival. In contrast, heat stress of superovulated cows at day 3, 5, or 7 after estrus did not affect embryonic development in one study.

Diagnosis: Accurate diagnoses of reproductive loss contribute to the cumulative herd history and provide criteria to evaluate the impact on herd performance

and the need for implementation of preventive measures. Laboratory assistance is needed in most cases. Carefully selected, properly preserved, quality specimens should be submitted to a diagnostic laboratory for analysis. Even with these, the exact cause of an abortion may not be detected, especially if it is noninfectious. Laboratory diagnosis of abortion may include serology and examination of the fetus and placenta. However, a definitive diagnosis of bovine abortion remains challenging because, in many cases, the causative agent may have challenged a cow months previously and may no longer be present when abortion occurs.

Defective newborn calves can be recognized only by a thorough examination and sometimes only after some time has passed.

Prevention and Control: Several factors are critical to prevent and control abortion and development of defective calves. Measurement and management of herd health status and planning to control infectious disease risk with appropriate boundary and purchased stock biosecurity alongside vaccination programs are essential. A balanced nutritional program helps control losses associated with mineral or vitamin deficiencies and poor-quality feeds, including moldy grains and forages. Genetic selection and accurate record-keeping help to detect and eliminate

bloodlines that prove to be carriers of recessive or lethal genes. Appropriate housing and handling facilities decrease the incidence of accidents and provide an environment conducive to health. The cattle producer and veterinarian should work together to assess the herd's reproductive performance, tailor a vaccination program to the herd's specific needs, and diagnose and control potential herd problems.

For successful abatement of heat stress, the environment of the cow must be modified to maintain the cow within a normal temperature range of 101.3°–102.8°F (38.5°–39.3°C). Common approaches include providing shade (to intercept solar radiation) and fans or sprinklers to promote evaporative cooling. Tactically avoiding breeding at hottest times of the year may be advisable.

Infectious diseases in a herd can disrupt and reduce reproductive efficiency by causing embryonic or fetal death, abortion, or illness and death of neonates. A complete vaccination program will not eliminate reproductive problems but may prevent or reduce losses associated with specific infections (*see* TABLES 7 and 8).

CALVING MANAGEMENT

Dystocia is expected to occur in ~10%–15% of first-calf heifers and in 3%–5% of mature cattle. Although dystocia cannot be eliminated from a herd, the incidence can be

TABLE 7 VACCINATION/IMMUNIZATION PROGRAM TO PROTECT AGAINST PREPARTUM DISEASES OF THE BREEDING HERD

	Disease	When to Vaccinate/Immunize
Heifers	Brucellosis	Calfhood
	IBR ^a , BVD ^b	Before weaning and before breeding
	Campylobacteriosis, leptospirosis, trichomoniasis	Before breeding
Cows	IBR, BVD	May booster early before breeding
	Campylobacteriosis, leptospirosis, trichomoniasis	Each year, before breeding
Bulls	IBR, BVD	Calfhood and booster before first breeding
	Campylobacteriosis, leptospirosis	Each year, before breeding

TABLE 8 VACCINATION/IMMUNIZATION PROGRAM TO PROTECT AGAINST DISEASES OF THE NEONATAL CALF

	Disease	When to Vaccinate/ Immunize
Heifers and cows	Rotaviruses and coronaviruses, <i>Escherichia coli</i> bacterins, clostridial bacterins	As on label
Calves	Rotaviruses and coronaviruses (if indicated)	As on label

greatly reduced by management decisions made before the breeding season and during gestation.

Nutrition: Heifers and cows should maintain body condition before calving, but overconditioning causes excess fat deposition in the udder and results in lower milk production. Excessive fat deposition in the pelvis also may result in dystocia. Good body condition aids in calving ease, early return to cyclicity in beef cows, and also milk production. There is a balance to achieve between avoiding excessive condition, which leads to dystocia, and insufficient condition, which leads to postcalving subestrus/anestrus.

Calving Facilities: Dedicated calving facilities may be needed in many herds. They should be in good repair and functional before the calving season starts. Weather conditions, geographic differences, and local experience usually dictate how much attention and individual care calves will need immediately after birth. The calving environment (eg, calving sheds, small pastures) must be clean, dry, and protected from the weather. A clean area to handle dystocia problems is also needed. Calving in a clean area, separated from the rest of the herd, helps to reduce calfhood diseases, particularly diarrhea (scours) and Johne's disease. In large herds, several small calving pastures that allow regular rotation may help to reduce buildup of disease-causing organisms. When calving stalls are used during inclement weather, they should be cleaned and disinfected between calvings.

Calving: Close observation of labor is necessary to determine when or whether a delivery should be assisted. Labor is divided into three stages. Stage 1 begins with uterine contractions and dilation of the cervix and ends with passage of the amnion and part of the fetus into the vagina. Stage 1 may last 1–24 hr, with 1–4 hr being normal.

Stage 2 is characterized by abdominal contractions due to the fetus in the vaginal canal and ends with expulsion of the fetus through the vulva. Birth should be expected within 1–4 hr for heifers. A mature cow should calve in <3 hr if the presentation of the calf is normal; if no progress is seen within 1 hr, assistance may be required. Disruption of labor may occur with inappropriate intervention or social group stresses. "Just in time" calving strategies are based around the need to minimize social group changes at the point of calving, because these social changes are associated with challenges to dry-matter feed intake. Stage 3 is expulsion of the fetal membranes and initiation of uterine involution. Expulsion of the fetal membranes normally occurs within 12 hr after parturition.

Feeding preparturient cows in the late morning (11 AM–noon) and again at night (9:30–10 PM) encourages cows to calve during the day (7 AM–7 PM), when a problem is more likely to be identified and assistance more likely to be available.

Parturition is often difficult for both fetus and dam. Many factors influence the degree of difficulty, including breed, age, nutrition, and pelvic area of the dam; breed and genotype of the sire; gestation length; and sex, size, position, and presentation of the fetus. Some, though not all, of these factors are directly influenced by management.

When dystocia (*see below*) develops, survival of both dam and calf depends on proper assistance. This requires identification of the problem, proper facilities, and adequate help. A delay in assisting may mean the loss of the calf or injury and even death of the cow. However, it is important to allow sufficient time for the dam to dilate before applying traction. Before assisting the delivery, the position of the fetus must be determined accurately, and any abnormal presentation corrected. If the calf is simply too large to pass through the birth canal without danger to the cow or calf, a cesarean section or other surgical assistance may be necessary.

Management After Calving: Muddy lots, crowding, filth, chilling, and inclement weather make the calf more vulnerable to disease organisms and may result in sickness and possibly death for both dam and calf. Provision of adequate trough space, ie, 1 m per fresh cow, and lying space in bedded yards, ie, 1.25 m²/1,000 kg milk yield, are key factors for freshly calved dairy cows to maximize feed intake and minimize risk of poor hygiene on udder health. (See also HEALTH-MANAGEMENT INTERACTION: CATTLE, p 2119, and MANAGEMENT OF THE NEONATE, p 2087.)

Passive Transfer: Calves receive immunity passively from the dam through ingestion of colostrum. The calf's immune system is immature at birth and depends on acquisition of passive immunity for disease protection in early life. Immunoglobulins (IgG and IgM) and lymphocytes are absorbed directly across the gut into the calf's circulation to provide immunity. The ability of the gut to absorb these large molecules and cells is a transient phenomenon; gut closure is complete by 24 hr, and absorption has decreased significantly by 6–8 hr of age. Ingestion of adequate amounts of quality colostrum as early as possible after birth is important for calf survival and growth. Calves with failure of passive transfer (FPT) are 3–9 times more likely to become sick before weaning, and 5 times more likely to die before weaning than calves with adequate passive transfer.

Minimizing the incidence of FPT should emphasize dystocia management, proper nutrition, and intervention for calves at high risk of FPT. Cows that have dystocia should be milked out immediately, and the calf actively fed colostrum to ensure ingestion. Calves should consume 3–4 L as soon as possible after calving by nasogastric tube as necessary. Cows with poor udder conformation or mastitis should be milked, and the colostrum fed to the calf to ensure timely intake. Colostrum supplements may not prove adequate, as shown in controlled clinical trials, to increase serum IgG levels. Vaccination of the cow with pathogens causing enteric disease in calves before calving may be a useful adjunct to good overall management in reducing morbidity. Hygienic management of colostrum is vital to effective absorption, and either careful pasteurization or cooling of lidded containers should be considered.

DYSTOCIA MANAGEMENT

Dystocia management must begin with proper heifer development. Fetopelvic

disproportion is a major contributing cause of dystocia. Calf birth weight, the size of the pelvic area of the dam, and the interrelationships of these two factors are major determinants of dystocia. The weight of the calf is a function of genetic and environmental factors. Genetic factors include sex, length of gestation, breed, heterosis, inbreeding, and genotype. Nongenetic factors include age and parity of the dam, nutrition of the dam during various phases of gestation, and environmental temperature. Efforts to manage the dystocia rate and moderate its effects should focus on replacement heifer development, sire selection using EBVs for calving ease, and early dystocia intervention.

Replacement Heifer Development:

Dystocia rates in beef heifers may not be controlled by nutritional restriction during late pregnancy. On the contrary, the loss of 0.5 kg/day during the last trimester of pregnancy in beef heifers is associated with weak labor, increased dystocia rate, reduced calf growth rate, prolonged postpartum anestrus, reduced pregnancy rate, and increased morbidity and mortality. It is recommended that heifers be fed to allow modest rates of gain (0.5 kg/day) during late pregnancy. Protein malnutrition in late pregnancy has been associated with weak calf syndrome and may be a factor contributing to neonatal mortality.

Measurement of the pelvic area of the dam to predict dystocia is sometimes used as a criterion for selection of replacement heifers, even though pelvic area alone explains only a small proportion of the variability in dystocia. Pelvic area measurements before the breeding season or at the time of pregnancy examination have been used to estimate the pelvic area before calving. Those heifers with a small pelvic area before the breeding season may then be culled or selectively mated to easy calving bulls, and those with a small pelvic area at the time of pregnancy examination may be aborted, culled, or identified for careful observation at calving. Some evidence suggests that culling heifers with the narrowest pelvic width may be more effective than culling based on pelvic area; however, such "pelvimetry" measurements may only detect the outlier animals in this multifactorial condition.

Sire Selection: A combination of culling heifers with small pelvic areas and using bulls that sire calves with small birth weights may reduce dystocia significantly. Using only the sires' birth weight to control calf birth weight and dystocia is not effective. A large

number of nongenetic influences affect birth weight, such as age of the dam, environment, and birth type. The ability to identify sires appropriate for use on replacement heifers has advanced significantly.

The use of estimated breeding values (EBVs) or expected progeny differences (EPDs) for birth weight is more effective than using only sire birth weight in selecting for acceptable birth weights. EPDs are reported in the units of the trait they reflect (eg, pounds for birth weight). Along with each EPD is reported an accuracy ranging from 0 to 1. Higher accuracies indicate a higher level of confidence that the stated EPD truly reflects the bull's effect. EPDs most effectively help compare bulls rather than identify the specific effect a bull will have on a herd. For example, a bull with a birth weight EPD of 4.0 would be expected to sire calves 6 lb heavier on average than a bull with a birth weight EPD of -2.0 when bred to the same group of heifers. An attempt should be made to identify bulls with good calving ease EBV figures and low birth-weight EPD for use on heifers while maintaining at least moderate weaning and yearling weight EPD. This is best achieved by the use of AI sires with high accuracy EPD. EPD can be calculated on yearling bulls with no progeny, but the accuracy is low. Until recently, EPDs were useful only in comparisons within breeds; however, methods for across-breed EPDs have now been developed. This is of particular use in selecting bulls to control dystocia in crossbreeding programs. Two recent innovations in the use of EBVs/EPDs for management of dystocia are the calving ease EPD and the maternal calving ease EPD. Calving ease EPD is related to birth weight EPD but may predict calving ease more effectively. Maternal calving ease is a measure of the effect of the maternal grandsire and the ease with which a bull's daughters will calve.

As the birth weight of the calf increases, the incidence of dystocia often also increases. Calving difficulty is higher for male than female calves. Abnormal presentations of the calf accounted for 22% of dystocias and 4% of all births in one study. Most dystocias are seen in primiparous 2-yr-old heifers, and the frequency decreases with increasing age and weight of the cow. Some studies have suggested that cows that previously experienced dystocia are more likely to do so again. Environmental effects may also have an effect on calf birth weight and dystocia. Cold weather may increase birth weights and subsequently increase the incidence of dystocia.

Appropriately Early Intervention:

Despite the best efforts to avoid dystocia, some cases will be seen. Early intervention minimizes the effects of dystocia on calves; however, heifers especially may require significant time to dilate to point of delivery. Heifers should be monitored regularly and provided with assistance promptly if stage II labor is prolonged (eg, 1 hr). Producers need to identify the level of dystocia and growth that is economically acceptable and select a bull to match. They must be well trained to intervene appropriately in dystocia and recognize when to call the veterinarian. A general rule is that if a heifer has not made significant progress in delivering her calf within 30 min, it is time to get help.

COW-CALF PAIR MANAGEMENT

Cows and heifers should be moved from winter grounds to calving grounds 2-3 wk before calving season begins. They should be sorted into groups based on estimated calving date. This date can be determined at the time of pregnancy examination, when cows and heifers are grouped based on estimated duration of gestation. Separation of the herd into groups allows more concentrated observation of a smaller number of cows or heifers that are more likely to calve and potentially need help.

Cows and heifers should be observed to ensure they accept and mother their calves. Heifers especially are at risk of calf rejection, which increases the risk of calf disease. If heifers do not accept their calves and allow nursing within a short time, they should be brought into the calving barn and restrained to allow the calf to suck. Heifers that experience dystocia and human assistance are at increased risk of rejecting their calves. Cows or heifers that experience difficulty in calving or mothering should be moved to the calving barn for assistance and monitoring. Pairs entering the calving barn are at increased risk of disease because of dystocia, mismothering, hypothermia, and exposure to a higher population density. Once a pair enters the calving barn, they should not go to the general nursery pasture but to a separate high-risk nursery. Calves in the high-risk nursery can be monitored more closely for morbidity and treated promptly. Segregation of these high-risk calves also avoids exposure of the rest of the herd. Consideration should be given to management of infectious diseases such as Johnes disease by segregating higher-risk cows from lower-risk cows throughout this calving management period.

Once cows or heifers have calved, the pair should be moved out of the calving area to a nursery pasture within 24 hr. When the pair has bonded and passive transfer has occurred, movement to a nursery with decreased population density minimizes infection rates. Sick calves in the healthy nursery pasture should be removed and brought to the barn for treatment if necessary and placed in a morbidity nursery. Infectious agents can

multiply in clinically ill calves and cause high levels of environmental contamination. The morbidity nursery may be combined with the high-risk nursery, but this increases exposure of the high-risk calves to pathogens. Ill calves should not be returned to the general nursery area. Treatment equipment should be disinfected thoroughly between calves to avoid transfer of infectious agents from calf to calf.

MANAGEMENT OF REPRODUCTION: GOATS

PUBERTY AND ESTRUS

Goats are spontaneously ovulating, seasonally polyestrous animals with peak sexual activity occurring in the fall when day length is decreasing. Factors that affect onset and length of the breeding season include geographic location (latitude and climate, specifically), breed, social structure, and photoperiod. In temperate regions, the natural breeding season is mostly restricted to the fall and winter to allow for kidding in the spring and summer, when nutritional conditions are adequate. Under tropical and subtropical conditions, where temperature and photoperiod are less variable, certain breeds can have an extended breeding period if appropriate resources are available to allow for kidding year-round. The average duration of the goat estrous cycle is 21 days but can vary with different breeds or environment. A relatively high frequency of short cycles is characteristic of goats and tend to occur in young does, at the onset of the breeding season, and with prostaglandin induction of ovulation. Longer cycles may be seen later in the season.

The average duration of standing estrus is 36 hr but can range from 24–48 hr depending on age, breed, season, and presence of a male. Breed-specific estrus duration has been reported for Mossi (20 hr), Angora (22 hr), Creole (27 hr), French Alpine (31 hr), Boer (37 hr), and Matou (58 hr) breeds. Estrus detection is based on behavioral signs, bleating, flagging of the tail, reddened vulva, vaginal discharge (which causes the tail hairs to stick together), and occasional “riding” by other does, although this last sign is far less common than in cattle. Goats can show overt signs of estrus while

pregnant, and although natural service will not interfere with pregnancy, these does should not be artificially inseminated. Ovulation can occur anytime from 9–72 hr after the onset of estrus, typically toward the end of standing estrus. The ovulation rate varies based on breed, season, and nutrition. Angora goats typically have a single ovulation but may have two if sufficient nutrition is available. The average ovulation rate has been reported to be 1.7 eggs per doe in Boer goats and 1.5 in Maure goats. “Focused feeding,” in which a nutritional boost is supplied in a short period of time, has enhanced reproductive efficiency in ruminants without affecting body condition. Also known as both “acute” or “immediate nutrient” effect, this practice leads to a positive energy balance, which increases leptin and insulin concentrations, enhances glucose uptake, and is positively associated with increased folliculogenesis and increased ovulation rate. Supplementation with β -carotene, a vitamin A and retinoid precursor, at 50 mg/goat/day has been shown to produce this effect in does.

The onset of puberty typically occurs at 6–8 mo of age but varies depending on the season of birth, breed, nutritional status, and presence of a male. Pygmy goats and does of larger breeds may reach puberty as early as 3 mo old; however, breeding should be delayed until the animal has reached at least 60% of its mature body weight to allow for higher conception rates and safer parturition. Larger goat breeds (eg, Nubian, LaMancha, Boer, and Saanen) can be safely bred at ~70 lb (32 kg). Angora kids should weigh a minimum of 27 kg and are frequently not bred until they are 1½–2½ yr old. Puberty in well-grown bucks can be seen as early as 4 mo.

BREEDING SOUNDNESS EXAMINATION

The external genitalia of does should be examined for abnormalities such as an enlarged clitoris, hypotrophic vulva, or increased urogenital distance that suggest intersex, a condition common in homozygous polled females, especially in Alpine, Saanen, and Toggenburg breeds. Intersex goats are sterile and should be culled. Occasionally, a doe has a shortened vagina and no cervix, and segmental aplasia of various parts of the tract can occur. A speculum can be used to examine the walls of the vagina, vestibules, and cervix to search for lesions in does with fertility issues. Transabdominal and/or transrectal ultrasonography can be used to examine the uterus and ovaries for cysts, pseudopregnancy, or other abnormalities. In cases of valuable breeding does, surgical laparoscopy or laparotomy may be used to check for causes of infertility such as oviductal blockage, tumors, adhesions, or segmental aplasia that may not be visible on speculum examination or ultrasonography.

A thorough physical examination of the buck before the breeding season is important to determine the ability of the buck to safely mount and breed a doe. Bucks should have a body condition score of 3–3.5 (out of 5) and be structurally sound with no visible foot or leg abnormalities. The buck should be in overall good health, because anemia due to heavy parasite infections and chronic debilitating diseases, such as pneumonia, can lead to loss of libido. Any degree of foot abnormalities, from overgrown hooves to severe laminitis, may cause the bucks to be reluctant to mount and should be treated appropriately. Bucks with caprine arthritis-encephalitis virus infection (see p 747) may have painful, enlarged stifles, and if they are even able to mount, are usually reluctant to ejaculate because of pain.

A complete assessment of the reproductive organs should be performed and include an evaluation of the penis and prepuce. The buck is set on his rump, and the shoulders pushed down to curve the spine convexly; this makes it easier to protrude the penis. Shearing wounds (especially in Angoras), prior balanoposthitis, and old fly-strike wounds and scarring around the prepuce may make protrusion of the penis impossible. Prior amputation of the urethral process to prevent obstruction by a calculus has no apparent deleterious effect on breeding ability. Although cryptorchidism is rare, a thorough

reproductive examination in a young breeding buck should include confirmation that both testicles have descended. The scrotum should be evaluated for size, lesions, or other signs of injury. Testicular hypoplasia occurs in only ~2% of intact bucks and is mostly associated with intersex condition, but it may also be a manifestation of malnutrition. As in other species, scrotal circumference is positively correlated with semen production capacity and should be >25 cm in mature bucks (>14 mo old). Scrotal circumference can vary by season and decrease by as many as 3 cm outside the breeding season. Because scrotal circumference and body weight are positively correlated in bucks, scrotal circumference measurements are of minimal value before 14 mo of age. The testicles and epididymis should be symmetrical and firm on palpation. Any asymmetry or changes in tone may indicate infection or injury and will likely adversely affect fertility. Orchitis and epididymitis are both rare, occurring in ~1% of breeding bucks, and affected bucks should be tested for *Brucella melitensis*, because bred does are at risk of stillbirths and abortions. Other causes of orchitis and epididymitis are of minimal concerns for transmission; however, treatments are generally unrewarding. Caseous lymphadenitis (see p 63), spermatc granuloma, and calcification of the testicles (which also may be due to *Corynebacterium pseudotuberculosis* infection) all reduce or eliminate the buck's fertility, and infected bucks should be culled. In extreme cases, ultrasound may be used to determine whether one or both testicles are affected and if hemi-castration is an option.

Evaluation of semen quality is another important part of the breeding soundness examination. Semen can be collected either by use of an artificial vagina or with an electroejaculator. The former yields a higher quality sample but requires the presence of a doe in heat to perform. Electroejaculation is more convenient and, thus, used more commonly. Once semen is obtained, it should be maintained at 37°C (98.6°F) and evaluated as quickly as possible. Grossly, the semen should be cloudy, white, and free of urine, blood, pus, or dirt. Occasionally, semen will be an off-yellow color and may be normal but should be examined more closely for urine contamination. The semen should be evaluated microscopically for motility, morphology, and presence of WBCs. Gross motility can be measured by placing a drop of undiluted semen on a warmed slide and

evaluating on low-magnification. A satisfactory sample should exhibit anywhere from general oscillation to vigorous swirling. Sporadic oscillation to no motility at all indicates poor semen viability. Individual and progressive motility should also be measured by diluting the semen with an isotonic diluent (eg, 0.9% saline) and evaluating microscopically. Sperm cells should be counted to determine a percentage of progressively motile sperm, with a minimum of 30% being acceptable. Sperm morphology should also be assessed microscopically, with a minimum of 70% normal being acceptable. (See also BREEDING SOUNDNESS EXAMINATION OF THE MALE, p 2234.)

BREEDING

Natural service is the easiest and most common breeding system. Most hobby operations have a low doe:buck ratio (5:1) because of multiple breeds and different bloodlines. Bucks have a strong libido and can breed far more does than this, although as they get older, and especially during the off-season, they are less efficient.

Artificial insemination (AI) is increasingly being used by goat producers, because it allows for both dissemination of valuable genetics and control of sexually transmitted diseases. Proper heat detection and/or hormonal synchronization of the estrous cycle is essential and may lead to increased labor and costs. Ovulation in does occurs toward the end of standing estrus; therefore, insemination must occur around this time to be effective. The AM:PM rule is generally used: if the doe is first noticed to be in standing heat in the morning, AI should be performed in the evening (or vice versa). However, breed-specific estrus durations should be considered when deciding the best time to inseminate. Vaginal (pericervical deposition) or cervical (intracervical deposition) insemination techniques are inexpensive and easy to perform and can result in acceptable pregnancy rates if fresh semen is used. However, if frozen semen is used, transcervical or laparoscopic intrauterine insemination techniques must be used, which are more expensive and require more skilled personnel. Frozen semen in 0.25–0.5 mL straws may be purchased directly from buck owners or custom collectors.

Semen can be collected for AI in an artificial vagina or with an electroejaculator. Most bucks will mount a doe in estrus and ejaculate; with training they can ejaculate year round and even mount wethers. Older bucks are often reluctant to breed does that

have had estrus induced outside the normal breeding season; therefore, collections are more successful when young bucks are used. The optimal sperm concentrations depend on the individual buck and production settings but should be ~200–400 million/mL to account for an approximate 50% death and damage rate during semen processing and thawing. There is no legislation or industry-wide standard in North America that governs the collection, processing, and sale of frozen semen, but country-specific legislations should be reviewed and followed before exporting semen.

Embryo transfer allows for dissemination of valuable female genetics. Its application in goats is somewhat limited because of the variable response of does to superovulation techniques. Control of the estrous cycle is crucial to ensure adequate timing for induction of superovulation, which is achieved by treating with commercially available follicle-stimulating hormone (FSH) products. Laparoscopic insemination of semen is recommended to confirm that superovulation occurred (via visualization of multiple corpora lutea) and to allow for the greatest conception rate. Embryo retrieval can be achieved surgically, laparoscopically, or transcervically, with surgical techniques providing the highest recovery rates. Embryos can then either be transferred immediately via laparoscopic or surgical techniques into synchronized does or frozen in liquid nitrogen.

INDUCTION OF ESTRUS

Estrus can be induced in several ways, depending on the time of year and the relationship to the doe's natural breeding season. Out-of-season breeding is of interest to dairy goat owners, because it reduces seasonal fluctuation in the herd's milk production. In meat production systems, increasing conception rates and litter sizes are important and can be manipulated using hormone therapy.

The sudden introduction of an odoriferous buck often advances the onset of cycling by a few weeks, and the does also may show some synchronization. The buck should be housed well away from the does (out of their sight and smell) for ≥3 wk before introduction. Even if the whole group does not cycle, this method can get a few to conceive in the theoretically out-of-season period.

Providing 20 hr of light per day in January and February (northern USA), with a sudden return to available daylight on

March 1, will bring goats into estrus several weeks later. In this system, it is more difficult for the owner to pick out the does that are in estrus; consequently, running a young, vigorous buck with the does gives the highest conception rate. If a portion of the herd is artificially synchronized, some of the remaining does also may come into estrus.

The Animal Medicinal Drug Use Clarification Act of 1994 (AMDUCA) places limits on extra-label drug usage in food-producing animals in the USA and restricts extra-label use to animals that are suffering or in danger of death. Under AMDUCA, pharmaceuticals cannot be used to alter reproduction for production purposes, and the following comments about manipulating reproduction are provided for use in countries outside the USA.

If the corpus luteum is functional, a synthetic PGF_{2α} analogue will induce estrus; however, this is not effective during anestrus. Additionally, it may provoke short cycles that tend to be seen normally at the beginning of the season. Melatonin implants may also be used to produce short-day effects and induce sexual activity in both does and bucks.

Progestagen treatment, followed by administration of FSH or pregnant mare serum gonadotropin (PMSG), will cause out-of-season estrous activity. Good conception rates can be achieved with this system, and fixed-time insemination is feasible, but these products (FSH and PMSG) are not approved for use in goats. Progestagen treatment can be in the form of injections with an oily base every 3 days, impregnated vaginal sponges (eg, flurogestone acetate or methyl acetoxypregesterone), norgestomet implants, oral administration of melengestrol acetate, or a controlled intravaginal drug-releasing device, or CIDR (which is a form of progestagen-impregnated silastic for vaginal use). A commercial product marketed for use in swine containing both PMSG and human chorionic gonadotropin will also cause does to cycle outside the normal breeding season when administered at the end of progestagen treatment.

PREGNANCY DETERMINATION

Pregnancy determination can be performed using real-time ultrasonography and is very accurate with a skilled operator. Transabdominal ultrasound is quick and reliable and can detect pregnancy as early as 25 days, with the fetal heart beat detectable by

day 27. Transrectal ultrasound is more difficult and time consuming but can diagnose pregnancy as early as 20 days. The accuracy of transabdominal ultrasound to differentiate the presence of a single fetus from multiples varies from 45%-55% (possibly higher with skilled operators). It is extremely difficult to accurately differentiate between twins, triplets, and quadruplets using ultrasound at any time during gestation. Fetal sexing may be performed by skilled ultrasonographers between days 55 and 70 of gestation and is more accurate in singles versus multiples. Routine radiography can be used to detect pregnancy with 100% accuracy after day 70 and can detect the number of kids after day 75.

Progesterone concentrations can be measured in milk or serum, but samples must be collected precisely one cycle after the doe was bred. Whereas low progesterone levels can confirm a nonpregnant status, high progesterone is not a positive pregnancy test, because it cannot differentiate between midcycle, true pregnancy, or false pregnancy. Plasma progesterone levels in pregnant does have been reported to be higher in triplets versus twins versus single fetuses at 84-21 days before kidding. The estrone sulfate test, performed on plasma, milk, or urine, is another way to determine pregnancy. Between 15 and 20 days after conception, the level of estrone sulfate, a conjugated estrogen produced by the conceptus, increases substantially and stays increased throughout pregnancy. Higher concentrations of estrone sulfate have been reported in does carrying twins or triplets than those bearing a single fetus. Abortion, fetal death, or resorption causes the estrone sulfate level to drop; therefore, the test also is a useful measure of fetal viability. Pregnancy-specific protein B (PSP-B), also known as pregnancy-associated glycoprotein, is produced by the placenta and can be detected in serum or plasma of pregnant does by ELISA at least 30 days after breeding.

Precocious milking is common in heavy-milking strains of goats. It can be seen in a virgin doe or during the first pregnancy. Therefore, udder development is no guarantee of pregnancy.

Hydrometra, or pseudopregnancy, is well documented in goats, although its cause is largely unknown. Aseptic fluid accumulates within the uterus and is accompanied by high peripheral concentrations of progesterone due to a failure of luteolysis. It can be both shorter or longer than a true pregnancy and occurs in 3%-30% of dairy herds.

Approximately 50% of pseudopregnancies occur as a result of early embryonic death at ≤ 40 days of gestation. An additional mechanism involves spontaneous persistence of the corpus luteum, which occurs more commonly in older goats, does bred out of the natural breeding season, or after induced ovulation. In some cases, ovarian cysts may also be present; therefore, it is recommended to always treat for both. Usually, the udder enlarges, but true filling does not occur. The doe may show behavioral signs of impending parturition, possibly even calling or searching for the nonexistent kid. The diagnosis can be made by excluding pregnancy coupled with the presence of clinical signs. This condition can be treated with prostaglandin to lyse the corpus luteum, and does may be able to conceive again if diagnosed and treated early. However, if the condition persists or recurs, the chances of future conception decline. For commercial dairy herds, this can produce moderate to severe economic losses.

Goats tend to have a high incidence of abortion, with chlamydiosis (*Chlamydia psittaci*) and toxoplasmosis (*Toxoplasma gondii*) being commonly identified causes in the USA (see ABORTION IN GOATS, p 1340). In cases of abortion, the fetus and placenta should be submitted to a diagnostic laboratory to exclude infectious causes. Paired serum samples should be obtained from the doe and saved in case serology is indicated. A thorough history, including nutrition and any recent changes in husbandry, should be taken.

PREGNANCY

Gestation length is 145–155 days (average 150 days) and can be affected by breed, litter weight, environment, and parity. Generally, first-kidding does have one or two kids, and in subsequent kiddings, triplets and quadruplets are not uncommon, especially in large, well-fed, heavy milkers. Quintuplets and sextuplets are rare. Progesterone production for maintenance of pregnancy is entirely dependent on the corpus luteum, with a drastic decline in progesterone occurring 12–24 hr before kidding. Induction of parturition is a useful technique to increase survival in dairy goat kids and to catch and separate kids from dams before they suckle in herds with control programs for caprine arthritis encephalitis virus and mycoplasma. Induction with synthetic $\text{PGF}_2\alpha$ analogues such as cloprostenol (125 mg) or dinoprost tromethamine (10 mg) usually results in delivery of kids ~30–35 hr after injection,

whereas dexamethasone (20 mg) requires ~48 hr to induce kidding. Viability of multiple fetuses may be compromised if parturition is induced before day 144.

Pregnancy toxemia in goats is similar to that in sheep (see p 1021). It occurs during the final 6 wk of pregnancy and is more common in overconditioned does and in does pregnant with multiple kids. It is caused by reduced feed intake coupled with high energy demand, leading to ketosis. Treatment depends on severity of the condition and can range from dietary modification with oral administration of propylene glycol to intensive supportive care with administration of IV fluids with dextrose, insulin, and pregnancy induction. Vitamin B_{12} may also be administered as an appetite stimulant. Lactational ketosis is similar and occurs within the first 3 wk of lactation in high-producing dairy goat breeds; clinical signs include irritability, anorexia, reduced milk production, and weight loss. Treatments include IV glucose, oral glucose, and/or oral propylene glycol, depending on severity. Hypocalcemia or milk fever (see p 991) is seen in high-producing, older (>3 yr) dairy goats, but not nearly so frequently, nor as severely, as in cattle. Treatment includes IV administration of calcium gluconate or calcium borogluconate solution.

Vaginal prolapse is fairly common (see p 1390) in does and is believed to have a hereditary component. It may intermittently occur during late pregnancy due to increased intra-abdominal pressure. If complete vaginal prolapse occurs, intervention is required to prevent injury, infection, or dystocia. Owners should be advised that vaginal prolapses will recur with each pregnancy, so they can decide whether to cull the animal.

PARTURITION

Parturition tends to be uneventful in goats, with the incidence of dystocia <5%. If the doe has been in active labor for 30 min with no progress, assistance is likely required. Most kids present cranially, in dorsosacral position, with limbs extended. If kids present caudally, which is more common in twins, triplets, and quadruplets than singletons, assistance for delivery is more likely to be required. The most common cause of dystocia is when two or more kids present at the same time; other causes include malposition, fetomaternal mismatch, failure of cervical dilation (ringwomb), vaginal prolapse, uterine torsion, and uterine inertia. Most dystocias

can be corrected by repositioning kids and providing lubrication and traction. However, in more severe cases, fetotomy or cesarean section may be indicated. Extreme care must be exerted when assisting with kidding to prevent uterine tears, which can be diagnosed on palpation of the uterus after the dystocia. Small tears can be treated by hastening involution of the uterus with oxytocin administration. Larger tears may require surgical intervention to minimize excessive bleeding and peritonitis. Systemic antibiotics, anti-inflammatory drugs, and a clostridial vaccine booster should be provided after a prolonged dystocia.

Retained placenta (not passed 12 hr after parturition) is uncommon in goats and is usually associated with selenium deficiency, the birth of a mummified or rotten fetus, or a difficult delivery. It can be treated by gentle traction or hormone therapy to facilitate expulsion, but diagnosis and treatment of the underlying cause will usually solve the problem. Metritis is almost always a sequela of retained placenta, and systemic

antibiotics are warranted. Clostridial organisms (*Clostridium tetani* and *C. perfringens*) may colonize the uterus, resulting in a frequently fatal toxemia that requires aggressive supportive care, antibiotics, and antitoxin therapy. Less severe causes of metritis may lead to a chronic endometritis and cause infertility if not treated.

Uterine prolapse is uncommon in goats but may occur after dystocia. Treatment is similar to that in other species, and prognosis is good if recognized and treated early.

In extremely cold weather, newborn kids should be dried (especially the ears) to prevent frostbite. Heat lamps are not necessary if the kids are dry, well fed, and out of a draft. Kids born in intensive systems should have their navels dipped in tincture of iodine to prevent infection. Angora, pygmy, and meat kids are typically raised on the dam. Dairy goat kids often are removed at birth and, after receiving colostrum, fed from a bottle or nipple-pail.

MANAGEMENT OF REPRODUCTION: HORSES

REPRODUCTIVE CYCLE

Nearly all mares are seasonally polyestrous and cycle when the length of daylight is long. Anestrus is seen during the winter when daylight length is short. During anestrus, the uterus is flaccid, and the ovaries are inactive with no significant

During the vernal transition, the mare's ovaries will enlarge and contain numerous large (>25 mm) follicles but no luteal structures. Courtesy of Dr. Patricia Sertich.

follicles or corpora lutea. The cervix may be closed but not firm and tight, or it may be thin, short, and dilated. As the length of daylight increases, mares undergo a vernal transition and the ovaries become active, with numerous large (>25 mm) follicles. The cervix and uterus have minimal tone. Mares have three or four prolonged intervals of estrus (periods of sexual receptivity to the stallion) during the vernal transition, but ovulation does not occur. The end of vernal transition is marked by a surge of luteinizing hormone and subsequent ovulation. After this ovulation, the first 21-day interovulatory period of that breeding season occurs and a regular estrous cycle is established.

Although the mare continues to ovulate regularly every 21 days throughout the breeding season, the length of estrus varies, ranging from 2–8 days, and the length of diestrus varies accordingly to maintain a 21-day interval. Early in the breeding season, estrus tends to be longer, whereas around the summer solstice the mare may be sexually receptive for only 2–3 days.

Mares have two follicular waves each cycle. The first wave of follicular development occurs during diestrus, and these follicles become atretic. The second wave occurs after luteolysis and is associated with estrus. Early in estrus, the endometrial folds of the uterus are edematous, but the edema wanes as ovulation approaches. Usually, one follicle becomes dominant and ovulates when it is ≥ 30 mm in diameter. The dominant follicle enlarges and then softens just before ovulation. The oocyte is released through the ovulation fossa. A corpus hemorrhagicum and subsequent corpus luteum form and produce progesterone, which stimulates closure of the cervix and an increase in uterine tone. This corpus luteum will be mature and become responsive to prostaglandin in ~5 days. If pregnancy is not established, luteolysis occurs at 14 days, and the mare returns to estrus and continues to cycle.

Artificial Manipulation of Photoperiod:

After winter anestrus and the vernal transition, cyclicity naturally starts sometime in the spring, when breeding can begin. Because changes in the mare's genital tract are seen in response to the length of daylight, the onset of ovulation and subsequent regular estrous cycles—and thus, the onset of the breeding season—can be hastened by exposing the mare to 16 hr of light per day; 8–10 wk are required for mares to respond. If the breeding season is scheduled to begin February 15, mares should be exposed to daily supplemental artificial lighting starting on December 1. Mares need to experience a natural photoperiod of decreasing length of daylight in the fall. Mares can then be abruptly exposed to 16 hr of light each day, or the supplemental light can be gradually increased to a 16-hr day throughout 60 days. In an abrupt lighting program, mares living in natural daylight are exposed to supplemental light from ~4:30 pm until 11:00 pm daily. In a less expensive, energy conserving, stepwise program, mares can be exposed to 3 hr of supplemental light in the evening the first week of December, and then the supplemental light is increased by 30 min each week until mares are exposed to 16 hr of light each day. An automatic timer aids compliance and saves on labor.

The supplemental light must be added at dusk; light added in the morning before dawn is not effective. A minimum of 10 foot-candles (107 lux) of incandescent or fluorescent light is necessary. The amount of light should allow one to comfortably read newsprint. Mares can be stimulated

individually in a stall or as a group in a lighted paddock.

Manipulation of Ovarian Activity:

Ovarian activity is frequently manipulated by administration of hormones to facilitate scheduling of breeding appointments and to limit the number of breedings per estrus. Breedings should be spaced for stallions with large books of mares so that semen use is optimized. Geographic locations and transportation constraints may also necessitate scheduled breedings. Many situations can benefit from an ovulation control program. (See also HORMONAL CONTROL OF ESTRUS, p 2244.)

Administration of prostaglandin ($\text{PGF}_{2\alpha}$), IM, to a mare in diestrus causes luteolysis and allows a follicle to mature and ovulate. The corpus luteum must be 5–14 days old to respond to $\text{PGF}_{2\alpha}$. The mare will come into estrus 2–5 days after administration of $\text{PGF}_{2\alpha}$. Time to ovulation is variable (3–10 days) and depends on the stage of the mare's current follicular wave and on the size and character of follicles at the time of $\text{PGF}_{2\alpha}$ administration. It is recommended that the mare's ovaries be examined by palpation and ultrasonography at the time of $\text{PGF}_{2\alpha}$ administration to optimize the prediction of ovulation.

Dinoprost, a naturally occurring $\text{PGF}_{2\alpha}$ (1 mg/45.5 kg, IM), may cause transient adverse effects such as lowered body temperature, increased heart and respiratory rates, sweating, muscle cramping, colic, ataxia, and weakness. Signs are seen within 15 min and usually subside within 1 hr. Synthetic preparations, eg, cloprostenol sodium (0.55 mcg/kg, IM), have fewer adverse effects.

Human chorionic gonadotropin (HCG) 2,500–5,000 IU, IV or IM, has been administered (off-label use) to hasten ovulation of a dominant follicle during estrus. If the mare has a preovulatory follicle ≥ 35 mm diameter, ovulation occurs within 36–48 hr after administration. An FDA-approved preparation of deslorelin acetate is available and eliminates the need to use HCG off-label. This sustained-release GnRH analogue will cause ovulation within 48 hr of administration to an estrous mare with a 30–40 mm follicle.

Ovulation can be timed accurately using the following protocol (not FDA approved): On days 1–10, 10 mg of estradiol 17- β and 150 mg of progesterone are administered IM. On day 10, dinoprost (1 mg/45.5 kg, IM) is also administered. On day 16, mares come into estrus, and insemination should be performed on day 19 or 20. Most (85%)

mares ovulate on day 20, 21, or 22. This regimen is effective at any time in cycling mares except when a large, dominant follicle <48 hr from ovulation is present. If a mature follicle is present, the protocol should not begin until after ovulation.

Altrenogest is a synthetic progestin that suppresses the receptive sexual behavior of estrus. Altrenogest is administered at 0.44 mg/kg, PO by dose syringe or top-dressed on feed for 12–15 days. Estrus occurs 4–5 days after treatment ends, with variable timing of ovulation (8–15 days). Although altrenogest effectively suppresses estrus (sexual receptive behavior), it does not consistently control the time interval to ovulation.

Estrus Detection: Frequent palpation and ultrasonography of the genital tract, excellent record keeping, and administration of hormones allow veterinarians to intensively monitor and manipulate a mare's estrous cycle. But breeding management can be optimized if a good estrus detection program is in place. A mare detected in estrus will prompt the breeding farm manager to examine and prepare the mare for breeding. Estrus may be the first indication that a pregnant mare has experienced early embryonic death or an abortion.

The mare should be presented to a stallion (teaser) daily or every other day during the breeding season, and the mare's behavioral response accurately interpreted and recorded. Mares in estrus raise their tail, squat, urinate, evert the vulvar lips to expose the clitoris, and ultimately tolerate copulation. Mares in diestrus usually squeal, kick, bite, and reject the stallion's advances. Adequate exposure to and contact with the teaser may be needed to elicit the mare's response; a mare with a dominant follicle may initially not appear receptive because of nervousness or inexperience. Some mares with foals by their side may not exhibit estrus to the teaser because of their protective nature. The mare's behavior when teased should be consistent with the findings on examination of the genital tract. Response to teasing can determine whether estrus has begun and indicate when a mare should be palpated and bred. Failure to return to estrus 2–3 wk after breeding may suggest that the mare is pregnant.

Mares in seasonal anestrus may remain passive in the presence of a stallion.

Some anestrus mares will be receptive when confronted by a stallion and will tolerate a stallion's sexual advances. This tolerance seems to be due to a lack of progesterone, similar to the tolerance seen in an ovariectomized mare when used as a

stimulus for semen collection from a stallion.

Mares normally have three or four prolonged periods (7–14 days) of sexual receptivity during the vernal transition before the first ovulation of the breeding season occurs. Similar long periods of sexual receptivity occur during the autumnal transition between the breeding season and winter anestrus.

BREEDING SOUNDNESS EXAMINATION OF THE MARE

A comprehensive reproductive evaluation is recommended for the mare that has unknown or questionable fertility. Abnormalities can be diagnosed and appropriate therapy instituted to correct any problem before breeding is scheduled. A coordinated plan of management should be developed based on the mare's history of reproductive performance, previous treatments, examination findings, laboratory test results, and intended use.

Theriogenologists typically examine mares for breeding soundness before purchase or breeding or when a mare is barren. A complete breeding soundness examination includes examination of the external genitalia and mammary gland, palpation and ultrasonography per rectum of the internal genitalia, manual and visual vaginal examination (vaginocopy), aerobic culture of an endometrial swab/sample, cytologic evaluation of an endometrial swab/sample, and histologic evaluation of an endometrial biopsy sample.

In the case of a young, healthy, maiden mare, palpation and ultrasonography per rectum to determine the presence of a uterus of normal size and consistency, normal active ovaries, and functional cervix may suffice. Perineal conformation should be evaluated. A manual vaginal examination should be performed to confirm the hymen is patent. If there is evidence of pneumovagina or vaginitis, commonly present in slim, fit, racing fillies, an endometrial swab and biopsies are indicated.

In postpartum mares, palpation and ultrasonography per rectum are required to evaluate uterine involution. A manual vaginal examination should be performed to ascertain whether the reproductive tract was traumatized during foaling. Thorough evaluation of the cervix requires direct manual palpation per vagina of the cervix after foal heat ovulation when the mare is in diestrus and under progesterone stimulation. Mares that had foaling problems (eg,

dystocia, retained placenta) require a more extensive evaluation. All postpartum mares have a transient endometritis during uterine involution; therefore, uterine swab and biopsy typically provide more useful information if delayed for ≥ 3 wk after parturition.

Barren mares require a complete breeding soundness examination. Occasionally, hysteroscopy, endocrine assay, or a karyotype may provide additional information.

Signalment and History: A standard breeding soundness examination form to record examination findings can be helpful in ensuring all areas are covered during the examination. The horse should be accurately identified.

Determination of stage of reproductive cycle and estrous cycle is essential for proper evaluation and interpretation of laboratory test results. The history should include previous length and character of estrus, breedings and their results, therapy, and specific reproductive problems. In particular, histologic findings of an endometrial biopsy sample reflect the stage of the mare's reproductive cycle and any recent intrauterine activities (breeding, treatment, foaling). Regardless of the history, the mare's nonpregnant status should be confirmed before performing any procedures (eg, endometrial swab, endometrial biopsy, direct manual cervical palpation) that would compromise an existing pregnancy (see p 2194).

Restraint: The mare can be restrained in hand, in stocks, or placed against a stall wall with the hindquarters positioned in a doorway. For fractious mares, a twitch may provide short-term restraint to allow completion of the examination. For the occasional situation in which the temperament of the mare poses risk of injury to the mare or examiner, chemical restraint may be used. A combination of acepromazine (0.02 mg/kg) and xylazine (0.3–0.5 mg/kg) administered IV works well for short procedures. If possible, the external genitalia should be evaluated before tranquilizers are administered, because the drug's use will alter the tone and competency of the perineum.

Physical Examination: The mare's tail should be wrapped and tied to one side. The tail and inner thighs should be examined for the presence of dried exudate indicative of genital infection or urine staining that may be associated with urine pooling or

incontinence. The size and shape of the clitoris should be assessed. A mare with an excessively large clitoris may have been androgenized either by excessive exogenous hormone administration during pregnancy or by endogenous hormones in an intersex condition (male pseudohermaphrodite). Normal vulvar lips have good tone and apposition and form the first barrier of the uterus against environmental contaminants. The vulvar lips should be parted to determine the competency of the vestibulovaginal fold. If air readily aspirates into the vagina, the mare may be prone to pneumovagina and may require a vulvoplasty (Caslick operation).

For per rectum procedures, the examiner, wearing a clean examination sleeve with water-soluble lubricant, must first empty the rectum of feces. Palpation and ultrasonography per rectum permit assessment of the internal genital tract. Each part of the genital tract should be systematically palpated. Typically, a real-time 5–10 MHz linear ultrasound probe, which produces a rectangular, cross-sectional image of the structure scanned, is used for ultrasonographic examinations of the reproductive tract. Ovarian size and character as well as the presence of an ovulation fossa should be noted. Anechoic follicles should be measured and counted, and the presence of a hyperechoic corpus luteum recorded. Normal oviducts are not routinely examined because their small size prevents palpation and imaging.

The size, shape, and contents of the uterus should be recorded. The mare's uterus is T-shaped with the horns perpendicular to the body of the uterus. It is suspended in the pelvic canal by the broad ligament, which is attached dorsally to the sublumbar region. Ultrasonography permits accurate assessment and measurement of the uterine horns. The size and character of any anechoic endometrial cysts should be recorded for reference so their presence will not be confused with a conceptus during subsequent early pregnancy examinations.

The uterus has several endometrial folds that increase the surface area of the uterine lumen. The endometrial folds should be carefully assessed during palpation per rectum by "slipping" the folds through the examiner's fingers along the entire length of each horn. The character of the uterus changes during the estrous cycle. During estrus, the endometrial folds become edematous, causing the uterine horns to have alternating areas of hypo- and hyperechogenicity when a cross-section is viewed

ultrasonographically. As estrus progresses, the edema in the endometrial folds wanes so that it is minimal by the time of ovulation. After ovulation and development of the corpus luteum, the uterus is stimulated by progesterone, uterine tone increases, and the endometrial folds are no longer edematous. After 14–18 days of gestation, the endometrial folds are not readily palpable because of the gradual but marked increase in uterine wall thickness.

The length, width, and tone of the cervix are palpable per rectum; however, complete evaluation of the cervix requires direct palpation per vagina (see p 2193). A cervical evaluation also serves as a bioassay, because the cervix changes in response to the steroid hormone status of the mare. During anestrus, ovarian steroid serum concentrations are low, and the cervix is either short, thin, and open or closed but readily opened. After the first ovulation of the season and during subsequent periods of diestrus, serum progesterone concentrations are increased and the cervix is closed, with a long cylindrical shape. During estrus, serum progesterone concentrations are low, and estrogen concentrations are high; the cervix is relaxed and edematous. Visual (speculum) vaginal examination will allow further assessment of the character of the cervix.

Urine in the vagina (urovagina) may be seen sporadically or be a chronic problem. Mares with urovagina may have an abnormal voiding pattern, and the endometrium may show histologic evidence of chronic irritation. The neck of the bladder can be used to indicate the caudal boundary of the vagina during ultrasonography. The vagina can be imaged dorsal to the bladder and examined for any accumulation of echogenic fluid caudal to the cervix. A definitive diagnosis of urovagina requires direct observation of urine in the vagina via vaginoscopy.

Endometrial Swab: Before an endometrial swab is taken, the nonpregnant status of the mare must be confirmed because the swabbing could lead to termination of a pregnancy (see p 2194). The perineum is cleansed with povidone-iodine scrub, rinsed, and dried. The operator dons a sterile sleeve or clean examination sleeve with the hand encased in a sterile glove. A water-soluble lubricant free of bacteriostatic chemicals is placed on the back of the hand and lower arm. When obtaining an endometrial swab sample, the vestibule, vagina, and cervix must be passed. Care must be taken to avoid contamination of the

swab by microorganisms in the structures caudal to the uterus that would hinder accurate interpretation of the culture results.

A double-guarded occluded uterine swab is gently guided through the cranial end of the cervix. Once inside the uterine body, the inner guard is advanced from the outer guard, and the swab is exposed to the uterine lumen for 30–60 sec. The swab tip is withdrawn into the inner guard, which is then withdrawn into the outer guard before the entire swabbing instrument is removed from the uterine body. The swab tip is carefully placed into a transport system, which is vital to maintain viability of the organisms from the time of sample collection until aerobic culture in the laboratory. Stuart's carrier medium may maintain microorganisms for as long as 72 hr if stored at ambient temperature. A second endometrial sample may be taken immediately after the first or simultaneously with a uterine swab or cytology brush. This sample is then evaluated cytologically by rolling it onto a glass microscope slide, fixing and staining with a Romanowsky-type stain, and viewing it microscopically for evidence of neutrophils, debris, and microorganisms.

A low-volume uterine lavage can be performed in mares with negative culture results despite obvious clinical signs of endometritis. Sterile saline (60–150 mL) is infused into the uterus using a closed system with a small uterine catheter. Oxytocin (20 IU, IV) is administered to enhance uterine evacuation. The effluent is collected by gravity flow into a sterile centrifuge tube and then centrifuged. The pellet is then swabbed, placed into transport media, and submitted for aerobic culture. A second swab can be made of the pellet for cytologic examination after staining.

Most laboratories streak the swabs on 5% sheep blood agar for general growth and on MacConkey's agar for growth of gram-negative organisms, after which cultures are aerobically incubated at 37°C (98.6°F).

Organisms commonly isolated that are associated with endometritis include β -hemolytic streptococci (90% *Streptococcus zooepidemicus*, 10% *Streptococcus equisimilis*), *Escherichia coli*, *Pseudomonas* (65% *P. aeruginosa*), and *Klebsiella pneumoniae*. Organisms isolated that are commonly suspected to be contaminants include α -hemolytic streptococci, *Actinobacillus equuli*, *Salmonella enteritidis*, *Pasteurella*-like species, and *Staphylococcus*, *Enterobacter*, *Acinetobacter*, *Proteus*, *Citrobacter*, *Alcaligenes*, and *Aeromonas* spp.

In most cases, the mixed growth of a few miscellaneous microorganisms is not significant. A heavy growth of any microorganism should be considered significant unless obvious contamination has occurred. Clinical signs must be correlated with culture results to determine clinical significance and to develop a therapeutic plan. Isolation of an organism transmitted venereally, such as *Taylorella equigenitalis* (requires a special culture system) and certain strains of *Pseudomonas* and *Klebsiella* spp, is considered a significant finding. Occasionally, microorganisms causing a pyometra may not be detected on aerobic culture, because products of the inflammatory reaction prohibit their growth.

Aerobic culture results of the endometrial swab should be used as a diagnostic adjunct and not as the sole determinant in diagnosing a uterine infection. A positive culture result must be accompanied by evidence of inflammation for the diagnosis of endometritis to be made. Mares exhibiting clinical signs of infection (uterine fluid as seen on ultrasonographic examination per rectum, tail matting or uterine discharge, and the presence of inflammatory cells seen on a stained smear from a uterine sample) with a positive endometrial swab are likely to have endometritis. Inflammation seen on histologic evaluation of the endometrium confirms the diagnosis of endometritis. In these cases, the culture results are useful in determining the sensitivity of the causative microorganism and developing an antimicrobial treatment plan.

The following antibiotics (see TABLE 9) have been used for daily (3–7 days) uterine

infusion by diluting with sterile saline to an infusion volume of 60–100 mL. Systemic administration of antibiotics may be considered if the microorganism, management situation, and ease of treatment indicate. Two doses of long-acting ceftiofur crystalline free acid (6.6 mg/kg, IM) can be administered 96 hr apart for adequate serum concentration for 10 days, which may be an efficacious treatment for endometritis due to *S. zooepidemicus*.

Endometrial Biopsy: An endometrial biopsy sample is usually obtained immediately after the endometrial samples have been procured. It should be kept in mind that manipulation of the endometrium can quickly cause a neutrophilic response in the endometrium. Preparation for biopsy is the same as for taking a swab (see above). The basket of the biopsy instrument should be kept closed during positioning to prevent accidental procurement of vagina, cervix, or examination glove. The instrument is manually guided with the gloved hand through the caudal genital tract into the uterine lumen. While keeping the instrument in place within the uterus with the nongloved (external) hand, the gloved hand is carefully withdrawn from the genital tract and inserted into the rectum to allow positioning of the basket of the biopsy instrument at the ventral luminal surface of the base of a uterine horn. The instrument jaws are then opened, the uterine wall is pressed into the side of the basket, and the jaws are closed. The jaws should be kept closed while the instrument is withdrawn from the genital tract. The tissue should be gently teased from the basket and placed into Bouin's fixative. If the sample will not

TABLE 9 INTRAUTERINE ANTIBIOTICS FOR USE IN MARES

Antibiotic	Intrauterine Dose
Penicillin (sodium or potassium salt)	5 million U
Ampicillin	1–3 g
Ticarcillin	3–6 g
Ticarcillin with clavulanic acid	3–6 g
Carbenicillin	2–5 g
Gentamicin sulfate diluted with 20 mL sodium bicarbonate and 20 mL saline	1 g
Amikacin sulfate	1–2 g
Ceftiofur sodium	1 g
Clotrimazole	400–700 mg

be processed within a few days, it should be transferred into 70% ethanol or 10% formalin.

It is not unusual for a small amount of uterine bleeding to occur after biopsy. The biopsy procedure is not detrimental to fertility, and a mare can conceive from a breeding that occurred during an estrus when biopsy was performed.

Histologic evaluation of the endometrium provides prognostic information about the mare's ability to carry a foal to term. The luminal contents may indicate the presence of uterine fluid or exudate. Epithelial cell height is related to hormone status; cells are cuboidal during anestrus and low to tall columnar during the breeding season. Transepithelial cells may indicate active inflammation. The pattern, character, and location of inflammation indicate the chronicity of response—neutrophils indicate an acute reaction, and lymphocytes and plasma cells indicate a chronic reaction. Focal or diffuse cellular distribution pattern, frequency of inflammatory cells, and degree of infiltration (slight to severe) relate to severity of inflammation. Histologic evidence of significant inflammation, combined with a report of growth of microorganisms from aerobic culture of endometrial swab and the presence of clinical signs of infection (uterine fluid, uterine discharge), support the decision that an endometrium would benefit from therapy to decrease inflammation.

Knowledge of the pattern of distribution and severity of periglandular fibrosis is prognostically useful. Fibrosis surrounding groups of glands ("fibrotic nest") is thought to be more clinically significant than fibrosis of individual glands. Periglandular fibrosis may interfere with endometrial gland function and may be a factor causing early embryonic death. Glandular distention normally develops during pregnancy, but widespread cystic glandular distention in the nonpregnant mare is undesirable. Cystic glandular distention is often associated with periglandular fibrosis and may result from an accumulation of gland secretions proximal to the occlusion of the endometrial gland by periglandular fibrosis.

Endometria are classified in four categories that attempt to predict ability to carry a foal to term. **Category I** indicates no significant changes are present in the endometrium, and no treatment is required. The estimated foaling rate is 80%–90%. An endometrium with any notable periglandular fibrosis cannot be classified as Category

I. Category II is a broad category that includes most mares. It has been divided into **Category IIA**, for mares with less severe changes, and **Category IIB**, for mares with more severe changes. The estimated foaling rate is 50%–80% in mares with Category IIA endometria and 10%–50% in mares with Category IIB endometria. Often, therapy may improve the state of the endometrium by reducing inflammation, cystic glandular distention, and lymphatic lacunae. Improvement in the endometrium may allow for better classification at a later date. There is no effective treatment to decrease the severity of periglandular fibrosis. **Category III** is the poorest classification, and these endometria have widespread, severe changes that include periglandular fibrosis or inflammation. A widespread pattern of distribution of slight to moderate changes may be more deleterious than more severe changes that are infrequent and only involve individual glands. The estimated foaling rate of a Category III endometrium is <10%.

During interpretation of the findings on histologic evaluation of an endometrial biopsy sample, the extent of normal, unaffected endometrium is more significant than the presence of any particular lesion. In barren mares with a Category I or IIA endometrium, other reproductive abnormalities or poor breeding management should be investigated as the cause of infertility.

Vaginal Examination: The perineum is cleansed, rinsed, and dried before the visual vaginal examination via speculum. The vulvar lips are separated, and the speculum is advanced cranially at a dorsal angle so as to pass over and through the transverse (vestibulovaginal) fold of the vagina. Resistance against the speculum by this fold of tissue indicates good tone and function. A bright light is necessary to adequately view the cervix and vaginal wall. The character of the cervix reflects the hormonal status of the mare. As the speculum is being withdrawn, it should be noted whether the vestibulovaginal fold occludes the vagina. The competency of the vestibulovaginal fold is important, because it forms the second barrier for the uterus against external contaminants.

Thorough evaluation of the completeness and competency of the cervix can be accomplished only by direct palpation per vagina while the mare is under progesterone stimulation (ie, cervix closed). The cervix forms the third barrier for the uterus against external contaminants.

PREGNANCY DETERMINATION

The schedule for determination of pregnancy varies among breeding farms. One schedule is as follows: 1) days 14–18—check for pregnancy and twins; if open, mare can be rebred on days 19–20; 2) days 25–30—evaluate normal embryo development (heartbeat present at 24–25 days), recheck for twins; 3) days 40–60—evaluate normal fetal development; 4) fall check—confirm mare is still pregnant.

Palpation Per Rectum: The pregnant cervix should be tightly closed and elongated with a prominent portio vaginalis 14–21 days after ovulation. Uterine tone increases and the uterine wall thickens so that by 14–18 days, the endometrial folds can no longer be readily palpated per rectum.

The conceptus develops in a recognizable pattern of size and shape, allowing estimation of age based on palpable characteristics. In maiden and barren mares, at 25–28 days of gestation, a careful, experienced examiner may be able to feel the embryonic vesicle ventrally at the base of one uterine horn, as a bulge 3.5 cm in diameter. At 30 days, the uterine horns are small with pronounced tone, and the conceptus can be felt as a ventral bulge 4 cm in diameter and positioned at the base of the gravid uterine horn. The uterine wall is thin over the expanding conceptus. At 42–45 days, the conceptus occupies about half of the gravid uterine horn and is 5–7 cm in diameter. By 48–50 days, the enlargement of the conceptus begins to involve the uterine body and is 6–8 cm in diameter and 8–10 cm long.

At 60 days, nearly the entire gravid horn and half of the uterine body is occupied by conceptus, but the nongravid horn remains small with considerable tone. The 60-day conceptus is 8–10 cm in diameter and 12–15 cm long. After 85 days, the turgidity of the conceptus decreases so that the fetus becomes palpable. At 90 days, the conceptus fills the entire uterus, and the cranial portion of the uterus may extend over the brim of the pelvis into the abdominal cavity.

After 100–120 days of gestation, the gravid uterus is positioned cranial to the pelvic brim in the abdominal cavity. The ovaries are positioned cranially and ventrally and closer together because of the downward traction exerted by the enlarging uterus on the broad ligament. After 150 days of gestation, the ovaries are not routinely felt per rectum. During midgestation, the gravid uterus may be difficult to reach, because it is positioned ventrally in the abdomen. But as the conceptus/gravid

uterus enlarges, its dorsal surface comes back into reach in late gestation. One should always confirm that two uterine horns with palpable endometrial folds cannot be identified in the pelvic canal before making a midterm pregnancy diagnosis.

Ultrasonography: The spherical shape of the equine embryo and the characteristic pattern of development of the fetal membranes permit accurate estimation of stage of gestation by ultrasonography until 45 days after ovulation. The embryo may first be imaged in the uterus with a 5–10 MHz linear transducer at 9–10 days as a round anechoic yolk sac 4 mm in diameter. The spherical conceptus moves throughout the lumen of the uterine horns and uterine body from day 6–16. The early conceptus is seen to have a bright white (echogenic) line on the dorsal and sometimes the ventral aspect of its image that is called a specular reflector, which is an artifact seen when the ultrasound beam strikes the wide, smooth surface of the conceptus at a 90° angle. This specular reflector, embryonic motility, and linear growth rate may help differentiate an early (<16 day), motile embryo from some uterine cysts.

Sonogram of 29-day conceptus in a mare. The dorsal anechoic yolk sac is nearly equal in size to developing ventral allantoic cavity. Courtesy of Dr. Patricia Sertich.

At day 17–18, the conceptus has a characteristic “guitar-pick” shape. At day 21, the embryo proper can be seen in the ventral aspect of the yolk sac, and by 24 days the allantoic cavity is visible as an anechoic compartment ventral to the embryo proper. At day 25, a heart beat should be present in the embryo proper. As the allantoic cavity enlarges, the yolk sac comprises a decreasing proportion of the conceptus. The position of the allantois and relative sizes of the developing allantoic cavity and the regressing yolk sac can indicate the stage of gestation between days 24 and 45. At 30 days, the allantoic cavity occupies approximately one-half of the conceptus, so that the size of the yolk sac is equal to that of the allantoic cavity. At 45 days, the only visible fluid cavity is the allantoic cavity, and the fetus appears to be suspended from the dorsal wall of the uterus by its umbilical cord and is positioned in dorsal recumbency.

Endocrine Tests: Cells from the chorionic girdle of the conceptus invade the endometrium to form endometrial cups that produce equine chorionic gonadotropin (eCG). Increased serum concentrations of eCG 40–120 days after ovulation indicate the presence of endometrial cups. Concentrations of eCG may remain increased until 120 days, even if fetal death occurs (false-positive). A false-negative result will be obtained if eCG assay is used as a pregnancy test in a pregnant mare before 40 or after 120 days of gestation.

Estrone sulfate is produced by the fetus and is a good indicator of fetal viability. Plasma and urine concentrations of estrone sulfate are increased after 60 days and 150 days, respectively, of pregnancy. Either endocrine assay can be used properly as a pregnancy test only if the breeding and ovulation dates are known.

PARASITE CONTROL DURING PREGNANCY

Most anthelmintics are safe for use throughout pregnancy, but precautions and contraindications on package inserts should be heeded. In general, anthelmintics should not be administered to mares during the first 60 days of gestation (organogenesis). Parasite control programs should be tailored to meet the particular farm needs. *See also* GASTROINTESTINAL PARASITES OF HORSES, p 315, and ANTHELMINTICS, p 2637. Pregnant mares should be administered ivermectin or a benzimidazole 1–3 days before foaling to prevent lactogenic transmission of

Strongyloides westeri, which can cause diarrhea in young foals.

VACCINATIONS

Vaccination programs should follow a continuous, year-round schedule based on local health problems. Vaccination against rhinopneumonitis should be performed at 5, 7, and 9 mo of gestation. Vaccines that require annual boosters should be administered 4–6 wk before the mare's due date to stimulate the dam to produce antibodies that will be transferred to the foal via the colostrum (*see* TABLE 10). Detailed information regarding current vaccination recommendations is available on the AAEP website (www.aaep.org). Colostrum should be ingested in the first 24 hr of life to effectively provide passive transfer of immunoglobulins.

ABORTION

See also ABORTION IN HORSES, p 1343. Twin pregnancy is the most common noninfectious cause of abortion in mares. In most cases, uterine capacity and subsequent placentation are inadequate to support two fetuses to term. Although twins may spontaneously reduce to a viable singleton early in gestation (<60 days), visible abortions tend to be seen after 7–9 mo. Premonitory clinical signs of impending abortion may be only premature mammary gland development. Fetal membranes should always be examined for large avillous areas typically located between the twin conceptuses.

Because of the risk of abortion and dystocia in a mare carrying twins, if twins are detected by ultrasonography per rectum at <30 days, reduction to one embryo by manual crushing per rectum is recommended. Between 30–60 days of gestation, transvaginal aspiration of one conceptus may result in a viable singleton. At approximately 60 days of gestation, one fetus may be eliminated by cervical dislocation. After 110 days of gestation, one twin may be reduced by intracardiac injection of potassium chloride guided by transabdominal ultrasonography. Success rates vary depending on the procedure performed, the experience of the veterinarian, and the character of the pregnancy. Pregnancy should be monitored repeatedly by ultrasonography after twin reduction.

The most common cause of viral abortion in mares is equine rhinopneumonitis, which is caused by equine herpesvirus 1 (EHV-1). These abortions occur predominantly in the last trimester and usually are not associated

TABLE 10 EXAMPLE OF VACCINATION SCHEDULE FOR BROODMARES

Vaccine	Schedule
Equine rhinopneumonitis (inactivated)	EHV-1 at 5, 7, and 9 mo of gestation; EHV-1/EHV-4 4–6 wk before due date
Tetanus (toxoid)	4–6 wk before due date
Equine influenza	4–6 wk before due date; if unvaccinated, initially administer two doses at 4–6 wk intervals and then a third dose 4–6 wk before due date
Eastern and Western equine encephalomyelitis	Usually administered to mares in late spring or early summer before onset of insect season; initially administer two doses at a 4–6 wk interval; 4–6 wk before due date
Rabies	4–6 wk before due date
Botulism (toxoid)	Initially three doses at 4–6 wk intervals, then annual booster 4–6 wk before due date
West Nile virus	Initially two doses at a 4–6 wk interval; 4–6 wk before due date
Rotaviral diarrhea	8, 9, and 10 mo of gestation
Equine viral arteritis (modified-live virus)	A negative titer should be documented by a USDA-approved laboratory before vaccination; pregnant mares should not be vaccinated; open mares should be vaccinated before breeding to a positive stallion that is shedding the virus; vaccinated horses must be isolated for 3 wk after vaccination; annual boosters recommended; positive titers may cause problems if mare is to be exported or bred on certain farms. (Stallions should also be vaccinated 3 mo before breeding.)
Equine monocytic ehrlichiosis (Potomac horse fever)	Initially administer two doses at a 3–4 mo interval; 4–6 wk before due date

with a respiratory infection. All pregnant mares should be vaccinated against EHV-1 at 5, 7, and 9 mo of gestation. *

The equine arteritis virus can cause equine viral arteritis (EVA) abortion. An EVA-seronegative mare scheduled to be bred to an EVA-positive stallion that is shedding the arteritis virus in the semen should be vaccinated before breeding. Horses must be isolated for 3 wk after EVA vaccination. Mares should not be vaccinated against EVA during pregnancy.

Sporadic abortions due to placentitis can be caused by bacterial and mycotic infections of the placenta. These are predominantly ascending infections acquired through the caudal genital tract but may also be focal or diffuse. Bacteria involved include *Streptococcus zooepidemicus*, *Escherichia coli*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, *Staphylococcus aureus*, *Rhodococcus equi*, and *Actinobacillus equuli*. Mycotic organisms include *Mucor*

and *Aspergillus* spp. Efforts to reduce the incidence of these abortions should include good breeding hygiene, treatment of genital disease before breeding, maintaining good body condition throughout pregnancy, and vulvoplasty (Caslick operation) to prevent pneumovagina. Mares at risk of placentitis should be examined by ultrasonography per rectum periodically during late gestation for evidence of genital infection and placental abnormalities as evidenced by uterine discharge and increased uteroplacental thickness.

Any aborted fetus and fetal membranes should promptly be submitted fresh or cooled (never frozen) to a diagnostic laboratory to determine the cause of the abortion.

PARTURIION

The pregnant mare should be taken to the foaling location 3–4 wk before the expected

foaling date to enhance immunity against pathogens present in the environment. Antibodies will be sequestered in colostrum for passive immunity in the newborn. Quality of colostrum will be improved by administering booster vaccinations 4–6 wk before the mare's due date (*see also* VACCINATIONS, p 2195).

Foaling box stalls should be large (at least 3.5 × 3 × 3.5 m). The foaling area should have good ventilation and be well bedded with clean, dry straw. The walls should be solidly constructed and free of sharp edges. Mares may benefit from foaling outdoors on turf, weather permitting. Regardless of location, the mare should be observed without disturbance.

Evaluation of the premonitory signs of parturition is useful but does not permit precise prediction of the time of delivery. The mammary gland starts developing 3–6 wk before foaling and distends with colostrum in most mares 2–3 days before parturition. Colostrum may drip from the teats and dry to form a waxy material at each teat orifice. This "waxing" develops in ~95% of mares 6–48 hr before foaling, but in some cases, it is not seen at all or it may precede parturition by many days. Before the mare foals, the calcium and potassium content of udder secretions increase, and the sodium content decreases. Water hardness chemical tests have been used to measure these in mammary gland secretions to predict parturition.

If a mare has had a vulvoplasty (Caslick operation) during pregnancy, it is necessary that an episiotomy be performed ~2 wk before parturition.

Stages of Parturition: It is critical to understand the normal progression of events during parturition. Abnormal events can then be identified and intervention provided as needed. Parturition is divided into three stages.

Stage I is characterized by signs of abdominal discomfort and restlessness due to uterine contractions. Patches of sweat on the flank and behind the elbows usually appear a few hours before foaling. The uterine contractions increase in frequency and intensity, causing the fetus to engage into the cervix and pelvic canal. The fetus rotates from a dorsopubic to a dorsosacral position before expulsion. Mares may roll during the first stage, which is thought to facilitate rotation of the fetus.

Increasing pressure in the uterus causes the chorioallantois to protrude through the internal os of the cervix. The chorion over the cervix is smooth—it does not have

microvilli and is referred to as the cervical star. The chorioallantois usually ruptures at the cervical star, and the release of the tea-colored allantoic fluid marks the end of the first stage of parturition. In lay terminology, this event is referred to as the mare "breaking her water."

Stage II starts with the rupture of the chorioallantois and ends when the fetus is expelled. Second stage labor usually lasts 15–30 min. When the fetus engages the cervix, the Ferguson reflex occurs and stimulates the mare to have abdominal contractions. The allantoic fluid lubricates the canal, facilitating expulsion of the amnion and fetus. Vaginal distention causes release of oxytocin and further myometrial and abdominal contractions. The amnion appears at the vulvar lips as a whitish, fluid-filled membrane. The straining efforts of the mare consist of three to four strong contractions, followed by a short period of rest. During the actual expulsion of the foal, the mare usually assumes lateral recumbency with all four limbs extended.

The foal is normally delivered in an anterior, longitudinal presentation and dorsosacral position with the head, neck, and forelimbs extended. One front hoof of the foal usually precedes the other hoof by ~15 cm, facilitating passage of the elbows and shoulder through the pelvic canal. The foal is usually born with the umbilical cord intact and covered by the amnion, which is ruptured by movements of the mare or foal. If amnion remains over the foal's nose, an attendant should remove it to prevent suffocation. If left undisturbed, the mare may lie for some time with the foal's hindlimbs in the vagina. If the foal has not been delivered within 30 min of the rupture of the chorioallantois and release of the allantoic fluid, obstetric intervention is indicated.

Stage III involves expulsion of the fetal membranes. Normally, fetal membrane passage occurs rapidly (within 3 hr) after delivery of the foal. The weight of the amnion and cord may help the chorion separate from the endometrium. Progressive traction by the amnion and moderate uterine contractions originating at the tip of the horn cause complete separation of the chorioallantois, which may become inverted during the process. The mare may stand with the amnion hanging from the vulva at the level of the hocks or below. If the mare kicks at the hanging membranes, endangering the foal, the exposed membranes should be tied in knots to shorten the length to above the hocks.

If the fetal membranes have not been passed by 3 hr after parturition, oxytocin

(20 IU, IV or IM) should be administered at 15- to 30-min intervals until membranes pass. If fetal membranes are still retained at 8 hr after foaling, therapy for retained placenta should be instituted (see p 1381).

Premature Separation of the Placenta: Normally, the translucent white amnion appears first at the vulvar lips during the expulsion stage of labor. Premature separation of the placenta is characterized by the appearance of the bright red, velvety, intact chorioallantois between the vulvar lips before the foal is delivered. The presence of the chorion at the vulvar lips indicates that it has separated from the endometrium before the foal is able to breathe spontaneously. The chorioallantois must immediately be ruptured and the foal manually delivered, or the foal will asphyxiate. The severity and duration of hypoxia that results determines the severity of neurologic abnormalities displayed by the foal (peripartum asphyxia or hypoxic ischemic encephalopathy [see p 2094]).

DYSTOCIA

Most causes of dystocia in the mare are due to abnormal presentation, position, or posture. A dead or compromised fetus often is not properly positioned in the pelvic canal. Dystocia due to fetal-maternal disproportion or primary uterine inertia is rare in mares. A vaginal examination should be performed if the foal is not delivered within 30 min after rupture of the chorioallantois or if second-stage labor does not begin after >4 hr of obvious first-stage labor.

The initial examination may be performed in the standing mare. The perineum should be cleansed with povidone-iodine scrub and rinsed well with water. Efforts should be made to maintain hygiene at all times. A diagnosis of the presentation, position, and posture must be made, and a plan formulated to mutate the fetus into an anterior longitudinal, dorsosacral position with head, neck, and front limbs extended. Copious amounts of clean lubricant will ease mutations and fetal expulsion. Excessive mechanical or manual traction should be avoided. Length of time spent on manipulations and any progress should be noted. Once the fetus is properly presented and positioned in the pelvic canal, if it cannot be delivered using traction exerted by two strong adults, the diagnosis should be reconsidered and plan of action altered. Compassion for the foaling mare must be considered in case management decisions.

Sedation can be provided by administration of xylazine (0.5–1 mg/kg, IV) and butorphanol (0.01–0.02 mg/kg, IV). If abdominal straining prevents adequate vaginal examination and fetal mutation, epidural anesthesia may be administered using xylazine (0.17 mg/kg) and lidocaine (0.22 mg/kg) diluted to a total volume of 8 mL.

The front legs of the fetus should be identified and extended out the vulva. Obstetrical chains should be applied with one loop of the chain at the distal metacarpus and a second loop around the pastern to decrease trauma to the fetlock joint. The chains will aid manipulation and assist the application of traction. Once the head is exposed and the neck extended, it may be possible to intubate the fetus and administer low-flow oxygen using a portable oxygen tank or ventilate with a resuscitator (bag-valve mask). Proper rotation of the fetus may be facilitated by the mare getting up and down. After confirming that the fetus is in the proper orientation, manual traction can be applied, initially dorsally and then caudally. Once the foal's chest is exposed, traction should be applied in a ventral caudal direction. Traction should be applied intermittently in rhythm with the mare's abdominal contractions.

After the foal is delivered, an internal examination of the genital tract per vagina should be performed to identify any lacerations in the mare's genital tract or the presence of a twin. A few low doses of oxytocin (5–10 IU, IV or IM) can be administered every 15–20 min to stimulate passage of the fetal membranes and uterine evacuation. Repair of primary perineal lacerations usually can be delayed until after foal heat, but the dorsal aspect of the vulvar lips should be temporarily sutured if pneumovagina/pneumometra develops.

Controlled Vaginal Delivery: If resolution of the dystocia seems challenging or not possible in the standing mare because of the mare's straining or the orientation of the fetus, a controlled vaginal delivery should be considered. This is performed in an anesthetized mare. Field anesthesia can be accomplished by first heavily sedating with xylazine (1 mg/kg, IV) followed by diazepam (0.05–0.1 mg/kg, IV) and ketamine (2.2–2.5 mg/kg, IV). If gas anesthesia is available, routine induction and maintenance by inhalation will provide longer working time and greater relaxation. If general anesthesia and a controlled vaginal delivery are likely, epidural anesthesia should not be done. The mare's

hindquarters are hoisted to allow the GI tract to move cranially in the abdomen, providing space to more readily perform fetal manipulations. It is prudent for managers of large breeding farms to have a designated location on the farm where a mare could be anesthetized and its hindquarters elevated (hobbles, winch, front end loader readily available) to hasten resolution of a dystocia.

Cesarean Section: If vaginal delivery attempts fail, the mare's value justifies it, and surgical facilities are available, a decision should rapidly be made to deliver the foal by cesarean section to spare the mare's caudal genital tract from further trauma. Treatment for retained placenta should be initiated immediately after surgery. Barring complications, mares can usually be rebred 60 days after cesarean section.

Fetotomy: If surgical facilities are not available or the economic situation prevents referral to a surgical facility, a fetotomy may allow delivery of the fetus. In the mare, fetotomy is usually recommended only if fetal expulsion can be accomplished after one or two cuts. Care should be taken to avoid damage to the mare's cervix and pelvic canal. Treatment for retained placenta should be initiated immediately after fetal delivery.

EXAMINATION OF THE FETAL MEMBRANES

Normally, the membranes are ruptured by the foal over the avillous cervical star region of the chorioallantois. The chorion (red velvety surface) and allantois (shiny surface containing many blood vessels) should be examined. Normally, the chorionic surface color ranges from red to brownish red. Patches of discolored, thick, exudate-covered chorioallantois at the cervical star or between the two horns may indicate an ascending or focal placentitis, respectively. The fetal membranes should be examined for completeness, paying particular attention to the presence of the edematous gravid horn tip and puckered nongravid horn tip.

The amnion has a white translucent appearance and may contain many blood vessels near the umbilical cord. Small, pale amniotic plaques can normally be seen along the umbilical cord.

Fetal and neonatal foal deaths may be associated with pathologic changes present in the fetal membranes. Typically, the fetal membranes weigh ~10%–11% of the foal's

body weight. Placentitis or placental edema may increase the weight of the membranes. Integrity of the junction between the fetal and maternal components of the placenta is essential for normal fetal development. The mare has a diffuse microcotyledonary, epitheliochorial, nondeciduate type of placentation, which directly reflects the presence of abnormalities in the endometrium.

Retained Fetal Membranes: Fetal membranes that are not expelled within 3 hr of parturition are considered to be retained. Fetal membrane retention may be complete, but commonly only the nongravid horn is retained. If the typically puckered nongravid tip is not observed, it is assumed to be retained. If any membranes are hanging from the vulva of a postpartum mare, the amnion and cord should not be cut and removed, because their weight provides tension thought to enhance placental separation and expulsion. Fetal membranes not passed within 3–10 hr are considered to be pathologic and can lead to metritis, endotoxemia, and subsequently laminitis with fatal results. Accordingly, it is prudent to treat the condition as potentially

If membranes are seen hanging from the vulva in a mare that foaled >3 hr prior, the mare is considered to have retained fetal membranes. Courtesy of Dr. Patricia Sertich.

serious. If dystocia or traumatic uterine manipulation has occurred, aggressive treatment for retained membranes should be instituted immediately after parturition.

For early (3–8 hr) retention, 10–20 IU oxytocin can be repeatedly administered IV or IM every 30 min until the fetal membranes have passed. The dose of oxytocin should be decreased if the mare shows severe signs of colic or discomfort. Milking or sucking also stimulates endogenous release of oxytocin. Mares that retain fetal membranes >8 hr should be administered broad-spectrum antibiotics, such as potassium penicillin (22,000–44,000 IU/kg, IV, qid), gentamicin (2.2 mg/kg, IV, qid), or flunixin meglumine (0.25–0.5 mg/kg, IV, tid).

THE EARLY POSTPARTUM PERIOD

Uterine involution is characterized by expulsion of the fetal membranes and contraction of the uterus, cervix, and broad ligaments to normal nongravid dimensions. To achieve maximal reproductive efficiency, a broodmare must produce a foal every year. Horses have an average gestation length of ~340 days. Therefore, to maintain a 12-mo foaling interval, the mare must be bred again within 25 days of foaling. Mares can be bred on "foal heat," which is the first postpartum estrus that occurs 5–11 days after foaling in most mares. However, mares that experienced dystocia or retained membranes and metritis should not be bred on foal heat. Foal heat pregnancy rates are higher for mares bred after 10 days postpartum.

The fertility of the first breeding may be increased if breeding is delayed and PGF_{2α} (dinoprost, 1 mg/45.5 kg, IM, or cloprostenol, 0.55 mcg/kg, IM) administered ~5 days after the foal heat (first) ovulation. The mare can then be bred at the ensuing estrus just before the second postpartum ovulation.

BREEDING SOUNDNESS EXAMINATION OF THE STALLION

See also BREEDING SOUNDNESS EXAMINATION OF THE MALE, p 2230. The breeding soundness examination should begin with a thorough history, including information regarding libido, mating ability, number of mares bred, pregnancy rates, prior illness or injury, and any medications administered. A general physical examination should be performed, noting lameness (particularly of the back and hindlimbs) and heritable conditions that may affect breeding ability or desirability as a sire. The penis and prepuce should be free of lesions. The testes and epididymides

should be evaluated for size, shape, and consistency. The testes should be freely movable within the scrotum and have a total scrotal width >8 cm. The length (L), width (W), and height (H) of the testicles can be determined using calipers or ultrasonography to calculate the volume of each testicle using the equation: $0.523 (L \times W \times H) = \text{testicular volume}$. The stallion's daily sperm output (DSO) can then be predicted by the equation: $\text{total testicular volume} \times 0.024 - 0.76 = \text{DSO}$. The internal genitalia, inguinal rings, and aorta and iliac vessels are evaluated by palpation and ultrasonography per rectum. For semen collection and evaluation techniques and criteria considered for determination of breeding soundness classifications, see p 2230.

Swabs of the external genital tract (penile fossa and the urethra before and after ejaculation) can be obtained and submitted for aerobic culture to detect the presence of possible pathogens. If consistent heavy growth of potential pathogens such as *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, or *Streptococcus zooepidemicus* is seen on aerobic culture of swabs of the penile fossa or urethra and there is a history of repeated infection in mares bred, it may be necessary to breed by artificial insemination using semen extender containing an appropriate antibiotic to which the isolated organism is sensitive. If natural service is required, semen extender containing that antibiotic may be infused into the mare's uterus before servicing.

Stallions found to have an overgrowth of *P. aeruginosa* on the external genitalia (penis, prepuce) may benefit from a once-daily rinse of the penis and prepuce using a dilute acid solution prepared by mixing 10 mL 38% HCl (concentrated) with 4 L of water. Rinsing should be repeated daily until *P. aeruginosa* is no longer isolated. Stagnant water should be removed from the stallion's environment.

If a heavy growth of *K. pneumoniae* is isolated from the stallion's penis and prepuce, a daily rinse of the penis and prepuce may be considered using a dilute bleach solution prepared by mixing 45 mL 5.25% sodium hypochlorite (bleach) with 4 L of water. This rinsing should be performed daily for 1–2 wk and then discontinued for 4 days, after which swabs should be taken from the penile fossa and preputial fold for aerobic culture. Treatment can be repeated if needed. Stagnant water and sawdust bedding should be eliminated from the stallion's environment.

If *Taylorella equigenitalis* is present, the stallion should not be used for breeding (see p 1371). The isolation of *T. equigenitalis* requires special culture conditions; the organism will not grow in routine aerobic cultures. Stallions with lesions of coital exanthema (see p 1357) should not be used for breeding until skin ulcers are completely healed.

BREEDING

Natural Service: Mares are commonly bred by natural service. The proper time to breed is determined by teasing, palpation, and ultrasonography per rectum, which permits detection of estrus and the presence of a dominant follicle. Estrous mares should be bred when a follicle >30–35 mm is present or beginning on day 2–3 of estrus and every other day until ovulation occurs or the mare goes out of heat. Mares ovulate 0–48 hr before the end of estrus. Breeding should take place before ovulation. Ovulation can be induced by administration of deslorelin if the mare has a dominant follicle. (See also MANIPULATION OF OVARIAN ACTIVITY, p 2188.)

A tail wrap should be applied on the mare, and the perineum cleansed. The stallion's penis should be rinsed with water before breeding to remove smegma and to minimize contamination of the mare's reproductive tract. The mare should be slowly introduced to the stallion and teased until obvious signs of receptivity (tail raise, abduction of hindlegs, eversion of vulvar lips, urination) are displayed. A nose twitch may be used for additional restraint but may interfere with the mare's expression of sexual receptivity. For breeding, the stallion should be fitted with a well-adjusted halter with large rings that allow the chain shank to freely slide. During breeding, the stallion should be controlled adequately to prevent injury to the mare. After breeding, the penis can be rinsed with

warm water to reduce contamination from the mare's genital tract.

Artificial Insemination: Semen is obtained using an artificial vagina; motility, morphology, and concentration of sperm are determined; and the number of morphologically normal, progressively motile sperm is calculated. Semen extender containing an antibiotic is then slowly added to semen to improve sperm survival. The temperature of the semen extender should be similar to the temperature of the semen at the time of dilution. A commonly used semen extender is glucose skim milk extender (made with 4.9 g glucose, 2.4 g instant nonfat dry milk, and 100 mL sterile distilled water). One of the following antibiotics can be added: piperacillin 100 mg (1 mg/mL); ticarcillin 100 mg (1 mg/mL); reagent grade gentamicin, which must be buffered with 2 mL 8.4% NaHCO₃, 100 mg (1 mg/mL); or amikacin sulfate 100 mg (1 mg/mL). Effective proprietary semen extenders are also available commercially.

The mare is prepared for insemination by application of a tail wrap and cleansing of the perineum. If soap is used, it should be rinsed thoroughly to remove any residue. Mares should be inseminated with at least 250–500 × 10⁶ progressively motile, morphologically normal spermatozoa before ovulation. Insemination is accomplished by depositing the semen into the body of the uterus using a sterile, plastic insemination pipette. Disposable sterile equipment is recommended to prevent contamination. Normal sperm can be expected to remain viable in the mare's reproductive tract for at least 48 hr. Mares should be examined by palpation and ultrasonography per rectum to confirm that ovulation occurs. Stallion semen can be extended, cooled to 4°C, and packaged for transport in a nonconcurrent transport device. If semen from fertile stallions is properly handled, good pregnancy rates can be achieved when the semen is used up to 48 hr later.

MANAGEMENT OF REPRODUCTION: PIGS

Management of commercial swine breeding herds involves a thorough understanding of reproductive physiology, genetics, nutrition, immunology, disease control, environment, and other factors. (See also ABORTION IN PIGS, p 1341.) The closed-herd concept, which emphasizes preventive medicine strategies

along with herd protection, minimizes the risk of disease loss when combined with intensive management, sound nutrition, and genetic selection. The breeding program should be evaluated at specified intervals to ensure that progress in both efficiency and productivity is being made. Several

efficiency/production parameters to review when analyzing herd reproductive performance are shown in TABLE 11. The postweaning performance of a breeding herd's offspring can be measured through assessment of such parameters as feed conversion ratio, average daily gain, total days to market, and postweaning death loss.

Problems on a swine farm can have a single cause or be caused by a combination of genetic, nutritional, environmental, health, and management factors. When investigating a herd problem, the practitioner can best benefit from remaining focused on the herd and not individual animals. Accurate, up-to-date records are essential when investigating a herd problem. When analyzing a herd and its records, a certain percentage of "abnormal" animals and/or reproductive problems are to be expected.

SOW AND GILT MANAGEMENT

Selection: Gilt selection for genetic improvement should be indexed based on such categories as growth rate, disease status, sexual development, reproductive history (including dam's performance as to wean-to-service and wean-to-estrus intervals, litter size, milking ability, and pigs weaned), structure/conformation, and underline (including teat number [7 pair] and placement). Of potential replacements, up to 30%-40% may be culled, with most eliminated because of problems with structure/conformation, teat issues, and genital defects. Prepubertal gilts are usually fed a sex-specific ration ad lib until they reach market weight (250–275 lb [113–125 kg]) or are 5–6 mo old. At that time, selected animals are then moved into gilt development, where they are fed a diet formulated

TABLE 11

REPRODUCTIVE BENCHMARKING INDICES USED IN COMMERCIAL SWINE HERDS

Reproductive Index	Target	Intervention Level
Wean-to-estrus interval (95% in estrus by 10 days postweaning)	<7 days	>9 days
Wean-to-service interval	≤5 days	>7 days
Repeat services at 21 (± 2) days	<8.5%	>11%
Abnormal returns to service (25–37 days)	<3%	>5%
Multiple matings (if not using fixed timed insemination)	>89%	<86%
Abortions	<1.5%	>2.5%
Not-in-pig	1%	2%
Farrowing rate	>86%	<82%
Total piglets born/litter	>12.5	<12
Live piglets born/litter	>11.5	<11
Stillbirths	<6%	>8%
Mummies	<1.5%	>3%
Litter scatter (≤8 pigs/litter)	<12%	>15%
Pigs weaned/litter	>10.4	<9.5
Prewaning mortality	<13%	>18%
Litters/mated female/year	>2.3	<2.2
Pigs weaned/mated female/year	>24	<22
Nonproductive sow days (without gilt pool)	<40	>50
Culling rate	30%–50%	<30% and >50%

specifically for introduction into the breeding herd and are exposed to boars to stimulate estrus cyclicity.

Disease Precautions: Porcine reproductive and respiratory syndrome (PRRS), parvovirus, porcine circovirus type 2, porcine epidemic diarrhea virus, pseudorabies (Aujeszky disease), Japanese encephalitis, influenza, brucellosis, chlamydiosis, leptospirosis, and other infectious diseases can directly or indirectly affect reproductive performance depending on animal age at infection and stage of gestation. The reproductive herd (gilts, sows, and boars) should be vaccinated, at a minimum, against leptospirosis, parvovirus, and erysipelas. Brought-in gilts should be isolated for a minimum of 45–60 days, during which visual observation and serial testing (ie, serology, oral fluids) for exposure to undesirable infectious diseases should be done. To minimize the number of days for introduction of these gilts into the breeding herd, the latter portion of the isolation period can be used for acclimatization to the herd's resident pathogens through the introduction of cull sows, internal grow-finish hogs, and manure exchange and/or feedback. This natural exposure to endemic herd pathogens can provide essential protection against diseases such as PRRS, parvovirus, and influenza.

Puberty: Early puberty is desirable to decrease production costs and is considered a good indicator of reproductive capability. Onset of puberty depends on a variety of factors, including genotype, liveweight, nutritional status, season, and management (including exposure to the boar). Exposure to a sexually mature boar, also known as the “boar effect,” is the most influential of all management factors. The boar effect is strongest when females are exposed to the sight, sound, touch, and smell of a mature boar, and it decreases as the number of sows stimulated by the boar decrease. Consequently, the boar effect is greatest with direct contact using a mature, sterile boar. Exposure of periparturient gilts (5–6 mo old) to a mature boar for 10–15 min/day appears to provide an adequate stimulus. Along with the boar effect, other management tools to manipulate the onset of puberty include select crossbreeding, housing changes (eg, confinement to outside pens and vice versa), and forming new groups by mixing gilts from different pens of similar health status.

Strict culling criteria should be established for the gilt pool. Gilts in which first visible estrus does not occur by 136 kg body wt and 210 days of age should be culled. Initial estrus in gilts may be weak, so a robust estrus detection program with experienced personnel is essential. Some producers may elect to use exogenous hormones to bring these reproductively inefficient gilts into estrus; if this is the case, the progeny should not be kept for breeding herd replacements. Gilts that have been serviced for two or three consecutive estrous cycles and do not conceive should also be culled.

Timing of estrus can be controlled by adding a progestagen to the feed (eg, altrenogest at 15–20 mg/day for 14–18 days). Estrus will be seen in gilts 4–9 days after the last feeding and with appropriate boar exposure. This allows estrus in gilts to be synchronized with that of a batch of weaned sows or formation of a group of gilts that will farrow together. Prostaglandins can also be used as an abortifacient to synchronize estrus when administered after day 12 and before day 55 of gestation; females generally come into heat 4–7 days later. The cost-benefit of these programs should be assessed before implementation.

BOAR MANAGEMENT

Male fertility in the breeding program more often than not receives too little attention in herd health programs. As with other food animal species, boars should be examined for breeding soundness before use in a breeding program, whenever they show lack of libido or inability to copulate, or if an increased number of females bred by the boar return to estrus ~3 wk later. At a minimum, a breeding soundness evaluation should include a history, general physical examination (including genital examination), a semen evaluation, and a behavior evaluation (*see* p 2237).

Selection: When selecting a boar for a breeding program, factors such as origin from a specific disease-free herd, performance, soundness and conformation, age of puberty, and other pertinent parameters related to reproduction should be considered. All boars that are to be used in a breeding program should, at a minimum, be seronegative for brucellosis, porcine reproductive and respiratory syndrome, and pseudorabies (Aujeszky disease). Additionally, all boars should be isolated and acclimatized for at least 45–60 days and be tested/retested for diseases

naive to the herd before introduction into the herd. If involved in the selection process, boars from large litters (>10 piglets) that reach puberty early ($5\frac{1}{2}$ –6 mo) tend to produce highly productive daughters who also reach puberty at an early age. Performance parameters such as feed efficiency, backfat, and average daily gain are also highly heritable.

Skeletal conformation and examination for current or potential locomotor dysfunction should be assessed. Any unsoundness that may interfere with the boar's ability to approach, mount, and successfully breed/ejaculate should be determined. Acute or chronic musculoskeletal conditions may elicit pain that causes the boar to appear uninterested in mounting. Boars are usually selected as breeding prospects at 3–6 mo. The genetic background of the boar should be consistent with the intended use. Selection of boars with heritable defects such as umbilical or inguinal hernias, cryptorchidism, rectal prolapse, and poor underlines can be avoided by careful analysis of the source herd production records.

History: A complete history should include the age and origin of the boar, source herd health, immunizations, previous disease problems and treatments, exposure to other animals and premises, as well as the time spent in isolation and exposure to the present premises and its breeding animals. It should also include, if available, a description of the boar's previous libido, mating behavior, conception rates, litter size, and performance of relatives and other boars in the herd. For young boars, observations of sexual behavior may be useful.

Physical and Genital Examinations:

A general physical examination should be part of every fertility evaluation. Attention should be given to body condition and conformation, including the back and legs, and locomotor function. Osteomalacia, osteoarthritis, and arthritis, which may result in lameness and reluctance to mount or bear weight on the rear legs, are serious problems.

The testicles, epididymides, and scrotum should be examined and palpated for size, symmetry (<1 cm difference in diameter), consistency, and pathologic changes. An appreciation of normal testicular consistency is necessary to detect subtle changes. The penis and prepuce should be examined for abnormalities during semen collection. Testicular size is directly correlated with

genotype, age, and weight of boars between 142–282 days of age and 185–375 lb (84–171 kg) body wt. Testicular size increases until ~18 mo of age; testicular growth and sperm numbers increase at the greatest rate between 5 and 12 mo of age. Because age and testicular weight are important identifiers of early sexual development, boars should be ≥ 8 mo old before use in a breeding program.

The testicles can be affected by diseases (eg, brucellosis, actinobacillosis) and are vulnerable to trauma by handlers or other animals or as a result of improperly designed or maintained facilities. They should contain no nodules or soft masses. The initial reaction of testicles to trauma or infection is swelling; if untreated, the longterm result is testicular atrophy, identified by increased firmness and loss of resiliency. Asymmetry, as a result of unilateral atrophy, is potentially deleterious to fertility, and semen evaluation may reveal azoospermia, oligospermia, asthenospermia, or morphologic changes indicative of testicular damage.

Behavioral Evaluation and Semen

Collection: Collection allows evaluation of libido and ability to mate and ejaculate; in addition, it provides a sample ejaculate. Precopulatory behavior involves visual and olfactory stimulation. The boar grunts or barks rhythmically, chomps jaws, salivates, and typically engages in head-to-head contact with the sow or dummy, followed by nuzzling her flanks to test for voluntary immobilization. These activities should be observed, because aberrant sexual behavior may result in infertility. Constant head mounting is a common problem with inexperienced boars.

Poor libido is likely caused by behavioral rather than endocrinologic problems. Fighting and domination by older boars and sows can inhibit libido in young boars. Breed and strain differences are also seen; the tendency to be timid, nervous, and nonaggressive can be influenced by selection in a breed over several generations and can result in boars with poor libido. Pain from genital lesions or musculoskeletal problems can have a strong negative effect. Libido can also be impaired by an unfamiliar environment, the presence of a feared person, or distractions such as available feed.

Once the boar has mounted, erection and protrusion of the penis occur as the boar searches for the vulva. Close observation is necessary to notice injuries and lesions of the penis as well as improper erection.

Congenital and genetic problems include incomplete erection, penile hypoplasia, masturbation into the diverticulum (ie, "balling up"), and persistent frenulum.

There are basically two methods of semen collection in the boar—the gloved-hand method and electroejaculation. A third method using a water-jacketed artificial vagina is no longer in common use. Although satisfactory ejaculates can be obtained using either the gloved-hand or electroejaculation methods, the gloved-hand method is preferable because it is simpler and reproductive behavior can be simultaneously assessed. The boar is allowed to mount an estrous female or collection dummy and attempt to copulate. Boars used for artificial insemination are usually trained from the onset to mount a collection dummy. The boar should then be approached quietly from the rear without being touched or frightened. Preputial fluids are first evacuated by massaging the prepuce to prevent contamination of the ejaculate. The back of the gloved hand is then placed against the ventral abdomen of the boar just cranial to the preputial orifice, and the penis is allowed to thrust into the gloved hand. Digital pressure is applied to the distal 3–6 cm of the penis. If properly stimulated, the boar will fully extend the penis and become very quiet. This is followed immediately by ejaculation. Once the tip of the penis is firmly in the hand and ejaculation has begun, it continues for 2–7 min. If the boar dismounts when the attempt is made to grasp the penis, he should be allowed to make several false mounts until he is aggressively attempting intromission again. Most experienced boar trainers achieve a >96% success rate in training boars to mount a dummy and to ejaculate.

A nervous boar may not allow the penis to be locked into the hand, even after several attempts. Semen can be collected from many such boars by allowing them to achieve natural intromission and lock the penis into the sow's cervix to begin the ejaculation, then quickly retrieving the penis and locking it into the hand. The boar will continue to ejaculate, and the major portion of the ejaculate can be collected.

A prewarmed (37°C) thermos or styrofoam cup is a convenient and economical collection vessel. The pre-sperm fraction, consisting of 5–15 mL of fluid, is usually ejaculated first and allowed to fall on the ground (ie, it is not collected). The boar then usually ejaculates a small amount of gel, which is filtered out of the ejaculate by a double layer of coarse gauze (placed over the mouth of the collection

receptacle), because it coagulates into a semisolid mass that can interfere with subsequent evaluation of semen quality. The boar then ejaculates the milky to cream-colored, sperm-rich fraction. The final, sperm-poor fraction contains the largest volume of fluid and gel. Care should be taken to let the boar complete the ejaculation, voluntarily withdraw the penis from the hand, and dismount. Some boars will go through two or more complete ejaculations before voluntarily dismounting.

Semen collection by electroejaculation is done only on an anesthetized boar. An injectable anesthetic that will allow for 15–30 min of general anesthesia is recommended. The rectum is cleaned out using a lubricated hand, and a lubricated rectal probe is inserted. The penis is then exteriorized with the aid of Bozeman sponge forceps and grasped with a surgical sponge wrapped around the penis 5–10 cm distal to the glans penis. Electrostimulation of the boar is performed as in the bull or ram, with the ejaculate collected in a clear, plastic bag that envelops the glans penis.

Semen Evaluation: Standard tests used to evaluate boar semen include sperm motility, morphology, concentration, total numbers, and ejaculate volume. The ejaculate should be protected from changes in temperature, osmotic pressure, and pH during handling and analysis. All equipment and materials that come into contact with semen should be warmed to 35°–39°C.

Sperm motility should be evaluated as soon as possible after collection. Estimating sperm motility in an ejaculate by examining the mass activity or swirl motion of a drop of semen on a slide is of limited value and is not recommended. Gross sperm motility is best estimated on prepared samples in which a monolayer of individual sperm can be visualized using light microscopy. To do this, a 5–10 μ L drop of semen is placed on a prewarmed slide and overlaid with a coverglass. Sample motility is then subjectively estimated to the nearest 5% by viewing several random fields under 20 $\times$ magnification.

Sperm morphology can be a valuable indicator of fertility potential, especially in those ejaculates with a high percentage of abnormal sperm. When using bright-light microscopy, stained slides are necessary to provide adequate contrast to evaluate sperm morphology. When using higher resolution microscopy (ie, phase-contrast, differential interference contrast), glutaraldehyde or buffered formalin preserved samples can be used. A minimum

of 100 (preferably 200) sperm should be assessed for morphology of the head, midpiece, and principal piece (ie, the tail distal to the midpiece). Sperm can be categorized into three groups: normal, sperm with abnormal heads, and sperm with abnormal tails (midpiece, principal piece, including cytoplasmic droplets). Samples with a high number of sperm defects can be examined further, and abnormalities classified as major and minor defects. Acrosome morphology should also be assessed if possible.

Several techniques are available to determine sperm concentration in a filtered boar ejaculate. A crude, subjective, qualitative estimation of sperm concentration can be done by assessing visual opacity of a raw ejaculate, either by direct examination or with the aid of a Karras spermiometer. Analytical determination of sperm concentration can be performed by measuring opacity via a calibrated (spectro) photometer on a diluted semen sample. It is essential that the photometer be calibrated for boar semen. Even with a calibrated photometer, estimates of sperm numbers may be $\pm 30\%$ from that of the actual concentration; this can be attributed, in part, to improper technique, human error, and/or the inherent opacity of the secretions of the accessory sex glands present in the boar ejaculate. Photometric readings can also be inaccurate if the reading is outside the calibration curve or optimal operating range. A second, more direct method to measure sperm concentration is with a hemocytometer or counting chamber. In this method, concentration can be determined by diluting a portion of the filtered ejaculate to a 1:200 ratio—most easily done using a Unopette® system. The hemocytometer should be charged, and the charged unit allowed to set for 5 min, so that the sperm settle into one visual field. Using microscopy, a sperm count is performed and calculated as normally done for RBC determination. Determining sperm concentration using a counting chamber is tedious and time consuming, making its use on a routine basis impractical in most commercial operations.

After calculating sperm concentration/mL, total sperm numbers in an ejaculate can be calculated by multiplying sperm concentration with the total volume (in mL) of the gel-free ejaculate. Ejaculate volume can be measured by using a warmed measuring apparatus (eg, graduated cylinder, disposable plastic measuring cups) or by measuring the weight of the ejaculate (with 1 g equivalent to 1 mL). More

frequently, computer-automated semen analysis systems are being used to objectively determine sperm motility, sperm morphology, and sperm concentration.

Interpretation of Findings: Semen values can be affected by frequency of boar use, age, environment, disease, level of nutrition, genotype, and method of sperm cell fixation. Therefore, boars that do not have acceptable semen values are not necessarily subfertile or infertile. Spermiograms can change dramatically over a short period of time, and boars should not be culled on the evaluation of a single ejaculate. Breed differences in onset of puberty, libido, mating ability, and conception rate have been seen.

Environment can affect fertility over a short period of time, primarily because of disturbances in the thermoregulation of the testes. Boars exposed to cold or hot environmental temperatures may have abnormal spermiograms for ≥ 7 wk after the insult. Severe exposure may result in abnormal spermiograms for a longer time or may even lead to permanent spermatogenic disruption. Any disease that increases body temperature, and thus disrupts thermoregulation of the testes, also has the potential to cause temporary sub- or infertility.

Guidelines for Boar Evaluation:

Ideally, libido, mating ability, semen quality (see TABLE 12), and breeding results (conception rate and litter size) should be considered. The duration of spermatogenesis and spermatozoal maturation is ~ 51 days in the boar. If a boar produces an ejaculate of low or marginal quality when examined in vitro, additional ejaculates should be assessed at 1- to 2-wk intervals to ascertain whether quality has improved over time. Boars with spermiograms that do not improve over 2–3 mo are unlikely to ever improve. Boars with azoospermia on two complete ejaculates or that are unable to achieve complete erection should be culled immediately. Those that have penile lesions or blood in the semen should be sexually rested for ≥ 2 –3 wk and reevaluated. For boars with persistent frenulum or that habitually masturbate in the diverticulum, surgical correction is recommended; however, the progeny should not be kept for breeding, because these conditions are most likely heritable. All results of the fertility examination must be considered in relation to age, disease history, environmental stress, prior breeding usage, mating system, and the techniques of semen collection and handling.

TABLE 12

SUGGESTED MINIMUM SPERMIOGRAM VALUES FOR BREEDING BOARS

Parameter	Natural Service	Artificial Insemination
Color	Opaque to white (vulvar discharge)	Opaque to white
Total sperm numbers	$>35 \times 10^9$ sperm/ejaculate	$>35 \times 10^9$ sperm/ejaculate
Gross motility (raw)	$>60\%$	$>70\%$
Abnormal morphology (including cytoplasmic droplets)	$<25\%$	$<20\%$ 25%
Cytoplasmic droplets (both proximal and distal)	$<15\%$	$<15\%$ 20%

BREEDING MANAGEMENT

Estrus: Sows and gilts are nonseasonal and polyestrous, with the estrous cycle lasting 18–24 (average 21) days. Sows are behaviorally anestrus during pregnancy. Ovulatory estrus usually is not seen during lactation except under conditions of group rearing, high feed levels, or boar contact. Partial weaning or gonadotropin treatment can induce estrus during lactation, but the results are inconsistent and not economical. Normal uterine physiology is reestablished by 20–25 days postpartum. Most sows exhibit estrus 3–7 days after weaning. Estrus in gilts and postweaning anestrus sows can be initiated with exogenous hormones. However, these hormones circumvent natural selection for reproductive efficiency, and this should be kept in mind when they are used in breeding management programs. Exogenous hormones should not be used as a long-term solution to address reproductive inefficiency in a herd.

Estrus lasts ~36–48 hr in gilts and ≥ 48 –72 hr in sows. Time to estrus after weaning and duration of estrus in sows can be influenced by length of lactation, nutrition, body condition, genetics, and other management practices (see TABLE 13). Estrus is characterized by behavioral (eg, mounting, fence walking, vocalizing, tilted ears, kyphosis) and sometimes physical (eg, vulvar swelling, vaginal discharge) changes. Ovulation generally occurs in mid to late estrus. During ovulation, ~15–24 ova are released over a 1- to 4-hr period. Ovulation rate increases over the first four parities, so that the fourth to sixth litters tend to be the largest in number. Ovulation rate can decrease when gilts or sows are undernourished. Most gilts are on full feed, thereby

averting the adverse affects of undernourishment on early reproductive performance. In countries in which gilts are not routinely provided full feed, increasing energy intake for 10 days before estrus (ie, “flushing”) is performed. This has optimized ovulation rate under these circumstances. To prevent undernourishment in recently weaned sows, an energy-dense diet should be fed until after estrus and breeding.

Behavioral changes are most pronounced when the sow or gilt is exposed directly to the sight, sound, odor, and attention (nuzzling and grunting) of a mature boar. A sow or gilt in standing heat normally assumes a rigid, immobile, receptive stance when exposed to a boar. Physical changes such as vulvar swelling and discharge are often unreliable; they do, however, appear to be more marked in gilts than sows and commonly develop 2–3 days before estrus. The ultimate criterion of estrus is either standing to the boar or a positive response to the “riding test” (an attendant applies pressure with the hands in the loin area, then gently sits on the pig’s back to elicit the standing reaction); this test is best conducted in the presence of a boar (eg, in an adjacent pen) or, as an alternative, after exposing the sow to a synthetic boar odor aerosol or taint rag.

Anestrus is a common problem. Failure to detect estrus must be distinguished from true cases of ovarian inactivity. First-litter and early-weaned sows are particularly vulnerable to postweaning anestrus. The primiparous sow must support her own growth as well as maintenance and lactation demands, while her feed intake capacity is not yet fully developed. This problem can be avoided by breeding only gilts in good condition; not overfeeding during the first gestation; and encouraging energy intake

^a Effect has been demonstrated

^b No evidence for effect

^c Effect uncertain

during the first lactation by frequent feeding of high-density diets, wet feeding, and avoiding high temperatures in the farrowing rooms. Management practices such as segregated early weaning, modified medicated early weaning, and medicated early weaning recommend weaning as early as 10 days postpartum; postweaning anestrus is not an uncommon sequela of these management techniques. General guidelines to minimize the negative effect of early weaning on sow reproduction recommend weaning at no less than 14–16 days into lactation for primiparous sows, at no less than 12–14 days into lactation for sows on their second litter, and at no less than 9–11 days into lactation for sows on their third or subsequent litters.

Hormonal Control of the Estrous Cycle:

Estrous synchronization may be achieved by synchronized weaning of lactating sows; estrus occurs 4–10 days later. Administration of a commercially available combination of 400 IU of equine chorionic gonadotropin (eCG) and 200 IU of human chorionic gonadotropin (hCG) per 5 mL dose given as a single IM injection within 12 hr after weaning tightens the synchronization, and estrus occurs 4–5 days after weaning. This eCG and hCG combination also induces estrus in gilts with delayed puberty and in sows with postweaning anestrus.

Fixed-time insemination protocols continue to gain interest in the swine industry. Current recommendations call for the use of progestins to prime the gilt before administration of a GnRH analogue. With sows, a GnRH analogue is administered 83–96 hr after weaning. Breeding of both gilts and sows is then performed 20–33 hr after GnRH administration (depending on product and route of administration).

Exogenous prostaglandin induces luteolysis of the corpus luteum only after day 12 of the estrous cycle and, therefore, is not a practical agent for estrous cycle control; however, estrus may be synchronized by induction of abortion in sows pregnant >15 days by administration of PGF_{2α} (15 mg, IM, then 10 mg, IM, 12 hr later) or an equivalent analogue. Estrus may also be synchronized by feeding altrenogest (15–20 mg, PO, daily for 14–18 days), with estrus being observed 4–9 days after the last dose with appropriate boar exposure. Combination eCG and hCG may be given on the day of progestagen withdrawal to better synchronize estrus.

Breeding: The three methods of breeding are pen mating (boar run with females), hand mating (supervised natural mating), and artificial insemination (AI). Pen mating is generally found on smaller operations and works best in a pen of pigs in various stages of the estrous cycle. Pen mating with a

group of recently weaned sows is less desirable, because their estrous cycles may occur close together and lead to overuse of the boar. In hand mating, the female is usually mated two or three times during estrus, with the first service on the first day of standing estrus, and subsequent matings at 24-hr intervals; confirmed matings should be recorded. Many commercial producers breed the sow or gilt once daily as long as she will accept the boar. The use of two different boars may increase the number of pigs per litter but may mask infertility in one of the boars.

In AI programs, heat detection is performed either twice or once per day. If heat detection is performed twice per day, gilts should be inseminated twice, 8–12 hr after the onset of standing heat and again 12–16 hr later. Sows should be inseminated 24 hr after onset of standing heat and again 18–24 hr later. If heat detection is performed once per day, gilts should be inseminated within 4 hr and sows within 12–16 hr from when they were first seen in standing heat. A second insemination should be performed as described above for those animals that remain in standing heat.

Timing of AI may need to be modified based on a particular farm's availability of labor, building design, or herd genetics. Some experienced users of AI obtain satisfactory results in gilts with a timed, single insemination; however, performing two inseminations is more common. Inseminations can be performed using either single-sire (sourced from one boar) or pooled (sourced from multiple [three to six] boar ejaculates) extended semen. In general, single-sire matings are performed when particular genetic (ie, breeding or show animals) offspring are desired, whereas matings with pooled semen are used as a means to produce

market hog offspring. Minimum suggested values for extended semen used within 72 hr after collection are provided in TABLE 14. Total sperm numbers in a dose of semen depend on quality and storage time of the semen.

Boars should not be overused (*see* TABLE 15). If sows are weaned in groups, a boar-to-sow ratio of 1:4 for mature boars and 1:2 for young boars is recommended. In hand mating, a mature boar should be used for ≤ 2 breedings/day. When using natural service, a boar-to-sow ratio of 1:15–1:25 (average 1:17 or 18) is usually needed. When using AI, the boar-to-sow ratio can be increased to 1:15 0 1:400.

Pregnancy: Sperm cells reach the oviducts within 30 min of mating, and fertilization can occur within 2–6 hr. Fertilization rates approach 100% in sows, but embryo mortality up to 30%–40% accounts for the usual litter size of 10–16 pigs. Embryos enter the uterus ~48–60 hr after ovulation. Embryos hatch from the zona pellucida and form blastocysts 144 hr after ovulation. Maternal recognition of pregnancy (embryos secreting estradiol) occurs by day 10–14 of gestation, with intrauterine migration and distribution of embryos. Embryo attachment begins by day 13–14, with implantation complete by day 40; a minimum of four embryos must be present at this time for pregnancy to continue. Skeletal mineralization develops by day 35, with fetuses immunocompetent by day 70–75. Fetal deaths that occur after day 35 can result in expulsion or retention of recognizable piglets. Retained dead fetuses in this sterile environment become mummified and are usually expelled at the time of farrowing. The average gestation length is 114 ± 2 days and is somewhat shortened in sows with large litters.

TABLE 14

MINIMUM SUGGESTED VALUES OF EXTENDED PORCINE SEMEN FOR USE IN AN ARTIFICIAL INSEMINATION PROGRAM

Semen Variable	Value
Gross sperm motility	$\geq 70\%$
Normal sperm morphology	$\geq 75\%$
Sperm concentration	25 to 65×10^6 sperm/mL
Dose volume (cervical deposition)	≥ 70 mL
Microbial content	No significant aerobic growth
Arrival temperature	15°–19°C

TABLE 15

SUGGESTED GUIDELINES FOR BOAR USAGE BASED ON BREEDING PROGRAM

Artificial Insemination		Natural Mating		
Boar Age (mo)	Semen Collection Frequency ^a	Matings/day	Matings/wk	Pen-breeding (females/mo)
6–8	1 time/wk	1	4	<8
8–12	1–2 times/wk	1	5–7	8–10
>13	≥4 times/2 wk	2 (spaced)	8–10	10–12

Adapted from Althouse GC. *Animal Health and Production Compendium*, 2002, by CAB International, Wallingford, Oxon, UK.

^a Depends on boar libido

Embryos are at greatest risk of dying during the first 30 days, and efforts should be directed toward avoiding stresses to the sow (eg, overfeeding, heat, handling or moving, immunization) during this critical period. Pregnancies of <16 days are especially sensitive to heat stress. Avoiding exposure to outside animals reduces disease risk. Feed intake should be reduced to the limit feeding level of 4–5 lb (~2 kg) immediately after breeding to avoid embryo loss due to high energy intake. Farrowing less than five piglets is indicative of embryo death after the time of attachment.

To increase colostral antibodies, the gilt or sow should be immunized during the last 6 wk of gestation. An immunization program may include vaccination against *Escherichia coli*, atrophic rhinitis, and erysipelas, and provision of any other vaccines appropriate for the disease situation on the individual farm.

Pregnancy Determination: Several techniques are available for pregnancy determination (see TABLE 16). Pregnancy is most commonly diagnosed by noting that the female does not return to estrus in 18–25 days; this is 75%–85% accurate. Ultrasonography is another popular technique, and three types can be used: pulse echo (A-mode), Doppler, and real-time. Pulse echo or amplitude depth involves emitting ultrasonic waves from a hand-held transducer placed on the skin in the flank area. Reflected waves from a fluid-filled area (ie, developing conceptus or fetus) are picked up by the transducer and converted into either an audible or visual signal. Doppler ultrasonography detects changes in sound frequency (fluid movement) using an audible signal; movements indicative of pregnancy

include blood flow in middle uterine or umbilical arteries, fetal heartbeat, and fetal movements. Real-time ultrasonography involves visualization of a 2-dimensional image of scanned tissues directly under the transducer. Ultrasonographic techniques are generally used at 22–75 days to determine pregnancy, with real-time ultrasonography being used as early as 18 days after breeding. Although uncommonly used for this purpose, rectal palpation can be performed to confirm pregnancy at >30 days gestation. The examiner palpates for fremitus, size, and position of the middle (medial) uterine artery in relation to the external iliac artery. The tone and tension of the cervix and weight and contents of the uterus can also be used to help confirm pregnancy. Other techniques such as hormonal assays (eg, estrone glucuronide, progesterone, prostaglandin) and vaginal biopsy can be used but are not economically feasible.

Parturition: The preparturient period involves restlessness and nest building the last 24 hr. Mammary glands become turgid, and the secretion changes from serous to milk as parturition approaches. Parturition is initiated by increased cortisol levels, which also stimulate release of prostaglandin (PG) $F_{2\alpha}$ from the uterus. PGF $_{2\alpha}$ causes luteolysis of the corpora lutea and release of relaxin, which causes relaxation of the birth canal and cervix. Oxytocin is released from the pituitary gland, which causes uterine contractions and onset of labor. Piglets are usually delivered at frequent intervals (10–15 min; 5–45 min range). Uterine horn evacuation is random.

The stillbirth rate usually is 5%–10%; intra-uterine deaths are due to infection, incorrect position in the uterine horn during delivery, or anoxia. Anoxia is seen

TABLE 16 COMMON TESTS FOR DETECTION OF PREGNANCY IN PIGS

Technique	Test Type	Application of Test After Breeding (Accuracy)
Estrus detection	Indirect	Daily testing 18–25 days (75%–85%) and through gestation (98%)
External physical signs	Indirect	>55 days (gilts); >84 days (sows)
Rectal palpation (sows)	Indirect	30 days (94%), >60 days (100%)
Ultrasonography		
A-mode	Indirect	30–75 days (95%)
Doppler	Direct/Indirect	≥35 days (>85%)
Real-time (B-mode)	Direct	≥22 days (>95%)

when the umbilical cord ruptures or becomes constricted because of the extreme length of the uterine horn, or when there is a delay in transit along the birth canal. Stillborn and weak piglets also may be due to low temperatures in the farrowing house or low Hgb levels (<9 g/dL) in the sow. Any increase in the time interval between pigs born (eg, due to exhaustion, atony of the uterus, or dystocia) increases the chance of injury or death to the piglets still in the uterus. Piglets are born in both cranial (60%) and caudal (40%) presentation. Assistance can be provided in the form of oxytocin injections (10–30 IU) and manual removal of piglets. Walking the sow for a few moments also can be helpful. The number of pigs born alive can be increased by approximately one per sow if an attendant is present to assist delivery (*see below*). Passage of the fetal membranes should occur within 4 hr of delivering the last piglet.

Farrowing can be induced by IM injection of 10–15 mg of natural PGF₂ α or equivalent dose of synthetic analogues. Farrowing generally occurs 18–36 hr later (most within 22–32 hr) in 80%–90% of sows when PGF₂ α is given at or after 112–113 days gestation. Induction can be used so that most farrowings occur during normal working hours, avoiding evenings, weekends, and holidays. Good records are essential, and average days of gestation for the sow herd and individual breeding dates for each sow must be known. PGF₂ α must be used within 72 hr of the expected farrowing date to prevent an increase in stillbirths. The slightly premature piglets require good environmental conditions, particularly in cold weather. Farrowings may be concentrated into an even shorter

period by injecting 20 IU of oxytocin IM 15–24 hr after the PGF₂ α injection. This shortens the interval to parturition but can be accompanied by an increase in dystocia. Successful farrowing can also be induced by giving a single vulvomucosal injection of 5–10 IU of oxytocin.

Incidence of dystocia is low (1%–2%) in sows. As with all polytocous species, uterine inertia accounts for most dystocia in swine. Other causes include fetal malposition, obstruction of the birth canal, deviation of the uterus, fetopelvic disproportion, and maternal excitement. A thorough digital examination of the birth canal is prerequisite to therapeutic intervention. Medical therapy for unobstructive dystocia may include use of an ecbolic agent (oxytocin at 20–30 IU every 30 min, up to three times). Administration of injectable calcium may be warranted if uterine inertia is suspected.

Lactation peaks at 3–4 wk postpartum. Sows that have been on an 8-wk lactation produce 400–700 lb of milk. Poor lactation is a significant cause of impaired productivity in pigs (*see POSTPARTUM DYS GALACTIA SYNDROME*, p 1373).

Prewaning Mortality: Supervised farrowing alone can help to reduce piglet mortality, because it minimizes stillbirths, facilitates access of piglets to needed warmth, allows for observation of nursing activity, and prevents crushing and cannibalism. Other management techniques available to reduce piglet mortality include cross-fostering, split-suckling, well-designed farrowing crates and pens, prepartum vaccination of sows, appropriate feeding programs for lactating sows, and cleanliness.

MANAGEMENT OF REPRODUCTION: SHEEP

When establishing a flock health management program for reproduction, it is important to remember these points:

1) Sheep are short-day polyestrous breeders, ie, estrus occurs in response to shortening day length. 2) The ovulatory season tends to be in the autumn and early winter months; the anovulatory season in the late winter, spring, and early summer months; and the transition season in the late summer months. 3) There is tremendous breed-to-breed variation in prolificacy and length of the ovulatory season.

REPRODUCTIVE PHYSIOLOGY

Ewes are seasonally polyestrous, cycling every 16–17 days during the breeding season. The major environmental factor controlling the estrous cycle is the photoperiod. Decreasing photoperiod after the summer solstice causes secretion of melatonin, which triggers the hypothalamus to produce gonadotropin-releasing hormone. Geographic location and environmental temperatures also modify the length of anestrus, as does the breed of sheep. Fine-wool breeds (eg, Rambouillet, Merino), tropical breeds, and Dorsets have a shorter anestrus period than other breeds such as the Suffolk, Hampshire, Border Leicester, and Columbia. Regardless of this breed-related variation in the length of the breeding season, all breeds are most fertile in the autumn, and anestrus is an unlikely problem associated with regular annual mating.

The duration of estrus (~30 hr) is influenced by the breed and age of the ewe, the onset of puberty, the presence of the male, and the season. Estrous periods that occur in the autumn are longer and more intense, and maiden ewes have a shorter and less intense estrus than mature ewes. The optimal time to mate ewes (naturally or artificially) is in the first half of the estrous period, or 12–18 hr after the onset of estrus. Ewes show no overt signs of estrus, and heat detection requires the presence of a ram, a teaser ram (made infertile by either vasectomy or epididymectomy), or a testosterone- or estrogen-treated wether.

The age of puberty of ewe lambs varies greatly and is influenced by breed, nutrition, presence of the ram, and season of birth.

Well-grown ewe lambs with a body condition score of 3–3.5, particularly of the meat breeds, can be mated at 7–8 mo of age and 70% of mature body wt. Two exceptions exist: lambs born in the autumn to a spring breeding will reach puberty in the spring and be less fertile to an induced estrus, and some breeds of sheep are slow maturing (eg, range breeds) and may not be fertile at 7–8 mo of age. However, breeding ewe lambs early is encouraged; ewes that breed as lambs are able to produce more lamb crops in their lifetime than those bred as 2-yr-olds.

Ewe lambs should be separated from ram lambs by 5 mo of age to avoid unwanted pregnancies, and from all market lambs to avoid overconditioning from a diet too high in energy. Overconditioned ewe lambs are less fertile and produce less milk than those fed to achieve a body condition score of 3.

Follicle development and ovulation rates are major determinants of fertility. Ovulation rate is a polygenic trait showing marked breed difference; heritability estimates are moderate (0.3%–0.5%). Although by selecting replacement animals born as twins or triplets will slowly increase prolificacy within a flock, using more maternal breeds is recommended because their offspring will also have desirable traits of better mothering and milk production.

Nutritional supplementation starting a few weeks before mating ("flushing") may result in higher ovulation rates if the ewes are not in good body condition (score <3). Ewes already in good fit will have a similar ovulation rate and will not respond further to flushing. The diet should be balanced for protein (not >14% crude protein) and have a good availability of energy. High levels of soluble protein can cause early embryonic death through increased urea nitrogen levels in the blood. Overfeeding of energy to ewes in good body condition can cause decreased fertility.

Estrus Induction in Acyclic Ewes:

Estrus and ovulation can be induced in anestrus ewes by the introduction of rams (ram effect) or by treatment with exogenous progestagen or equine chorionic gonadotropin (eCG), or through the effects of melatonin either by manipulating the photoperiod in housed sheep or through the use of

exogenous melatonin in the feed or as an implant. (See also HORMONAL CONTROL OF ESTRUS, p 2244.) Factors affecting fertility after estrus induction include breed, season, lactation, nutritional status, and postpartum period, as well as the ewe's dry/suckling status, ram to ewe ratio, time of ram introduction, mating by natural or artificial insemination, and number of inseminations (one or two).

The sudden introduction of novel rams or teasers ("ram effect") to anestrus ewes can induce the onset of ovarian cyclicity during the transition season, most often 4–6 wk before the onset of the ovulatory season in seasonal breeds; however, it works poorly to synchronize estrus once the ewes have started to cycle. Responding ewes commonly ovulate within 48 hr of ram introduction but usually are not receptive, ie, the estrus is silent. In ewes with a silent estrus, ovulation is followed by the formation of either a normal or a short-lived (5–6 days) corpus luteum (CL). After regression of a normal CL, most ewes display estrus (~19 days after ram introduction). After regression of a short-lived CL, ewes ovulate without displaying estrus and commonly form a normal CL. Regression of this CL results in estrus (~25 days after ram introduction). This gives two peaks of breeding activity and very good synchronization of estrus without the use of exogenous hormones.

Acyclic, seasonally anestrus ewes can be induced into estrus and ovulation with exogenous melatonin. Ewes are given melatonin 6 wk before joining and are isolated from rams during that period. The joining period should cover two complete estrous cycles (35 days). Exogenous melatonin is more successful toward the end of the seasonal anestrus period, ie, transition period. This product is not commercially available in many countries. A similar effect can be obtained by manipulating the photoperiod under management programs in which the ewes and rams are in confinement housing. Usually starting in late autumn up to the winter solstice, ewes are exposed to artificial light, usually 16 hr/day for 8–12 wk. At the end of this period (eg, mid-winter), the length of light exposure is reduced to 8 hr/day. This may require darkening windows to reduce exogenous light sources and completing barn chores during only those 8 hr to avoid using lights during the dark period. After 6–8 wk, ewes will start to cycle. If the rams are housed under similar conditions, scrotal circumference and breeding capacity will increase.

Estrus Induction/Synchronization:

Estrus induction in acyclic ewes requires exposure to exogenous progestagen for a minimum of 5 days; most programs use 7 days. The progestagen used may be either natural progesterone delivered intravaginally in a controlled intravaginal drug-releasing device (CIDR), or melengestrol acetate (MGA) fed at 12-hr intervals at a dose of 0.125 mg/head. ● Ovulation and subsequent fertility is usually poor unless eCG is given at removal of the progestagen; usually 500 IU is administered. If ewes are cycling, then either the progestagen exposure needs to be sufficiently long to outlast any CLs present on the ovaries. This is usually 11–14 days. Use of eCG at progestagen removal time is optional (200–400 IU) and is generally not necessary during the ovulatory season if artificial insemination is not being used. Shorter exposures in cycling ewes can be used if prostaglandin (PG) $F_{2\alpha}$ or its analogues is administered either at, or 12–24 hr before, pessary or CIDR removal. Estrous cyclic ewes can also be synchronized by two injections of PGF $_{2\alpha}$ or its analogues 8–11 days apart, although fertility is poorer than with progestagen programs. Estrus commonly is seen 1–3 days after progestagen removal, with a shorter interval during the autumn or with the use of CIDRs, or within 3 days of the second PGF $_{2\alpha}$ injection.

Ram Management: Before a program is set up, the veterinarian should be sure sufficient numbers of rams are available for the program and that the rams are fertile. During the normal ovulatory season and without synchronization, a ram to ewe ratio of 1:40 is usually sufficient, although if the rams are young, or the environment is rough, then the number of ewes per ram should be lowered. This is also true if estrus is synchronized, in which case the ram to ewe ratio should be ~1:10 to 15. When breeding out of season, ram fertility is usually lower, and if estrus is synchronized the ram to ewe ratio should be ~1:5 to 7.

MEASURING REPRODUCTIVE PERFORMANCE

Reproductive performance is measured by several parameters. The most commonly used ones are the proportion of ewes exposed or mated to the ram that lamb (the measure of fertility), the proportion of lambs born (alive and dead) per ewe lambing (also called drop rate and a measure of prolificacy), and age at first lambing. Also often

measured are lambs tail-docked per ewe lambing (lambs marked); lambing percentage (number of lambs born per ewe exposed to the ram); and weaning percentage (percentage of lambs weaned per ewe exposed to the ram), although the latter is more of an economic measure. To measure lamb losses, it is preferable to calculate stillbirth rates and preweaning mortality rates as a proportion of lambs born and lambs born alive, respectively.

Goals for reproductive performance vary tremendously between different sheep-raising systems and must be matched with the management system and constraints. Extensive range flocks that produce primarily wool (eg, the Australian Merino) may seek only flock replacement so that lambing rates of <90%, 1 lamb born/ewe lambing, and <0.8 lambs weaned/ewe lambing are considered acceptable. Ewes are traditionally not expected to lamb until 2 yr of age. Conversely, flocks that produce primarily meat under conditions that require the feeding of stored feeds (eg, where growing seasons are short) and/or housing for a significant proportion of the year must have much better fecundity and lamb weaning percentages to be economically viable. Age at first lambing should be 12–14 mo, and a ewe should raise at least 1.8 or more likely 2 lambs/yr. Fertility rates during the ovulatory season should be 95%–100% in ewes and 90% in ewe lambs.

Producers seeking to further increase ewe production and to reach the more lucrative lamb meat markets also practice accelerated lambing in which ewes lamb every 8 mo (ie, three lambings in 2 years) or every 7.2 mo (the Cornell Star system, *see p 2216*). Both of these systems require that ewes breed during the anovulatory and transition season, as well as the ovulatory season. However, in most of the world, autumn breeding with spring lambing is the predominant reproduction management system, which coincides with optimal grass production for the lambs and lactating ewes, regardless of the desired prolificacy of the management system.

FACTORS AFFECTING REPRODUCTIVE PERFORMANCE

Reasons for reproductive failure in the ewe and ram are numerous. Performance must be considered in light of the management system and genetics of the breed. If targets are not being met, the following can be used as a guideline to investigate contributing factors.

Breed: Breed selection can greatly influence reproductive performance, particularly prolificacy and age at first lambing. Sheep breeds around the world are very diverse in performance, and it is advisable to be familiar with the traits of some of the more popular ones. Terminal sire breeds such as Suffolk, Hampshire, and Texel are often used to obtain rapid growth and muscling. Traditionally, these breeds are only moderately to lowly prolific and so are not preferred in the ewe flock except to produce replacement terminal sire rams. Maternal breeds should possess the following characteristics: fertile, prolific, easy lambing with good maternal instincts (eg, bonding), high milk production, longevity, suitable for the environment (eg, grassland, confinement, hilly country), and for some management systems, long ovulatory seasons. Within each geographic region and production system, specific breeds tend to be more commonly used. Some of the more popular maternal breeds in northeastern North America are the Finnish Landrace, Romanov, and Polled Dorset. In western USA, range breeds are more popular.

Some regions commonly use a crossbred sheep that includes traits from several breeds. In a crossbreeding system, maternal heterosis is used to improve performance, ie, the offspring (the F1 generation) possess traits that are better than the average of their parents, also known as hybrid vigor. A well-known example is the British “mule” sheep in which ewes of a hill breed (eg, Scottish Blackface) that possess the traits of hardiness and good mothering but are not prolific are crossed with a ram of a lowland prolific heavy-milking breed (eg, Bluefaced Leicester). The resultant F1 ewe is a prolific, heavy-milking mother with longevity and hardiness. No ram lambs are retained for breeding. These ewes are then bred to a terminal sire (eg, Suffolk or Texel). The offspring of this mating—a terminal cross—gain well and have good carcass characteristics.

Composite breeds are the result of a planned crossbreeding program coupled with stringent selection based on preselected production traits. The more successful are phenotypically stable and are considered new breeds. In the USA, the Polypay, a composite of the Finnish Landrace, Targhee, Dorset, and Rambouillet, is very prolific and hardy and has excellent wool production. The Rideau sheep, developed in Canada, is a composite of Finnish Landrace, Dorset, Suffolk, and East Friesian. These ewes are very prolific,

heavy milkers, and excellent mothers and are frequently used in accelerated lambing programs. Other examples of popular composites include the Katahdin (North American haired sheep), Dorper (South Africa and North America), Coopworth (New Zealand and Australia), Corriedale (New Zealand), and British Milk Sheep (UK and Canada).

Reproductive Failure of the Ram:

Rams may fail to mate the ewes, even when the ewes are in estrus, or mating may occur but pregnancy does not ensue. Possible reasons are numerous. For failure to mate, these include: 1) The ewes are being mated but the marking harness or crayon is not functioning properly. 2) The ram lacks libido because it is ill with another disease, is too thin, is too old, it is during the anovulatory period, or the weather is too hot. 3) The ram is reluctant to breed, perhaps because of the pain of infectious balanoposthitis (pizzle rot), contagious ecthyma of the penis or prepuce, or because it is lame and cannot mount comfortably. 4) The ram may be inexperienced and has not been "taught" how to breed by observing a more experienced ram. 5) The ram may not be able to cope properly with the environment, eg, a barn-raised ram turned out to mountainous pasture. 6) Too few rams are available to breed the ewes (ram to ewe ratio) for the type of ram (age, experience), conditions (paddock vs range), time of year (ovulatory vs anovulatory), or synchronization programs. 7) Rams may have behavioral issues such as inter-ram aggression, shy rams, or rams "falling in love" with or disliking specific ewes.

Mating not followed by pregnancy may present as ewes being marked repeatedly, a spread-out lambing period, and/or poor prolificacy in the ewes. Many of the reasons for failure to mate can also influence failure to achieve pregnancy. Additional reasons for lack of pregnancy after mating include impaired fertility due to disease such as *Brucella ovis* infection, chorioretinitis, impaired fertility due to mechanical reasons such as excessive heat or cold, inguinal hernia, or injury from fighting; impaired fertility due to environmental hormone disruptors (eg, phytoestrogenic plants); inadequate testicular circumference because of age, season, genetics, or disease; abnormalities of the penis due to a congenital defect or trauma; and sperm abnormalities.

Reproductive Failure of the Ewe: As with the ram, ewes may fail to be mated, or be mated but do not become pregnant. In addition, the ewe may not maintain the pregnancy or have decreased prolificacy. Again, the possible reasons are numerous. Ewes may not be mated because of the following: 1) The ewe may already be pregnant. 2) It may be anovulatory season, which is longer in ewe lambs. 3) The ewe lamb may be prepubertal, influenced by growth (nutrition) and breed. 4) If a synchronization/estrus induction program is used, there could be a fatal error in the program, eg, loss of CIDR, too low dose of eCG, or improper MGA feeding program. 5) Phytoestrogens or specific mycotoxins may temporarily or permanently suppress estrus. 6) Ewes may be too thin, lactating, or recently weaned. 7) Ewe lambs that are overfed postpubertally may not cycle. 8) Ewes may display behavior such as dominating the ram or being shy, particularly maiden ewes. 9) There may be a freemartin/pseudohermaphrodite condition.

Ewes may not conceive or maintain pregnancy because of the following: 1) The synchronization program is not correct, eg, rams are joined too early with the ewes before they are in estrus or too low a dose of eCG is given and ovulation does not occur. 2) There is pathology of the reproductive tract. 3) Early embryonic death occurs, which can be due to a number of issues, eg, selenium deficiency, specific abortion disease (eg, border disease, toxoplasmosis, chlamydiosis), stress, heat shock in early pregnancy, or high levels of soluble protein in the feed leading to high urea nitrogen levels in the blood. 4) Abortion (mid to late term), if not observed, may also present as failure to conceive or maintain pregnancy.

Reasons for poor prolificacy in ewes that become pregnant include insufficient energy at breeding when in poor body condition (low body condition score), very young or very old age, anovulatory or transition season, insufficient dose of eCG, early embryonic death (see above), and genetics.

BREEDING PROGRAMS

The most common breeding program is annual lambing in which autumn-mated ewes lamb in the spring. However, to produce lambs for more lucrative markets, ewes are bred in early autumn or late summer to lamb in winter (eg, January for the Easter lamb market in March or April) or bred in late spring to lamb in autumn (eg,

September for the Christmas lamb market). This requires the use of programs that advance the ovulatory season into the late summer (ram effect, melatonin) or induce estrus during the anovulatory period in the spring (progestagens in the form of CIDR devices or MGA; photoperiod manipulation). However, producers whose flocks lamb out of season rarely adhere to an annual breeding program, because overall production is generally too low to account for the increased costs associated with lambs born in the winter or autumn; instead, these producers adopt an accelerated program to take advantage of the ewe's ability to lamb more than once per year.

The two most popular accelerated lambing programs are the "3 lambings in 2 years" (3 in 2) and the Cornell Star system. The former requires the producer to manage two flocks that lamb every 8 mo (January, May, and September), alternating the first and second flocks. For example, in the northern hemisphere, over 24 mo, a ewe would be bred in the ovulatory season to lamb in the spring (December to lamb in May), then the transition season to lamb in the winter (August to lamb in January, and then the anovulatory season to lamb in the autumn (April to lamb in September). If the ewe was found to be open at pregnancy scanning ~50 days after breeding, it could be "slipped" to the other flock and reexposed to the ram. To be successful, breeding exposures would need to be short to shorten the lambing interval, and lambs would need to be weaned by 2 mo of age to allow breeding back.

The Cornell Star system is similar but more tightly controlled. Ewes lamb every 7.2 mo instead of every 8 mo. This means a ewe can lamb five times in 3 yr. Length of exposure to the ram, time for ewes to wean lambs and be rebred, lambing, and lactation are all very short.

Although the benefits of these programs are considerable in terms of increased productivity and access to lucrative lamb markets, they require a high level of management to work well. Poor flock fertility tends to create a system heavily weighted to spring lambing, because ewes bred in the late spring that do not conceive are rebred in the autumn when more naturally fertile. Disease control programs must be very well managed; there is little "down time" in the barns or pastures for cleanup of contaminated environments. In addition, ewe nutrition must be such that body condition scores do not get too low during lactation, because there is no opportunity for ewes to regain weight after

weaning and before breeding. Breeds that are naturally fertile out of season (eg, Dorset, Merino) have an advantage in these systems.

Accelerated lambing systems are commonly used in northeastern USA and Canada and are becoming more common in South Africa and New Zealand. However, the increased revenue from extra market lambs sold into higher value markets must be carefully weighed against the increased input costs such as feed availability, labor, and housing (for winter lambing).

PREGNANCY DETERMINATION

Accurate determination of pregnancy facilitates differential ewe management by allowing the separation of multiple pregnant ewes for supplementary feed and lambing supervision and the culling of nonpregnant ewes. Procedures for diagnosis of pregnancy can involve detection of ewes that do not return to estrus (nonmarking by ram or teaser fitted with harness and crayon); transabdominal, real-time ultrasonographic scanning; rectoabdominal palpation (from 70 days); abdominal palpation (from 100 days); measurement of plasma progesterone concentrations 18 days after mating (detectable progesterone levels indicate an active CL); and laparoscopy (from 30 days). Real-time ultrasonography is a rapid, highly sensitive and very specific test for pregnancy diagnosis of ewes (and does). For detection of early pregnancy (eg, 20–40 days), it is done most accurately transrectally. When imaging is done later in pregnancy, the ultrasonographic transducer is placed in the woolless area of both flanks and the beam directed forward and upward toward the last rib on the opposite side. It is possible to examine, at low cost, 100–150 ewes/hr and to accurately diagnose single and multiple fetuses.

PRENATAL LOSSES

In healthy sheep, fetal losses after pregnancy diagnosis is performed are normally low, ie, <2%. However, embryo loss can be surprisingly high without an apparent problem at lambing (up to 30% of conceptions). Embryo death before day 12 does not disturb the normal cycle length, whereas embryo death after this time increases cycle length and may appear as repeat marking and a stretched-out lambing period. Pathologic levels of embryo loss are due to issues mentioned previously, but

some losses occur in healthy ewes, with higher levels in more prolific breeds.

Fetal loss in the second and third trimester is generally low in healthy flocks. However, when it is abnormally high and due to a pathologic process, it may appear as an observed abortion, abnormal discharge during pregnancy, open ewes at lambing, stillbirth, early neonatal mortality, or all of the above. Causes are most often infectious but may also be nutritional deficiencies or toxins. The most commonly diagnosed causes of abortion are *Chlamydia abortus*, *Campylobacter jejuni*, *Campylobacter fetus fetus*, *Toxoplasma gondii*, border disease virus, *Coxiella burnetii*, Cache Valley virus, *Salmonella* Abortusovis and other salmonellae, iodine deficiency, selenium deficiency, and some plant toxins (eg, locoweed). Abortion rates of 25%–30% are not unusual in these outbreaks, but in general an abortion rate >5% is considered abnormal and should be investigated.

RAM MANAGEMENT

To achieve maximal fertility, rams should be physically examined for reproductive fitness to detect any abnormalities that may limit mating. (See also BREEDING SOUNDNESS EXAMINATION OF RAMS, p 2233.) The scrotum and its contents and the penis and prepuce must be carefully examined. The size and symmetry of both testes and epididymides should be assessed, and both testes should be firmly palpated for consistency and resilience. Any palpable lesions, particularly of the epididymis, should be considered potentially contagious (eg, *Brucella ovis* and *Histophilus somni/Actinobacillus seminis*). Appropriate tests should be performed to establish a flock diagnosis to initiate a test and eradicate program for infected rams. Semen can be collected and evaluated to screen potential sires, particularly in single-sire mating systems. All screening procedures should be done 6–8 wk before mating to allow management changes of the ram team or purchase of replacements for defective rams.

Supplementary feeding of the rams can be started 6 wk before joining. High-protein grains, particularly lupines, increase both testicular size and the number of cells in the germinal layers of the testicle, resulting in increased sperm production. However, dietary protein levels >14% have been associated with infectious balanoposthitis due to *Corynebacterium renale* (see p 1372, also called pizzle rot).

Mating activity can be monitored by using a breeding harness on the rams and

changing the crayon color every 14–17 days. When fewer than expected ewes are marked, poor ram libido, insufficient number of rams to breed the ewe flock, or anestrus is suspected. When ewes are serially marked with different colors, conception failure or early embryonic death is suspected.

The ram to ewe ratio varies with breed, maturity of ram, and whether synchronization or induction of estrus is being practiced. Ratios of 1:40 are common in farm flocks, but excellent fertility can be achieved with a lower ratio if rams from prolific breeds are used (eg, Finnish Landrace). For ram effect, the ratio should be 1:20; for estrus synchronization, 1:10 to 15 (in season); and for estrus induction (out of season), 1:5 to 1:7.

Length of ram exposure during the ovulatory season should be limited to two or three cycles so as to tighten the lambing period to optimize lambing management and lamb survival. Excellent fertility can be achieved with a breeding exposure of 35–42 days (2–2½ cycles). Poor fertility indicates an issue with the breeding management. Flock dispersion should be avoided at mating, but normal handling should not affect mating. Because younger ewes have a shorter, less intense estrous period, they are better mated separately from older ewes with experienced, although not necessarily older, rams.

Collection of Semen: The artificial vagina is used most commonly for collection of ram semen. It is prepared for collection by the introduction of warm water (100°–130°F [40°–55°C]) and air between the outer casing and soft inner sleeve, lubrication with petrolatum in the end where intromission of the penis occurs, and attachment of a graduated collecting glass at the opposite end. Rams quickly learn to mount a restrained ewe, and intromission and ejaculation are extremely rapid.

The second method of semen collection is by electroejaculation, for which the ram may be restrained on its side. The lubricated bipolar electrode is inserted into the rectum. The withdrawn penis is held with a piece of gauze to facilitate insertion of the glans into a 10- to 15-mm diameter graduated collecting tube. Ejaculation usually occurs after a few short electrical stimulations; “stripping” of the urethra may be helpful when expulsion of semen seems incomplete. Electroejaculation is less reliable than the artificial vagina; specimens vary in quality and can be contaminated with urine.

The volume of semen collected with the artificial vagina is 0.5–1.8 mL, and the concentration of the spermatozoa is 2.5–6 × 10⁹/mL. Semen obtained by electroejaculation generally is of larger volume but lower concentration.

Evaluation of Semen: Immediately after collection, the semen is assessed for contamination, volume, concentration of spermatozoa, and sperm motility (wave motion and sperm progression).

Extension of Semen: Semen can be processed by extending or diluting, packaging, and storing. Semen may be extended 5-fold, depending on the initial concentration, the processing and storage method, and whether the semen will be used fresh, chilled, or frozen-thawed. Most semen extenders or diluents are based on Tris, egg yolk, and additional cryoprotectants such as glycerol. Commercial extender concentrates contain cryoprotectants and require the addition of egg yolk and double-distilled water. These extenders can be used for either fresh or frozen semen.

Extenders for fresh and chilled semen include whole, skimmed, or reconstituted cow's milk that has been heated to 92°–95°C for 8–10 min in a water bath to inactivate toxic factors, egg yolk/glucose/citrate (15% egg yolk, 0.8% glucose [anhydrous], 2.8% sodium citrate dihydrate in glass-distilled water). The addition of Tris or glycerol improves the sperm survival of frozen-thawed semen. The reconstitution of frozen-thawed semen with fresh seminal plasma improves its fertilizing ability when used for intracervical insemination but not for intrauterine insemination. The number of motile spermatozoa and the volume of an insemination dose for the ewe depends on the site of insemination and the method of processing. For vaginal insemination, 0.3–0.5 mL with 300 million motile spermatozoa is used; for cervical insemination, 0.05–0.2 mL is used with 100, 150, and 180 million spermatozoa of fresh, liquid-stored, and frozen-thawed semen, respectively. Intrauterine insemination by laparoscopy requires 0.08–0.25 mL (with a total of 20 million motile spermatozoa) into each uterine horn.

Storage of Semen: Ram semen may be stored for up to 24 hr by cooling the extended semen to 2°–5°C over 90–120 min and by holding at this temperature. Fertility decreases rapidly and is low by 48 hr.

Freezing and storage of ram semen in 0.25–0.3 mL, three-dose pellets or in 0.25

mL, single-dose synthetic straws at liquid nitrogen temperature (196°C) is successful in maintaining sperm viability, but there may be a range in motility after thawing and in fertility between rams or processing batches. Use of frozen-thawed semen may result in lambing rates of 50% with cervical insemination and 50%–80% with intrauterine insemination.

Freeze-thawing reduces the numbers of motile sperm. Chilling results in membrane changes that reduce the longevity of sperm. The membrane changes are similar to capacitation and acrosome reactions, and affected sperm are thus ready to fertilize oocytes. Fresh seminal plasma mitigates the effects of some of the capacitation changes.

ARTIFICIAL INSEMINATION

The optimal time for insemination with nonfrozen semen is 12–18 hr after the onset of estrus. When estrus has been synchronized or induced using progestagens and gonadotropins and/or ram effect, most ewes are in estrus within 36–48 hr and ovulate at ~60 hr. Insemination should be done 48–58 hr after pessary removal for cervical insemination, or 48–60 hr for intrauterine insemination with frozen-thawed semen, with highest conception at ~53–54 hr.

Extended fresh or chilled semen can be placed into the vagina or cervix, and extended fresh, chilled, or frozen-thawed semen can be placed into the uterus. Frozen-thawed semen reconstituted with fresh seminal plasma can be placed into the cervix with conception rates >50%.

Vaginal Insemination: An artificial insemination pipette with a 1–2 mL syringe attached is placed deep into the vagina. This method is quick and involves minimal restraint of the ewe. For cervical insemination, the ewe is restrained to limit movement and to present the hindquarters at a convenient height for easy access to the vagina. After cleaning the vulvar region, the cervix is located with the aid of a speculum and suitable illumination, and the insemination made as deeply as possible into the cervical canal. A long, thin inseminating tube with attached syringe or a semiautomatic inseminating device can be used. The relatively long, tortuous, and firm-walled cervical canal of the ewe usually precludes penetration by the tube for >1 cm. In old, multiparous ewes with cervical tissue distortion, the difficulty increases, and the semen is deposited into the posterior folds of the cervix. In periparturient ewes, the cervix may be fully penetrated. In maiden

ewes, in which insertion of the speculum and dilation of the vagina can cause injury, the semen should be deposited in the anterior vagina.

Intrauterine Laparoscopic Insemination:

Food and water should be withheld from the ewe for ~12 hr. Ewes should be sedated with 1.5–2 mg xylazine, IM, and placed in cradles that restrain and invert them, first in dorsal recumbency for preparation of the abdomen. Local anesthetic may be injected SC at two sites (~4 cm on each side of the ventral midline and ~6 cm anterior to the udder). The cradle

is then raised at the posterior end so that the ewe is tilted at ~45° with the lateral abdomen presented to the operator. The anesthetized sites allow for entrance of two trocars and cannulae; carbon dioxide is insufflated through the first cannula to distend the abdomen. The laparoscope is inserted through the near cannula, the uterine horns are visualized, and a glass or plastic inseminating pipette or sheathed inseminating gun is inserted through the second cannula. Semen is deposited into the lumen of the uterus. Conception rates are similar if semen is deposited into one or both horns of the uterus.

MANAGEMENT OF REPRODUCTION: SMALL ANIMALS

BREEDING SOUNDNESS EXAMINATION

Female: The breeding soundness examination should begin with a thorough reproductive and medical history, including information on previous cycles (onset and regularity), breeding management (past and intended), outcome of any breeding(s), and relevant family history, as well as routine medical information (diet, medications, environment, health status). A thorough physical examination, with particular attention given to the genitalia and mammary glands, should be performed. Vestibulovaginal defects (strictures) should be excluded by digital examination. Evaluation of the mammary glands should include inspection of the nipples for normal anatomy. Screening for hereditary defects common to the breed should be advised, which may require techniques such as radiography (eg, elbow dysplasia), ultrasonography (eg, renal dysplasia), ophthalmoscopy (eg, cataract), specific DNA testing (eg, progressive rod-cone degeneration), as well as the physical examination (eg, patellar luxation).

Digital vaginal examination and vaginoscopy of the bitch may detect strictures or other defects of the vulva or vagina that may hinder copulation or whelping. Vaginal strictures are more commonly congenital than acquired and may be in the form of either a septate strand or a circumferential band. They most commonly form at the vestibulovaginal

junction, cranial to the urethral papilla. The heritability of such defects is unknown. Strictures of the vagina or vestibule are not uncommon in the bitch and usually prevent normal copulation, but if pregnancy ensues from mating without a tie or from artificial insemination, dystocia can result. Septate strands can be easily resected surgically, but circumferential strictures are difficult to resolve without episiotomy and major revision, and tend to reform. Elective artificial insemination and cesarean section may be preferable if the bitch has outstanding breeding potential.

Routine vaginal cultures are not advised because the vagina normally harbors a wide variety of bacteria, including β -hemolytic streptococci and *Mycoplasma* spp. Bitches should be screened for brucellosis before each estrus when breeding is planned. A negative *Brucella canis* screening test is reliable; positive results warrant further specific (eg, agar gel immunodiffusion [AGID]) serologic evaluation, culture, or PCR, because false-positives are common. Clinicians should contact their commercial laboratory or veterinary school for updated screening protocols. Queens should be screened for feline leukemia virus and feline immunodeficiency virus as medically indicated. Bitches and queens >5 yr old should also have their general health assessed by performing a CBC, serum chemistries, and a urinalysis.

Before an anticipated breeding, females should be in optimal body condition to improve conception rate and whelping

outcome. Breeders commonly skip cycles between breedings; this is not optimal husbandry because the inevitable exposure to estrogen (queen) and progesterone (bitch, sometimes queen) during the estrous cycle promotes cystic endometrial hyperplasia and may result in pyometra. Bitches and queens kept in optimal health can be bred sequentially and should be ovari hysterectomized or ovariectomized when no further breedings are planned. Proper nutrition and exercise strategies for pregnancy and lactation should be outlined.

Bitches should be currently vaccinated for core infectious diseases (canine distemper, parvovirus, adenovirus 2, and rabies). Other noncore vaccinations should be administered only according to good medical practice (appropriate for the dog's age, health status, home and travel environment, and lifestyle). Queens should similarly be vaccinated appropriately (based on duration of immunity recommendations) for feline distemper, rhinotracheitis, and calicivirus. Vaccination against rabies virus, feline leukemia virus, and other noncore diseases should be done when indicated by good medical practice, based on risk factors associated with the cat's age and husbandry. Unnecessary revaccination of bitches and queens before breeding is not advised, because little improvement in immunity can be expected and adverse effects may be seen. Vaccination during pregnancy is advised only when prior vaccination status is lacking or unknown, and risk of exposure is high (eg, a shelter). In that case, the use of recombinant core vaccines is optimal.

The use of preventive medication for heartworm disease and internal and external parasite control (according to manufacturers' recommendations) during pregnancy and lactation is advised. Appropriate isolation of the pregnant female during the last half of pregnancy for infectious disease prevention is important (eg, avoiding exposure to canine herpesvirus in the bitch and upper respiratory infections in the queen). Client education concerning normal whelping and queening events and about the timely identification of dystocias is essential. Fetal and uterine monitoring systems developed for routine use in the bitch and queen improve neonatal survival with reduced morbidity and mortality for the dam.

Male: The breeding soundness examination for males should begin with a thorough reproductive and general health history, including past and intended breeding

management, outcome of any breedings already performed, relevant family history, as well as routine general history (diet, medication, environment, and health status). Screening for relevant heritable defects of concern for the breed should be advised.

A thorough physical examination should be performed, with particular attention given to the genitalia. The penis should be fully extruded from the prepuce and examined. This may require sedation in toms. If hair accumulates around the base of the feline penis, it can prevent copulation and should be removed. Prostate size and symmetry should be assessed in dogs by simultaneous abdominal and rectal palpation or with ultrasonography; this is not generally necessary in cats because prostate disease is rare. Palpable abnormalities (pain or asymmetry) or semen abnormalities always warrant ultrasonographic evaluation of the prostate and further clinical testing as indicated (eg, urinalysis, cytology, culture). The testes and epididymi should be palpated carefully for symmetry and normalcy—abnormalities again warrant ultrasonographic evaluation. The scrotum should be evaluated for evidence of dermatitis or trauma, which can impact fertility. A small amount of mucoid discharge at the preputial opening is normal in dogs. (See also REPRODUCTIVE DISEASES OF THE MALE SMALL ANIMAL, p 1400.)

Cryptorchidism, a common genital defect in males, is diagnosed if either or both testes are not present in the scrotum at puberty; testicles normally descend into the scrotum by 6–16 wk of age. Descent as late as 10 mo has been documented in dogs. Unilateral cryptorchidism does not result in infertility. In dogs, cryptorchidism is hereditary, and affected animals should not be bred. Both late descent and failure of descent are heritable. Both parents of affected individuals should be implicated as carriers. Because retained testes have a higher incidence of neoplasia and torsion, bilateral orchiectomy is recommended. Attempts at inducing descent with medical therapy with gonadotropins or testosterone have been unsuccessful and are not ethical. Orchiopexy is also considered unethical. Failure of one testis to develop (true monorchidism) may be seen in dogs but is rare. Serum luteinizing hormone (LH) levels are high (>1 ng/mL) if a dog or cat is completely neutered.

A persistent penile frenulum prevents protrusion of the penis from the prepuce and thus copulation. Treatment is surgical. Deviation of the penis is uncommon; these

animals require assistance in breeding or may be bred via artificial insemination. Hypospadias prevents normal sperm transport from the testes to the glans penis and is easily detected by physical examination. Small defects may close spontaneously, but some type of reconstructive surgery involving urethrostomy and penile amputation is usually necessary. Phimosis can be caused by stenosis of the preputial opening, which may be congenital or result from chronic inflammation (trauma or bacterial dermatitis). Any underlying cause should be treated and then, if necessary, the opening enlarged surgically.

Semen Evaluation: Ideally, a complete semen evaluation should be performed in male dogs intended for breeding and repeated at least annually in active stud dogs. Semen is readily collected from most dogs by manual stimulation; the presence of a teaser (estrous) bitch is advised to optimize results by improving libido. All equipment (artificial vagina, collecting tubes, pipettes, slides, and coverslips) should be room to body temperature, dry, and free of water and contaminants such as chemical disinfectants. The canine ejaculate consists of three fractions—the first and third are of prostatic origin, while the second is sperm-rich. Sperm production is related to testicular size, so large dogs should produce higher sperm counts than small dogs.

Semen evaluation should include an assessment of libido, total sperm count per ejaculate (normal in dogs is 200–400+ million), sperm motility (normal >90% progressively motile, with moderate to fast speed), and morphology (>90% normal). The sperm count (sperm/mL) is usually determined with a hemocytometer or by spectrophotometry. Sperm per ejaculate is calculated by multiplying the sperm count by the volume of semen collected. Motility is evaluated in an unstained sample as soon as the sample is collected, ideally using clean slides prewarmed on a slide warmer. Several commercially available stains are suitable for morphology examination; eosin-nigrosin and Giemsa stains are used most commonly.

An adequate amount of the third fraction should be collected to ensure that the entire sperm-rich fraction has been acquired and to permit evaluation of the prostatic component, which should be clear (free of urine and cellular contamination). Subfertility or infertility should never be diagnosed based on one collection. If the sample is azoospermic, semen alkaline

phosphatase can be measured in the ejaculate to assess whether the ejaculate was complete, because it is an epididymal marker. Levels >5,000 mcg/dL indicate the ejaculate included the second, normally sperm-rich fraction. Levels <5,000 mcg/dL indicate either bilateral obstructive disease or libido problems preventing the release of the second fraction. Sperm function is not assessed with routine semen evaluation. Acrosomal evaluation requires special techniques that are not usually commercially available.

Collection of semen for evaluation is difficult in toms, unless the cat has been trained to ejaculate into an artificial vagina or electroejaculation equipment is available. Cats can be trained to ejaculate with manual stimulation in some instances, but training can take weeks to months. Chemical ejaculation using urethral catheterization under dexmedetomidine sedation or by fine needle aspiration of the testes for sperm cytology has been described. Nonspecific methods of evaluating a tom for spermatogenesis include evaluation of urine for sperm and collecting a vaginal wash from the queen immediately after copulation.

Sperm disappear from the vagina within 1–2 hr of copulation. Warm saline (0.05–1 mL) is flushed into the vagina of the queen and aspirated, the sample is centrifuged, and the sediment examined (new methylene blue or routine hematologic stains are adequate). Breeding a questionable tom to a proven queen may be the most practical way to assess his fertility. Adequate coital contact to induce ovulation should be confirmed by measuring progesterone levels in the queen 1–2 wk after breeding.

BREEDING MANAGEMENT

Dogs

Bitches may be bred naturally or also artificially inseminated using fresh, chilled, or frozen-thawed semen. The practice of ovulation timing has become increasingly desirable to breeders. Owners of popular stud dogs commonly permit a limited number of breedings (usually two) and may need to prioritize bitches based on their timing. Owners of bitches wish to minimize travel time to the stud dog facility. Boarding of bitches in season can be reduced with recognition of their fertile period. The use of extended and chilled semen and frozen semen, or subfertile stud dogs, necessitates ovulation timing for optimal conception. Proper ovulation timing permits accurate evaluation of gestational length and is

essential in the evaluation of apparent infertility in bitches. In addition, litter size is optimal with properly timed breedings.

Sound knowledge of the canine reproductive cycle is essential. (See also REPRODUCTIVE DISEASES OF THE FEMALE SMALL ANIMAL, p 1393.) Individual bitches may vary from normal, be presented at variable times during their estrous cycle for evaluation, and sometimes exhibit pathologic variations in cycles. Each of these scenarios requires veterinary interpretation. The normal canine reproductive cycle can be divided into four phases, each having characteristic behavioral, physical, and endocrinologic patterns, although considerable variation exists. Bitches with normal estrous cycles but unexpected patterns must be differentiated from those with true abnormalities. Detection of individual variation within the normal range of events in a fertile bitch can be crucial to breeding management. Evaluation of the estrous cycle for true abnormalities is an important part of the evaluation of an apparently infertile bitch.

The interestrus interval is normally 4–13 mo, with 7 mo the average. The **anestrus** phase of the estrous cycle is marked by ovarian inactivity, uterine involution, and endometrial repair. An anestrus bitch neither attracts nor is receptive to male dogs. No overt vulvar discharge is present, and the vulva is small. Vaginal cytology is predominated by small parabasal cells, with occasional neutrophils and small numbers of mixed bacteria. The endoscopic appearance of vaginal mucosal folds is flat, thin, and red.

The physiologic controls terminating anestrus are not well understood, but the deterioration of luteal function and the decline of prolactin secretion seem to be prerequisites. The termination of anestrus is marked by an increase in the pulsatile secretion of pituitary gonadotropins, follicle stimulating hormone (FSH), and luteinizing hormone (LH), induced by gonadotropin-releasing hormone (GnRH). Hypothalamic GnRH secretion is itself pulsatile, its intermittent secretion is a physiologic requirement of gonadotropin release. Mean levels of FSH are moderately increased, and those of LH slightly increased, during anestrus. At late anestrus, the pulsatile release of LH increases, causing the proestrous folliculogenesis. Estrogen levels are basal (2–10 pg/mL) and progesterone levels at nadir (<1 ng/mL) in late anestrus. Anestrus normally lasts 1–6 mo.

During **proestrus**, the bitch attracts male dogs but is still not receptive to breeding, although she may become more playful. A

serosanguineous to hemorrhagic vulvar discharge of uterine origin is present, and the vulva is mildly enlarged. Vaginal cytology shows a progressive shift from small parabasal cells to small and large intermediate cells, superficial-intermediate cells, and finally superficial (cornified) epithelial cells, reflecting the degree of estrogen influence. RBCs are usually, but not invariably, present. The vaginal mucosal folds appear edematous, pink, and round. FSH and LH levels are low during most of proestrus, rising during the preovulatory surge. Estrogen rises from basal anestrus levels (2–10 pg/mL) to peak levels (50–100 pg/mL) at late proestrus, while progesterone remains at basal levels (<1 ng/mL) until rising at the LH surge (2–4 ng/mL). Proestrus lasts from 2 or 3 days to 3 wk, with 9 days average. The follicular phase of the ovarian cycle coincides with proestrus and very early estrus.

During **estrus**, the healthy bitch displays receptive or passive behavior, enabling breeding. This behavior correlates with decreasing estrogen levels and increasing progesterone levels. Serosanguineous to hemorrhagic vulvar discharge may diminish to variable degrees. Vulvar edema tends to be maximal. Vaginal cytology remains predominated by superficial cells; RBCs tend to decrease but may persist throughout. Vaginal mucosal folds become progressively wrinkled (crenulated) in conjunction with ovulation and oocyte maturation. Estrogen levels decrease markedly after the LH peak to variable levels, while progesterone levels steadily increase (usually 4–10 ng/mL at ovulation), marking the luteal phase of the ovarian cycle. Estrus lasts 3 days to 3 wk, with an average of 9 days. Estrous behavior may precede or follow the LH peak—its duration is variable and may not coincide precisely with the fertile period. Primary oocytes ovulate 2–3 days after the LH peak, and oocyte maturation is seen 2–3 days later; the life span of secondary oocytes is 2–3 days.

During **diestrus**, the healthy bitch becomes refractory to breeding, with diminishing attraction of male dogs. Vulvar discharge diminishes, and edema slowly resolves. Vaginal cytology is abruptly altered by the reappearance of parabasal epithelial cells and frequently neutrophils. The appearance of vaginal mucosal folds becomes flattened and flaccid. Estrogen levels are variably low, and progesterone levels steadily rise to a peak of 15–80 ng/mL before progressively declining in late diestrus. Progesterone secretion depends on both pituitary LH and prolactin

secretion. Proliferation of the endometrium and quiescence of the myometrium develop under the influence of increased progesterone levels.

Diestrus usually lasts 2–3 mo in the absence of pregnancy. Parturition terminates pregnancy 64–66 days after the LH peak. Prolactin levels increase in a reciprocal fashion to falling progesterone levels at the termination of diestrus or gestation, reaching much higher levels in the pregnant state. Mammary ductal and glandular tissues increase in response to prolactin levels.

Estrogen, LH, and progesterone are important in ovulation timing. All may be assessed as part of a reproductive evaluation.

Estrogen: Increased estrogen causes an increased turnover rate of vaginal epithelial cells, resulting in the progressive cornification seen on vaginal cytology. Progressive edema of the vaginal mucosa also develops and can be visualized with endoscopic examination. Estrogen assays are performed by many commercial laboratories; however, the information is of little value for ovulation timing because peak estrogen levels vary from bitch to bitch, and even relative changes do not correlate to ovulation or the fertile period. Estrogen is best assessed by serial vaginal cytologies and vaginoscopy. Estrogen levels do not indicate the fertile period, because ovulation is triggered by the LH surge and not an estrogen peak.

Examination of the cells on the surface of the vaginal epithelium can provide information about the stage of the estrous cycle. Proper technique is important so that the cells obtained are representative of the hormonal changes occurring. The sample should be collected from the cranial vagina; cells from the clitoral fossa, vestibule, or caudal vagina are not as indicative of the stage of the cycle. Under the influence of rising estrogen levels, the number of layers composing the vaginal epithelium increases dramatically, presumably to provide protection to the mucosa during copulation. As estrogen rises during proestrus, the maturation rate of the epithelial cells increases, as does the number of keratinized, cornified epithelial cells seen on a vaginal smear. Full cornification continues throughout estrus until the “diestral shift” occurs 7–10 days after the LH surge, signifying the first day of diestrus. The vaginal smear then changes abruptly, with appearance of neutrophils and epithelial cells changing from full cornification to 40%–60% immature (parabasal and intermediate) cells over the next 24–36 hr.

If vaginal cytology is performed until the diestral shift is seen, the LH surge, ovulation, and the fertile period can be analyzed retrospectively.

Luteinizing Hormone: At the end of the follicular phase of the estrous cycle, a marked increase in LH over usual baseline values develops over 24–48 hr, followed by a return to baseline values. This surge is thought to occur in response to the decline in estrogen levels and increase in progesterone levels. The LH surge triggers ovulation, making it the central endocrinologic event in the reproductive cycle of the bitch.

Daily serial measurement of LH to identify the exact date of the LH surge is an accurate diagnostic tool to time breedings. Affordable semiquantitative in-house kits are available to measure serum LH levels in dogs and to identify the preovulatory LH surge and thus the time of ovulation and the true fertile period. Blood samples must be drawn daily (at approximately the same time) for LH testing, because the LH surge may last only 24 hr in many bitches. The kits can be subject to variable interpretation, so the same person should run the tests if possible. Progesterone testing should always be performed concurrently in case the LH surge is missed.

Progesterone: Progesterone levels begin to rise at approximately the time of the LH surge (before ovulation). Rising progesterone acts synergistically with declining estrogen to reduce edema of the vulva and vagina, which can be seen on vaginoscopic examination. Other observable clinical signs are minimal. Serial blood samples performed every 2 days may identify the initial rise in progesterone (usually >2 ng/mL), which indicates that the LH surge has occurred. Progesterone can be assayed by radioimmunoassay at most veterinary commercial laboratories. Several in-house semiquantitative kits are also available.

No single absolute value of progesterone correlates to any particular stage of the cycle. Progesterone varies from 0.8–3 ng/mL at the point of the LH surge, from 1–8 ng/mL at ovulation, and from 4–20+ ng/mL during the fertile period. However, if accurate serial quantitative progesterone assays are obtained, the LH surge may be estimated as the day a distinct increase in progesterone level is seen. Although this is not as accurate as actual identification of the LH surge by assay, estimation by progesterone levels is still very useful and is often more widely available and convenient.

When timing breeding using semiquantitative in-clinic progesterone assays, only a range of progesterone is obtained, which makes it difficult to accurately identify the day of the initial rise in progesterone or the true fertile period. Technical problems with these kits have also been seen. Therefore, these assays should be used only for routine breedings in which a wider margin of error is acceptable. A general guideline is that when progesterone is >2 ng/mL, breeding should begin. Optimal ovulation timing should use quantitative progesterone assays from commercial laboratories (the cost difference is minimal). Regardless of which assay is used, an additional test should always be performed 2–4 days after the first rise is detected to indicate that the cycle has progressed as expected, a functional corpus luteum has been formed, and ovulation has occurred.

Use of Hormonal Evaluation to Time Breeding:

Owners of breeding animals should be advised to notify their veterinarian when they first notice that a bitch for which timing is planned is in season, based on vaginal discharge or vulvar swelling/attraction to males. Even the most astute owner may not notice the true onset of proestrus for a few days. Early proestrus should be documented with vaginal cytology ($<50\%$ cornification/superficial cells). A baseline progesterone level (usually 0–1 ng/mL) might be informative if the true onset of the cycle is unknown. Vaginal cytology should be performed every 2 days until cornification progresses significantly, usually $>70\%$ superficial cells. At that point, serial hormonal assays should begin. For routine breedings, progesterone testing may be done every other day until a rise in progesterone >2 ng/mL is identified. The day of the initial rise in progesterone >2 ng/mL is identified as “day 0.” Breedings are advised on days 2, 4, and 6.

When increased accuracy of ovulation timing is necessary (eg, frozen or chilled semen breedings, infertility cases, breedings with subfertile stud dogs), daily LH testing is recommended. Once the LH surge is identified, breeding days may be planned. The day of the LH surge is also “day 0.” It is useful to perform vaginal cytology every 2–3 days until cornification is complete (generally $>80\%$ – 90% superficial cells). This maximal cornification usually develops before the fertile period and continues until the onset of diestrus, which is usually a few days after the end of the fertile period. Vaginal cytology may be continued until the diestral shift is

identified, which gives a retrospective evaluation of the breeding just completed. In addition, at least one progesterone assay should be performed after day 0 is identified to document that levels continue to rise. This illustrates sustained corpus luteum function and strongly suggests that an ovulatory cycle has occurred.

Insemination with extended, chilled semen should be done on days 4 and 6, or 3 and 5, after day 0. The days chosen can depend on overnight shipping possibilities and the schedules of all involved parties. Frozen semen breedings should be done on day 5 or 6.

Vaginoscopy may be performed throughout the cycle as an adjunct to vaginal cytology and hormonal assays, especially when evaluating an unusual cycle. Behavior and other observations should also be made. Ovulation timing is most accurate when information from several tests is pooled (vaginal cytologies, vaginoscopy, and progesterone or LH tests).

Artificial Insemination: Artificial insemination is becoming more common in canine reproduction, permitting the use of shipped semen, assistance for geriatric or subfertile males, coverage of dominant females, and advanced reproductive technology such as intrauterine deposition of semen. Insemination may be performed with fresh, chilled, or frozen semen. All instruments should be clean and free of any chemical contamination. After semen has been collected and evaluated (see p 2221), it can be deposited in the cranial vagina of the bitch using a rigid insemination pipette of appropriate length, or into the uterus via transcervical catheterization. Access to the uterus via laparoscopy or laparotomy is less desirable because of invasiveness.

Semen (the second fraction) may be diluted with extenders and chilled for later or distant use (within 48 hr), or extended and frozen in liquid nitrogen (in straws or pellets) for long-term storage. Phosphate-buffered egg yolk diluent or Tris-buffered diluent is used most often; several commercial extenders are available. A drop of chilled semen should be warmed for evaluation before use. Frozen semen should be thawed as directed by the cryopreservation center, evaluated, and immediately inseminated. Dogs should be screened for *Brucella canis* when semen is collected for cryopreservation.

Cats

The queen should be taken to the tom when showing signs of estrus. The breeding area

should be familiar to the tom, quiet, and have good footing and a minimum of interference, while permitting observation. The courtship should not be interrupted unless there is concern for the safety of either cat. Toms have been known to mate to the point of physical exhaustion, but queens normally go through a period of rolling and grooming after a breeding and may not let the tom remount for some time.

Because ovulation is induced by vaginal-cervical stimulation, multiple breedings over 2–3 days are advised. Periods of separation between matings prevent exhaustion and diminish the chances of fighting. The stress of transportation may affect reproductive functions in nervous queens. Evaluation for pregnancy can be performed 21–30 days after breeding by abdominal palpation and ultrasonography.

MANIPULATION OF THE ESTROUS CYCLE

The estrous cycles of dogs and cats are not as easily manipulated as in other species. Most protocols are not based on controlled studies, so manipulation of the estrous cycle in valuable breeding individuals is not advised. Although onset of a particular cycle may be delayed, return to normal cycling is highly variable. Induction of estrus is possible in late anestrus bitches by using prolactin inhibitors (eg, bromocriptine, cabergoline).

Ovariohysterectomy or ovariectomy is the best method to prevent estrus in the bitch and queen. Longterm suppression of estrus by using androgens is not advised, because it is not documented to be safe in breeding bitches. Common adverse effects are breakthrough proestrus, clitoral hypertrophy, vaginitis (especially in prepubertal bitches), increased activity of skin sebaceous glands, mild epiphora, and alterations in hepatic function studies. After treatment is discontinued, return to estrus is ~70–90 days but variable. Conception rates are reportedly normal by the second cycle after treatment. If given to pregnant bitches, synthetic androgens induce severe developmental anomalies in the urogenital system of female puppies. The safety and efficacy of injectable testosterone, as is practiced commonly in racing Greyhounds, has not been supported by controlled studies and is not advised. Androgens should not be given to cats.

The use of megestrol acetate, a synthetic progestagen, is not advised in breeding

females because of the increased risk of cystic endometrial hyperplasia and pyometra, as well as other adverse effects (eg, mammary hyperplasia and neoplasia, hyperglycemia secondary to insulin resistance, and rebound hyperprolactinemia and lactation).

Suppression (and induction) of estrous cycles by the use of synthetic GnRH implants has been described in the bitch; it can be successful, but the products are not universally available. Estrus induction in the bitch can be accomplished with oral prolactin inhibitors (cabergoline 2.5–5 mcg/kg/day); anestrus of at least 2 mo duration must precede induction.

Ovulation can be induced in estrual queens physically or, more reliably, hormonally to produce a luteal phase (diestrus or metestrus) of ~45 days. Physical methods include mating with a vasectomized tom (very effective) or inserting a sterile swab or glass rod into the vagina. The latter should be performed repeatedly for best results. Hormonal methods include administration of human chorionic gonadotropin at 500 IU/cat or GnRH at 25 mcg/cat. Both are given IM, once daily for 2 days.

PREGNANCY DETERMINATION

Fertilization occurs in the oviducts in both the bitch and queen. Implantation of zygotes in the uterus occurs at ~18 days in the bitch and 14 days in the queen. This is accompanied by the formation of small swellings along the uterine horns (deciduomata) by ~21 days. These are palpable, assuming the animal is cooperative, at this time. Fetal growth is rapid during early pregnancy, and these swellings double in diameter every 7 days. After day 35–38, they become indistinct, and palpation becomes difficult until late pregnancy when fetal heads and rumps are palpable as firm, nodular structures in the ventral posterior abdomen. A commercial relaxin assay, specific and sensitive for pregnancy diagnosis in the bitch after 30 days gestation, is available.

Although the fetal skeleton begins to calcify as early as day 28, it is not detectable by routine radiography until approximately day 42–45 and is quite prominent by day 47–48. Radiography at this time is not teratogenic. Late gestational radiography (>55 days) is the best method to determine litter size. Fetal dentition becomes visible at term, and its appearance can be used to confirm fetal development adequate for an elective cesarean section when ovulation

TABLE 17 GESTATIONAL AGE IN DOGS AND CATS

Dogs: Gestational Age $\pm$ 3 days		Cats: Gestational Age $\pm$ 2 days
<40 days	>40 days	>40 days
$(6 \times \text{GSD}^a) + 20$	$(15 \times \text{BP}^b) + 20$	$25 \times \text{BP} + 3$
$(3 \times \text{CRL}^c) + 27$	$(7 \times \text{BD}^d) + 29$	$11 \times \text{BD} + 21$
	$(6 \times \text{HD}) + (3 \times \text{BD}) + 30$	
Days before parturition = 64–66 minus gestational age		Days before parturition = 61 minus gestational age

^a Gestational sac diameter (cm)^b Biparietal diameter (cm)^c Crown rump length (cm)^d Body diameter at the liver (cm)

timing is not available and breeding dates are vague or spread over many days.

Ultrasonography is also useful in pregnancy determination and permits evaluation of fetal viability. Ultrasonography is best performed at 25–35 days gestation. Before 21 days, “false-negative” results are seen. Dopplertype instruments allow one to “hear” the fetal heart, which beats 2–3 times faster than that of the dam. Placental sounds may also be heard. Ultrasonography is especially helpful in differentiating pregnancy from other causes of uterine distention (eg, hydrometra, pyometra, mucometra). Ultrasonographic measurements can be used to calculate gestational age (see TABLE 17).

Gestational age in cats can also be determined by the following formula:

$$\text{mean litter crown rump length (in cm)} = 0.2423 \times \text{gestational age} - 4.2165$$

PREVENTION OR TERMINATION OF PREGNANCY

Unplanned and unwanted mating of cats and dogs is a common concern. Pregnancy can be completely prevented or terminated by ovariectomy. Sixty percent of misbred bitches do not conceive, so confirmation of an undesired pregnancy is advised before proceeding. Postcoital douches are of no value in preventing unwanted pregnancy. Although injectable estrogens, when administered appropriately, can prevent pregnancy, their use involves great risk of serious adverse effects, including pyometra and potentially fatal bone marrow suppression, and they are not advised. If used, they must be administered soon after copulation, before potentially fertilized ova reach the uterus. Oral estrogens given during diestrus greatly

increase the risk of pyometra, are unreliable in terminating pregnancy, and are not advised.

Safe and effective termination of pregnancy is possible in both the bitch and queen by administration of prostaglandin $F_{2\alpha}$ (natural hormone) at 0.1 mg/kg, SC, tid for 48 hr followed by 0.2 mg/kg, SC, tid to effect (until all fetuses are evacuated as confirmed by ultrasonography). Treatment times can reach 14 days. In the bitch, treatment time can be reduced (usually by 48 hr) by the concurrent administration of prostaglandin E (misoprostol) intravenously at 1–3 mcg/kg/day. The adverse effects of prostaglandins at this dosage (panting, trembling, nausea, and diarrhea) are mild and transient. The therapeutic window for prostaglandins is narrow, and doses should be calculated carefully. Synthetic prostaglandins (cloprostenol 1–3 mcg/kg every 12–24 hr to effect) more specifically target the myometrium, causing fewer systemic adverse effects, and are currently preferred.

Pregnancy can also be reliably terminated in the bitch by administration of dexamethasone at 0.2 mg/kg, PO, bid to effect. The owner should be informed of the adverse effects of corticosteroid administration (eg, panting, polyuria, polydipsia).

Combination drug protocols (cabergoline 5 mcg/kg, PO, divided every 24 hr for as long as 10 days, cloprostenol 1 mcg/kg given SC twice at ~28 and 32 days after the LH surge) have been reported to terminate pregnancy reliably with minimal adverse effects, shortest treatment times, and greatest success rates; their cost and need for compounding are disadvantages.

Antiprogestins (aglepristone) are safe and effective abortifacients; availability remains problematic.

WHELPING AND QUEENING

Normal gestation in the bitch is 56–58 days from the first day of diestrus, or 64–66 days from the initial rise in progesterone from baseline (generally >2 ng/mL), or 58–72 days from the first instance that the bitch permitted breeding. Parturition in the queen occurs 64–66 days from the LH surge triggered by copulation.

Predicting length of gestation without prior ovulation timing is difficult because of the disparity between estrual behavior and the actual time of conception in the bitch, and the length of time semen can remain viable in the reproductive tract (often ≥ 7 days). Breeding dates and conception dates do not correlate closely enough to permit accurate prediction of whelping dates. Additionally, clinical signs of term pregnancy are not specific—radiographic appearance of fetal skeletal mineralization varies at term, and fetal size varies with breed and litter size. A drop in rectal temperature to a mean of 98.8°F (range 98.1° – 100.0°F) (37.1°C [range 36.7° – 37.8°C]) is seen in most bitches 8–24 hr before whelping. Breed, parity, and litter size can also influence gestational length. Subtle signs of impending delivery include relaxation of the perineum, mammary engorgement, and a change in the appearance of the gravid abdomen, but these changes are not sensitive or specific. Because there is no means to effectively manage prematurely born puppies, premature intervention in the whelping process is undesirable. Likewise, an excessively conservative approach resulting in intrauterine fetal death is undesirable as well.

Bitches typically enter stage I labor within 24 hr of a decline in serum progesterone to <2 – 5 ng/mL, which develops in conjunction with increased circulating prostaglandins and is commonly associated with a transient drop in body temperature ($<99^{\circ}\text{F}$ [37.2°C]). Monitoring serial progesterone levels for impending labor is problematic because in-house kits enabling rapid results are inherently inaccurate between 2 and 5 ng/mL. Commercial laboratories offering quantitative progesterone by radioimmunoassay or hemiluminescence typically have a 12–24 hr turnaround time, which is not rapid enough to make decisions about immediate obstetric intervention. Progesterone levels can drop rapidly in a matter of hours. If progesterone is <2 ng/mL, gestation is likely at term and labor pending. Clearly, it is beneficial to obtain information about ovulation timing,

minimally by determining the onset of cytologic diestrus, to evaluate length of gestation at term.

A predictable and safe way to induce successful parturition in the bitch and queen has not been developed.

LABOR AND DELIVERY

Normal Labor: Stage I labor in the bitch and queen normally lasts 12–24 hr, during which time the myometrial contractions of the uterus increase in frequency and strength and the cervix dilates. No abdominal efforts (visible contractions) are evident during stage I labor. Bitches and queens may exhibit changes in disposition and behavior during stage I labor, becoming reclusive, restless, and nesting intermittently, often refusing to eat and sometimes vomiting. Panting and trembling may be seen. Vaginal discharge is clear and watery.

Normal stage II labor is marked by visible abdominal efforts, which are accompanied by myometrial contractions that culminate in the delivery of a neonate. Typically, these efforts should not last >1 – 2 hr between puppies or kittens, although great variation exists. The entire delivery can take 1 to >24 hr; however, normal labor is associated with shorter total delivery time and intervals between neonates. Vaginal discharge can be clear, serous to hemorrhagic, or green (uteroverdin). Typically, bitches and queens continue to nest between deliveries and may nurse and groom neonates intermittently. Anorexia, panting, and trembling are common.

Stage III labor is defined as the delivery of the placenta. Bitches and queens typically vacillate between stages II and III of labor until the delivery is complete. During normal labor, all fetuses and placentae are delivered vaginally, although they may not be delivered together in every instance.

Dystocia: Dystocia results from maternal factors (uterine inertia, pelvic canal anomalies), fetal factors (oversize, malposition, malposture, anomalies), or a combination of both. Clinically, uterine inertia developing after the delivery of one or more neonates (secondary inertia) is the most common cause of dystocia.

Dystocia can be objectively diagnosed if uterine contractility is inappropriate (generally infrequent, weak myometrial contractions) for the stage of labor, or if excessive fetal stress results from labor. Subjectively, dystocia is diagnosed if stage I labor is not initiated at term, if stage I labor is >24 hr without progression to stage II, if

stage II labor does not produce a vaginal delivery within 1–4 hr, if fetal or maternal stress is excessive, if moribund or stillborn neonates are seen, or if stage II labor does not result in the completion of deliveries in a timely manner (within 12–24 hr).

Uterine and fetal monitors can be used to detect and monitor labor and to manage dystocia. Unresponsive uterine inertia, obstructive dystocia, aberrant uterine contractions, or progressive fetal distress without response to medical management are indications for cesarean section.

Medical management includes administration of calcium gluconate and oxytocin based on the results of monitoring. Drugs are given only after 8–12 hr of an established contraction pattern (stage I labor) as detected by the uterine monitor and only if inertia is detected when stage II labor is anticipated. Premature administration of drugs results in suboptimal response.

Generally, the administration of calcium increases the strength of myometrial contractions, while oxytocin increases the frequency. Calcium gluconate (10% solution, 1 mL/22 kg body wt bid-qid) is given when uterine contractions are ineffective or weak. It can be given SC, avoiding the potential for cardiac irritability associated with IV administration. Oxytocin (0.5–2 U in bitches; 0.25–1 U in queens) is given when uterine contractions are less frequent than expected for the stage of labor. The most effective time for treatment is when uterine inertia begins to develop, before the contractions stop completely. High doses of oxytocin saturate the receptor sites and make it ineffective as a uterotonic. If fetal stress is evident (persistent bradycardia) and response to medications is poor, cesarean section is indicated.

POSTPARTUM CARE

Palpation and, if necessary, radiography should be used to determine that all puppies or kittens have been delivered. The routine postpartum administration of oxytocin or antibiotics is unnecessary in healthy dams with nursing neonates, unless the placenta has been retained. The dam's body temperature and the character of the postpartum discharge or lochia and milk should be monitored. Normally, the lochia is dark red to black and is heavy for the first few days after parturition. It is not necessary that the dam consume the placentas. Disinfection of the neonatal umbilicus with tincture of iodine helps prevent bacterial contamination.

The neonate should be weighed accurately as soon as it is dry and then twice daily for the first week. Any weight loss beyond the first 24 hr indicates a potential problem and should be given immediate attention (eg, supplemental feeding, assisted nursing, evaluation for sepsis). Neonates should gain 10% of their body weight daily.

PERIPARTURIENT PROBLEMS

Bitches and queens should deliver in a familiar area where they will not be disturbed. Unfamiliar surroundings or strangers may impede delivery, interfere with milk letdown, or adversely affect maternal instincts. This is especially true in young or primiparous animals. The dam's apprehension or nervousness may subside in a few hours, but in the meantime the neonates must receive colostrum and be kept warm; nursing should be closely supervised. The use of acepromazine at low dosages (0.01 mg/kg, PO, bid-tid) can effectively relax nervous dams and does not sedate neonates detectably nor interfere with milk production.

A nervous dam may ignore the neonates or give them excess attention. She may lick and bite at the umbilical stump, causing hemorrhage or damage to the abdominal wall that may lead to evisceration. Excess grooming of the neonate may prevent it from nursing. If the dam's maternal instincts fail, she may assume sternal recumbency and not allow nursing, or leave the neonates unattended. It is not unusual for the dam to pick up the pups and to rearrange them in the box, especially after delivery of each pup; however, she should then assume the normal nursing position.

The principal metabolic disease associated with pregnancy is puerperal hypocalcemia (see p 992). It is rare in cats and most common in dogs weighing <20 kg, exacerbated by improper perinatal nutrition (excessive calcium/phosphorus supplementation or an imbalanced prenatal diet).

Common inflammatory diseases in the postpartum period include metritis and mastitis. Retention of a placenta or its remnants could lead to metritis. Signs include continued straining as if in labor, the presence of a fusiform mass associated with the uterus (best identified by ultrasonographic evaluation), abnormal vulvar discharge, fever, and lethargy as the infection develops. If given within 24 hr of labor, oxytocin may cause passage of the placenta; if oxytocin is ineffective, prostaglandin $F_{2\alpha}$ (0.1 mg/kg, SC, every

12–24 hr) or cloprostenol (1–3 mcg/kg, SC, every 12–24 hr to effect) can usually induce passage of the placenta.

Mastitis (*see* p 1396) is more common in bitches than in queens. The bacteria associated with mastitis tend to be coliforms or *Staphylococcus* spp. Galactostasis can predispose bitches to mastitis, as can excessive human manipulation of the mammary glands. Mammary glands should be observed to ensure that all are being nursed.

Significant postpartum uterine hemorrhage is rare. Oxytocin (<24 hr postpartum) and prostaglandins can be administered if the uterus is healthy; ovariectomy must be performed if hemorrhage is unabated and significant (ie, causing blood loss anemia). Screening for an underlying coagulopathy and appropriate therapy should be undertaken.

Uterine subinvolution results in hemorrhagic spotting for >12–16 wk (the normal period of involution in the bitch). Treatment is unnecessary unless blood loss is significant, because the condition resolves spontaneously. Future fertility is unaffected.

Agalactia (other than that caused by severe illness) is uncommon in dogs and cats. Determination that lactation is adequate should be performed before elective cesarean section. If an emergency cesarean section is required, regardless of the status of lactation, intervention is indicated (*see* below). Bitches and queens with inadequate lactation at term should be thoroughly evaluated for metabolic or inflammatory disorders (metritis, eclampsia, mastitis), nutritional and hydration status, or periparturient pain, and treated appropriately. Evaluation of a hemogram, serum chemistries, vaginal discharge, and ultrasonographic evaluation of the uterus may be required. The normal presence of colostrum (typically not copious) should not be confused with agalactia. The level of neonatal contentment and daily weight gain (after the first 24 hr) indicates adequate lactation. Milk letdown is promoted by oxytocin release, a reflex triggered by nursing; therefore, neonates must spend adequate time suckling. Disruption of the pituitary-ovarian-mammary gland axis can result in idiopathic agalactia. Agalactia can be associated with premature delivery of neonates. Iatrogenic agalactia can result from progesterone supplementation during gestation and should be avoided unless essential.

Because estrogen promotes lactogenesis, the adequacy of mammary development should be assessed before removal of the ovaries at cesarean section. Ovariectomy

should not have a negative effect on bitches and queens with adequate lactogenesis at term. If this is seen, a genetic component may be involved.

Lactation can be stimulated if treatment is prompt. Mini-dose oxytocin (0.5–2 U/ dose, SC, every 2 hr) should be administered. The neonates should be removed from the dam before each injection and returned 10 min later. The neonates should be supplemented adequately to ensure survival, but not excessively, so that they will suckle vigorously. Mammary glands should be gently hand stripped if suckling is not vigorous. Concurrent administration of metoclopramide (0.1–0.2 mg/kg, SC, tid-qid) promotes prolactin release. Acepromazine at mild tranquilization dosages may also facilitate milk letdown. Therapy should continue until lactation is adequate, usually 12–24 hr later.

INFERTILITY

The most common cause of infertility in dogs and cats is related to husbandry problems. Breeding with a proven fertile male must occur at the optimal time for the female. Infectious, anatomic, metabolic, and functional problems associated with infertility are seen less frequently. (*See also* INFERTILITY, p 1328.)

The only confirmed infectious cause of infertility in the bitch is brucellosis (*see* p 1402). This highly contagious disease caused by *Brucella canis* results in abortion and infertility in bitches and infertility in males. A rapid slide agglutination test (RSAT) kit to detect serum antibodies is commercially available. If the RSAT is negative, the bitch is presumed to be *Brucella*-free; if positive, further confirmatory laboratory testing is indicated (eg, AGID, PCR, 2-mercapto-ethanol RSAT).

In cats, infectious causes of infertility include toxoplasmosis, feline leukemia virus infection, feline infectious peritonitis, and feline viral rhinotracheitis. These may cause abortion, neonatal death, fetal resorption, and apparent infertility.

Anatomic causes of infertility include acquired and congenital problems. Fibrosis of the oviducts or uterine horns, probably a result of inflammation after infection or trauma, leads to infertility. Diagnosis is via laparotomy with dye studies. There is no reliable treatment, although microsurgery may be attempted. Similarly, bilateral obstruction of the sperm ducts can cause azoospermia and infertility. High environmental temperature and excessive conditioning resulting in increased body

temperature can induce either temporary or permanent azoospermia. Kennel or cattery management should allow for breeding males to remain cool during the summer. Scrotal dermatitis can have the same result. Disorders of sexual differentiation result in infertility (eg, hermaphroditism, pseudohermaphroditism).

Metabolic causes of infertility, other than in severely ill individuals, are rare. Hypothyroidism has no effect on male libido or semen quality. Hypothyroid bitches might not cycle or have increased abortion rates, or neonatal survival may be poor.

Estrous cycle abnormalities can cause infertility. Prolonged anestrus may be congenital or acquired. Some large breeds of dogs may not have their first estrus until they are ≥ 2 yr old, and some individuals and some breeds typically have only one estrous cycle each year. Congenital forms of anestrus may be due to lack of function of the hypothalamic-pituitary axis or ovarian dysgenesis.

The diagnosis of congenital anestrus is based on the age of the animal and exclusion of all other possible causes (including chromosomal defects, endocrine disorders, and previous oophorectomy). Because cyclicity in queens is determined by photoperiod, lighting conditions should be appropriate for several months before congenital anestrus is diagnosed and exogenous hormones are administered. One reported method to induce estrus in cats is FSH at 2 mg/cat, IM, once daily until signs of

estrus appear (not administered for >5 days).

Acquired anestrus may result from previous oophorectomy, exogenous hormonal treatment (including glucocorticoids), profound hypothyroidism, or ovarian disease (cysts or neoplasia).

Diagnosis is based on history, physical examination, biochemical evaluation, ultrasonography, and laparotomy.

Prolonged estrus may be caused by ovarian cysts that produce estrogen, functional ovarian tumors, or exogenous estrogens (including human transdermal hormone replacement therapy). Exogenous hormones should be discontinued. Laparotomy with histopathology is usually indicated, because medical attempts at inducing ovulation (human chorionic gonadotropin, FSH, GnRH) are usually unrewarding. Prolonged diestrus can result from luteal cysts in the ovary. Medical manipulation with prostaglandins is usually unrewarding, and ovariectomy with histopathology is indicated.

Prostatitis can be subclinical or contribute to subfertility and infertility in dogs. Benign prostatic hyperplasia does not affect fertility.

Testicular neoplasia, commonly producing estrogen, usually causes infertility. Castration of the affected testis may allow the other testis to regain its ability to produce sperm, but the prognosis is guarded.

BREEDING SOUNDNESS EXAMINATION OF THE MALE

The breeding soundness examination (BSE) involves a complete and systematic evaluation of the reproductive potential of a given male, including mating ability and libido, general physical examination and inspection of the genital organs, and assessment of sperm production and quality. The BSE is not a direct evaluation of fertility: this can be confirmed only by successful production of offspring after breeding a fertile female. The specific male animal must be properly identified, and a detailed history is important because sub- or infertile males might require more exhaustive evaluation. The evaluation of mating ability and libido is possible only when collecting semen via artificial vagina

or manual stimulation in the presence of a female in estrus. Therefore, mating ability is seldom evaluated in bulls and rams for routine BSE in which semen is typically collected via electroejaculation.

The components of semen quality evaluation are: 1) semen volume and sperm concentration, which allow for the calculation of the total number of sperm in the ejaculate; 2) sperm motility, including gross motility (ruminants only) and percent individual sperm motility (total and progressive) of a diluted sample; and 3) the percent morphologically normal sperm. A Romanowsky-stained cytology sample also allows for evaluation of red (hemospermia) or white (pyospermia) blood cells in the

ejaculate. When collecting semen from ruminants via electroejaculation, the sperm production potential is estimated by measuring scrotal circumference. Scrotal circumference is correlated with daily sperm output and therefore the serving capacity of a bull or ram (ie, number of females he can settle in a limited time).

After the BSE is complete, the male is classified as a satisfactory, questionable, or unsatisfactory prospective breeder. An animal with physical defects that may be inherited (including cryptorchidism) should be declared unsatisfactory. Guidelines for the BSE in each domestic species are included in the following species-specific discussions.

Spermatogonial Stem Cells and Prospects for Preservation of Male Fertility:

Spermatogonial stem cells (SSCs) are stem cells located against the basement membrane of the seminiferous tubules. As such, they can regenerate themselves but also give rise to daughter cells that follow the replication and differentiation path toward the generation of mature sperm. Of particular interest is that SSCs are present throughout the life of a given male and hence may provide an avenue to preserve or even restore male fertility.

Although much work is still needed for SSCs to become a reality in the management of male infertility, these cells have been isolated and partially characterized in boars, bulls, tom cats, and stallions. Most knowledge derives from studies in the mouse, in which SSCs can be cultured indefinitely, cryopreserved, genetically modified, and transplanted into the testes of sterile recipient mice for generation of mature sperm cells. Studies are underway to pursue these goals in domestic species. In the future, SSCs may be used to preserve fertility in valuable domestic species as well as in their endangered wild counterparts (eg, felids). Moreover, SSCs could also become an integral tool in the assessment of male fertility or ability to restore fertility in a given male. In addition, and given some of the advances in assisted reproductive technologies in domestic species, it is feasible that SSCs could be differentiated into haploid germ cells in vitro for intracytoplasmic sperm injection and the generation of offspring from valuable azoospermic males.

BULLS

In bulls, assessment of libido is often not possible during a routine breeding

soundness examination (BSE). However, if possible, the bull should be observed serving cows to allow assessment of his desire to breed, ease of mounting, ability to achieve erection and extend the penis, and presence of penile deviation or other abnormalities that may prevent successful service. Libido and serving capacity tests (scoring the number of services achieved during a set time that a bull is in a pen with a restrained cow) have been devised but are time consuming and difficult to standardize under field conditions. In addition, the results are difficult to interpret in light of the variety of stocking conditions used, eg, single versus multiple bulls or small paddocks versus large ranges.

BSE forms have been developed and should be used to ensure the systematic completion of the examination and accurate reporting of results. The bull should be restrained in a chute for the examination. Body condition should be scored, and a general physical examination conducted with special attention paid to the feet, legs, eyes, and sheath. The inguinal rings and internal genitalia should be palpated per rectum to detect any abnormalities, eg, seminal vesiculitis. The scrotum should be palpated to evaluate the testes, epididymides, spermatic cords, and scrotal skin. The testes should be symmetrical in size, smooth, resilient, and freely movable within the scrotum. Cryptorchidism is considered an undesirable heritable trait and renders a bull unsatisfactory for breeding even though his semen quality might be acceptable. In ruminants, the epididymides run caudomedially along the testes in a dorsoventral orientation, with the tail most ventrad. The epididymis should have no palpable masses. The measurement of scrotal circumference (SC) is considered a reliable predictor of paired testis weight, which in turn provides an accurate estimate of daily sperm production and quality. The SC should be measured at its maximal diameter, and size depends greatly on bull age and breed. As a general rule, SC should be ≥ 30 cm for bulls < 15 mo old, 31 cm for bulls 16–18 mo, 32 cm for bulls 19–21 mo, 33 cm for bulls 22–23 mo, and 34 cm for bulls ≥ 24 mo old. However, readers should consult the latest published breed-specific average SC measures.

Although not used routinely in practice, additional techniques to evaluate the scrotal contents include thermography and ultrasonography. Bull testes must be 2° – 6° C (35.6° – 42.8° F) cooler than core body temperature for optimal sperm production, and increases in scrotal temperature negatively affect semen quality. Infrared

thermography can be used to evaluate scrotal temperature, which should yield a left to right symmetry with a 6° to 4°C (42.8° to 39.2°F) temperature gradient from top to bottom. Abnormal thermograms are almost always associated with poor sperm quality and have been correlated with decreased pregnancy rates. Conversely, evaluation of the testes by ultrasonography does not appear to improve the predictive value of standard evaluation techniques (physical examination, palpation, SC measurement, sperm evaluation). Therefore, it appears that the value of ultrasonography as a tool in BSE in bulls rests on assessment and characterization of grossly detectable lesions of the testes.

For the purpose of a routine BSE, semen is most often collected via electroejaculation; semen can be collected with an artificial vagina (AV) in bulls trained to use one (eg, those in bull studs). The penis usually extends during electroejaculation and should be examined at that time for any abnormalities. If it is not extended during electroejaculation, it should be gently exteriorized for examination by grasping the glans with a cotton gauze and, if necessary, by putting pressure on the sigmoid flexure immediately caudal to the scrotum. Preputial wash samples may be taken for isolation and culture of *Campylobacter fetus venerealis* (using Clark's medium) or *Tritrichomonas foetus* (using Diamond's medium or a commercially available diagnostic medium kit), in particular when investigating subfertility in bulls ≥ 4 yr old.

The electroejaculator consists of a rectal probe that has a series of linear banded electrodes connected to a variable current and voltage source. The bull is restrained in a chute, the rectum is emptied, and the entire lubricated probe is inserted rectally with the electrodes oriented ventrally. A hand-operated rheostat permits intermittent pulses of current to be given as the voltage is gradually increased. The response varies considerably, but it is common to use 2- to 4-sec pulses repeated at 5- to 7-sec intervals. After a variable number of such stimulations, erection and protrusion of the penis may be seen, followed by a flow of seminal fluid, or the bull may ejaculate into the sheath without protruding the penis. The semen may be collected by any convenient method; typically a rubber AV cone inserted within a plastic cylinder attached to an 18-in. handle, with a test tube attached to the cone, is used. In some bulls, ejaculation is seen only after a final series of momentary pulses at 1- to 2-sec intervals. Older bulls

usually require a higher voltage for ejaculation. In some large bulls, the probe may not reach the correct areas for stimulation; having two or more probe sizes is recommended if BSEs are to be done on a variety of sizes of bulls. The semen collected via electroejaculation is not representative of a full ejaculate in regard to volume and concentration, and thus the sperm production potential of the bull is based on the evaluation of SC. Conversely, sperm quality (motility and morphology) does not differ from that in an ejaculate collected with an AV.

If an AV is to be used, bulls are induced to mount a teaser animal (eg, restrained steer, cow, or phantom), and the erect penis is directed into the AV by the collector as the bull mounts. In preparing the AV, the temperature, which is a critical factor in stimulating ejaculation, is maintained at 105° – 107°F (40.5° – 42°C). Temperatures up to 118°F (48°C) may assist collections in untrained bulls. The AV should be lubricated with nonspermicidal jelly. The typical volume of an ejaculate is 4–8 mL, and the concentration 1–1.5 billion sperm/mL. A semen sample can be collected from some bulls by transrectal massage of the accessory sex glands. With this technique, erection seldom occurs. After the rectum is completely emptied, the vesicular glands are massaged with a backward motion until a few mL of fluid drop from the sheath. The ampullae are then massaged, and an assistant collects the semen as for electroejaculation. This method is not always successful, and the quality of the semen emission is usually lower than the ejaculate collected by the other two methods.

Sperm concentration, ejaculate volume, and the total number of sperm in the ejaculate are evaluated only if the sample has been collected with an AV. The semen sample should be evaluated immediately for sperm motility. The materials that contact the sperm should be at the same temperature as the sperm (to avoid temperature shock), clean, dry, and nontoxic. Motility evaluation is best when the temperature of the semen is either maintained at $\sim 37^{\circ}\text{C}$ ($\sim 98.6^{\circ}\text{F}$) during the short time before it is evaluated, or when the semen is gently warmed to 37°C before evaluation. Both gross motility ("swirl pattern") in the semen and motility of individual spermatozoa should be assessed; individual motility is the more accurate measure and should be used for classification of the bull.

Gross motility is a function of sperm concentration and individual sperm motility

and is evaluated in an undiluted drop of semen placed on a slide without a coverslip and examined at low power ($\sim 100\times$). The intensity of wave motion may be classified into four categories: very good—intense swirling, rapid dark and light waves; good—slower swirling, waves not as intense; fair—slow movement with fewer waves; or poor—very little or no swirl activity. Individual motility is assessed in a sample diluted with warmed saline or semen extender. A drop of diluted sperm is placed on a slide, covered with a coverslip, and examined at $200\text{--}400\times$. The proportion of sperm that are moving progressively across the field of view is estimated by finding multiple groups of ~ 10 sperm and estimating how many sperm are progressive versus how many are not.

The environments in which BSE are done are variable, and there is a high chance of temperature shock to sperm before they may be evaluated. Therefore, $>30\%$ individual progressive motility, or fair gross motility, is considered acceptable. If the examination is performed under optimal conditions, some associations (eg, the Canadian Bovine Practitioners Association) recommend a minimum of 60% motility for a bull to be classified as a satisfactory potential breeder.

Visual estimates of sperm motility are considered appropriate for bull classification in field BSEs. However, in commercial artificial insemination centers, sperm motion evaluation is performed using computer-assisted sperm analysis (CASA), which provides more objective values as well as specific measures not only of percent motile sperm but also of velocities and the track followed by each sperm. For instance, the combination of measures such as beat cross frequency, linearity, average path velocity, straightness, and curvilinear velocity have been correlated with bull fertility. Moreover, some of the motion measures evaluated by CASA such as curvilinear velocity, straightness, and linearity correlate with sperm function such as the acquisition of hyperactivated motility.

The presence of cells other than spermatozoa in the sample should be investigated while estimating motility. RBCs, WBCs, and excess numbers of round epithelial cells and developing forms of spermatozoa may indicate a genital tract abnormality. Careful evaluation of the tract, especially the internal genitalia, may indicate the source of WBCs. The most common cause is seminal vesiculitis. Round, immature germ cells and spermatozoa with proximal cytoplasmic droplets may indicate immaturity or,

alternatively, testicular degeneration. For a better assessment of the types of cells present in semen, staining an air-dried smear of fresh semen with Romanowski stain is recommended. This simple technique can provide critical information, in particular when cells other than mature sperm are present in the sample.

A sample of the semen should be fixed in a buffered formaldehyde saline solution to evaluate sperm morphology. This is best done with the fixed, unstained sperm examined under high power ($1,000\times$) using a phase-contrast microscope. At least 100 sperm should be counted, and the proportion of sperm showing different types of abnormalities noted. However, the only number used in the evaluation of the bull is the proportion of normal sperm, which should be $>70\%$. Sperm plasma integrity, which is required for sperm function, can be assessed with the use of a vital stain such as eosin. Eosin penetrates cells with a disrupted sperm membrane, which appear pink on evaluation under light microscopy, in contrast to live cells, which do not stain. Eosin is often combined with nigrosin, which provides a dark background that allows better observation of live/dead sperm cells. An eosin-nigrosin-stained smear can also be used to assess sperm morphology, although it is considered less reliable than using phase-contrast microscopy of an unstained wet preparation. Other, more sophisticated measures of sperm function are not used routinely in cattle BSEs, although they may become more common in referral and artificial insemination centers. Such tests may include combinations of fluorescent probes and flow cytometry to assess membrane integrity, mitochondrial function, or sperm chromatin integrity, and functional assays such as ability of sperm to undergo in vitro capacitation, zona binding, and/or homologous in vitro fertilization.

Bulls are classified as "satisfactory potential breeders" if they have no physical abnormalities that would prevent breeding and if they meet the minimal qualifications for SC, sperm motility, and sperm morphology. Bulls that do not meet these criteria are classified as "unsatisfactory potential breeders" or, if the results are marginal or questionable, they are considered "classification deferred" and a retest should be recommended.

RAMS

In rams, the breeding soundness examination (BSE) is performed much as for bulls,

using an electroejaculator with a smaller (ram) probe. Body score is classified as 1–2, questionable (underconditioned); 3–4, satisfactory; and 5, questionable (overconditioned). Any major abnormalities of the external genitalia or lumps or irregularities of the testes or epididymides render the ram unsatisfactory. Epididymal masses are commonly found to be sperm granulomas caused by infection with *Brucella ovis*, which is a major cause of reproductive loss in sheep. *B. ovis* may also be associated with testicular atrophy. Scrotal circumference should be ≥ 28 cm for rams 8–14 mo old (>36 cm is exceptional) and ≥ 32 cm for rams >14 mo old (>40 cm is exceptional). Scrotal circumference lower than satisfactory is questionable. Motility of individual spermatozoa is evaluated as for bulls, with $>70\%$ progressive motility being exceptional, $>30\%$ satisfactory, 10% – 30% questionable, and 0% unsatisfactory. The percentage of morphologically normal sperm should be $>50\%$; between 30% and 50% is questionable, and $<30\%$ unsatisfactory; $>80\%$ normal sperm is exceptional. Presence of >5 WBCs per high power field is questionable (WBCs are correlated with *B. ovis* infection). An ELISA test for *B. ovis* should be done on range rams and rams >9 mo old. A positive test renders the ram unsatisfactory. Suspect tests should be repeated. (See also RAM MANAGEMENT, p 2217.)

Any ram with one unsatisfactory rating in any parameter is classified “unsatisfactory”; a ram with a questionable rating in any parameter is “questionable.” For a ram to be classified exceptional, he must have exceptional ratings in scrotal circumference, sperm motility, and sperm morphology. All other rams are considered “satisfactory.”

BUCKS

Breeding soundness examination in bucks has not been detailed to the extent that it has in rams. The testes should be palpated carefully. *Brucella ovis* infection is rare, but sperm granulomas are frequently related to the polled condition; these are most often found in the head of the epididymis. Cryptorchidism is also common and heritable; as in other species, cryptorchid bucks should not be used for breeding. Testicular degeneration is a common cause of fertility loss in older bucks. Semen is collected using an artificial vagina (AV); bucks are easily trained for this method and do not tolerate an electroejaculator. An electroejaculator might be used only if the buck is sedated. Parameters for semen evaluation are similar to those for rams.

Because the ejaculate is typically collected with an AV, sperm production may be measured rather than estimated from scrotal circumference. Semen volume should be 0.5–2 mL, and concentration 1.5–4 billion sperm/mL.

STALLIONS

Given the high economic value of some stallions and the willingness to breed horses based more on their competitive potential than on their breeding soundness, many resources and expensive tests are sometimes used to evaluate breeding soundness, and especially to assess sperm function in those stallions proven subfertile after their first breeding season or displaying potential defects after a routine breeding soundness examination (BSE). Classically, a complete BSE of the stallion has comprised a history, general physical examination, examination of the external and internal genitalia, culture of urethral and possibly penile swabs, and collection and evaluation of at least two ejaculates collected 1 hr apart for total sperm number, sperm motility, and sperm morphology.

The history should include the stallion's prior fertility and type of management used for breeding. If <10 mares were bred, individual mare fertility should be considered if pregnancy rates were low. If the stallion has been racing or training recently, he may have been receiving anabolic steroids or other drugs. Stallions recently retired from a performance career may be evaluated again in 3–6 mo if they fail the initial BSE.

During the physical examination, the stallion should be evaluated for general body condition and the presence of any conditions that might interfere with breeding. Genetically inherited defects, including parrot mouth and cataracts, render the stallion unfit for breeding. Blindness, lameness or ataxia, penile paralysis, or other defects that prevent the stallion from breeding also render him unsatisfactory as a breeding prospect. Recent evidence supports cryptorchidism as a potentially inherited defect in horses, thus rendering the stallion an unsatisfactory prospective breeder.

Scrotal palpation should be performed and may be done after the first ejaculation when the stallion may be more relaxed. Total scrotal width should measure >8 cm (preferably >9 cm), as assessed with a blunt caliper across both testes together. The testes should be firm, resilient, and homogeneous on palpation. The epididymides run dorsally along the testes, in a craniocaudal orientation, with the tail most

caudad. The tail of the epididymis is easily palpable, whereas the body and head of the epididymis tend to blend with the dorsal surface of the testis. Rotation of one testis 180° (the tail of the epididymis being palpated on the cranial aspect of the testis; also called torsion of the spermatic cord) is common and has no clinical significance in healthy stallions.

Ultrasonography is also commonly used to evaluate scrotal contents and to take individual measurements of each testis. A portable console fitted with a linear 5 MHz transducer typically used for reproductive evaluation of mares can be used. The testes should have a homogeneous echoic appearance; a cross or longitudinal section of a central vein that runs along the longitudinal aspect of the testis starting at the cranial pole is a hallmark of the normal equine testis and should not be confused with pathology. The tail of the epididymis and spermatic cord display a homogeneous "cheeseclothlike" appearance; asymmetric dilations of the vessels of the spermatic cord may be consistent with varicose veins and may or may not affect blood flow and testis function. Measurements of the width (W), height (H), and length (L) of each testis can be used to calculate testis volume and to estimate expected daily sperm output by applying the following formulas: testis volume = $(W \times H \times L) \times 0.5233$ for each testis; daily sperm output = $(0.024 \times \text{testis volume}) - 0.76$, in which testis volume is the total volume, or the sum of volume for both testes.

The penis is usually examined while it is washed before the first semen collection. The penis can vary in size with no effect on fertility. It should be freely distensible from the sheath without lesions. Of the internal genitalia of the stallion, the ampullae, vesicular glands, and lobes of the prostate gland are palpable per rectum. The vesicular glands are difficult to palpate unless the stallion is first teased to a mare in estrus to stimulate filling of the glandular lumina with fluid. The bulbourethral glands are covered by muscle, making it impossible to palpate their structure. Transrectal ultrasonography can be used to more thoroughly evaluate each of the accessory sex glands and pelvic urethra. Because of the danger inherent in adequately restraining a stallion, some veterinarians perform a transrectal examination only if deemed necessary because of an abnormal finding on the remainder of the examination, such as blood or pus in the ejaculate. When performing palpation per rectum on a stallion, the internal inguinal rings should also be palpated to determine their size and presence

of any abnormalities. They are felt as flaps of peritoneum that form pockets in the abdominal lining at the 3 o'clock and 9 o'clock locations at the entrance of the pelvis.

Semen is collected from the stallion using an artificial vagina (AV) filled with water at ~50°C (~122°F), which typically cools to 42°–45°C (107.6°–113°F) by the time of collection; some stallions might be accustomed to higher AV temperatures (50°–55°C [122°–131°F]) for adequate stimulation, but the internal temperature of the AV should not exceed 55°C (131°F) at the time of semen collection. The stallion is teased to an estrous (or ovariectomized) mare; once an erection is achieved, the penis is washed with warm water and blotted dry with a paper towel. If the penile skin is suspected to harbor potentially transmissible bacteria (eg, *Klebsiella pneumoniae* or *Pseudomonas aeruginosa*), a culture swab of the sheath and fossa glandis should be obtained before the penile area is washed and rinsed for semen collection. Smegma can fill the dorsal urethral diverticulum, located dorsal to the urethral process, and harden to form a "bean." This can cause irritation and swelling and should be removed. After the penis is washed and dried, a swab sample of the distal urethra is obtained. The stallion is then allowed to mount the mare or phantom (breeding dummy), and the semen is collected by diverting the penis into the AV. A second swab sample is taken from the distal urethra immediately after ejaculation. The stallion should be given 1 hr of rest before the second ejaculate is collected.

The culture results of the urethral swab samples can be difficult to interpret. Prewash penile cultures usually show moderate to heavy growth of mixed bacteria. Preejaculate urethral swabs also may reveal growth of a mixed bacterial population. Growth of *Pseudomonas* or *Klebsiella* may indicate that the penis has been colonized by these organisms; in the USA these are the only bacteria (besides *Taylorella equigenitalis*, the cause of contagious equine metritis, see p 1371) that, in some cases, may be passed to mares and cause endometritis. The postejaculate urethral swab should yield less bacterial growth, because the urethra has been "washed" by the ejaculate. High numbers of bacteria, especially of a single species, on the postejaculate swab may indicate infection of the internal genitalia, most commonly the urethra and/or seminal vesicles.

The ejaculate should be evaluated for gross appearance, volume, sperm concentration, sperm motility, percentage of morphologically normal sperm, and

percentages of specific spermatozoal morphologic abnormalities. The ejaculate should be free of pus, urine, or blood. The normal ejaculate may contain gel, a viscous, clear to cloudy material, that originates from the seminal vesicles and forms the third and last fraction of the ejaculate. Because it is ejected last, the gel fraction can be removed by having an in-line filter at the mouth of the collection bottle in the AV (preferred), or alternatively, by pouring the ejaculate through a milk filter once in the laboratory.

The analysis of the semen is done on the gel-free (sperm-rich) fraction. Concentration may be determined using a hemocytometer or a properly calibrated photometric instrument. Several instruments specially designed for this purpose are commercially available. Sperm motility and morphology evaluations are performed as described for the bull (*see* p 2231); however, the sperm concentration is much lower in stallions (typically 100–400 million/mL), so only individual sperm motility is evaluated. Assessment of motility should be performed with both raw semen and semen diluted with a good quality extender. Semen should be warmed to 35°–37°C (95°–98.6°F) before assessing spermatozoal motility.

Notably, conventional measures of sperm quality correlate only moderately with fertility, and variations in the percentages of motile/progressively motile and morphologically normal sperm account for only 20% of the total variation in fertility. Given the limitations of standard sperm tests in predicting fertility or identifying subfertile stallions, other sperm tests have been evaluated and may be applied for stallion BSEs performed in referral centers. While not necessarily providing a better correlation with fertility, CASA offers a more objective and complete assessment of sperm motion characteristics. As in bulls, certain changes in different motion parameters, namely increases in curvilinear velocity and decreases in linearity and straightness, correlate with the acquisition of hyperactivated motility, which has been recently characterized in stallions. In addition, computer-assisted sperm head morphometry (shape) assessment has been suggested as a useful adjunctive test to predict stallion fertility. Membrane integrity can be easily evaluated via eosin-nigrosin staining (as in bulls), and the hypoosmotic swelling test or ability of sperm to swell to establish an osmotic equilibrium with a hypoosmotic surrounding medium may also hold some value for sperm membrane evaluation; however, a direct correlation with fertility has not been established. Fluorescent probes such as rhodamine 123

or JC-1 in conjunction with flow cytometry have also been used to evaluate mitochondrial potential and hence integrity. In addition, the combination of these with other fluorescent stains offers the advantage of concomitantly evaluating viability and chromatin integrity in a large number of sperm. In this regard, the sperm structure chromatin assay, which assesses sperm chromatin stability, has been thoroughly researched in stallions and moderately correlated with fertility. It is a good adjunctive test for stallions in which routine laboratory test results do not correlate with subfertility or infertility. Finally, true tests of sperm function (ie, ability to fertilize an oocyte) have been restricted because of the inability to capacitate stallion sperm *in vitro* or to perform *in vitro* fertilization in this species. Recent advances in this area may permit the application of these assays for more meaningful evaluation of stallion sperm.

In addition to assessing sperm quality, once two ejaculates have been collected, the total number of spermatozoa in each is calculated as volume (gel-free) $\times$ concentration.

The total number of sperm in the second ejaculate of two collected 1 hr apart is considered a rough estimate of the daily sperm output for that stallion (ie, ejaculates are considered to be representative if the second ejaculate contains about half the number of sperm as the first). The second ejaculate should have about the same, or a slightly higher, percentage of morphologically normal sperm, as well as the same or better motility than the first. If sperm numbers or quality differ from this guideline, then either prolonged sperm storage in the excurrent ducts has occurred (*see* below), or one of the ejaculates was not complete, and a third ejaculate should be obtained. The third ejaculate should have about half as many sperm as the second ejaculate, and the same or better morphology and motility. A third ejaculate may also be collected if the sperm evaluation does not appear to agree with the total scrotal width (eg, high sperm numbers from a stallion with small testes) or the calculated daily sperm output. Prolonged storage of sperm in the excurrent ducts results in high numbers in the initial ejaculate, but these sperm may have poor motility and morphology.

Some stallions with extreme sperm storage require daily collection for 7–10 days before representative ejaculates are obtained (sperm evaluation results are consistent on successive collections). In extreme cases, sperm may accumulate in the ampullae and inspissate, causing blockage of the ductuli

deferentiae. This may result in no sperm or few sperm, typically with detached heads, present in the ejaculate. Multiple attempts at collection may be necessary before the blockage is cleared. Relief of the blockage is typically evident by the ejaculation of very large numbers of dead sperm with detached heads.

In cases of severe ampullary blockage or in stallions with ejaculatory problems, attempts at semen collection might initially yield only clear seminal fluid. In such instances, it might be warranted to differentiate between these problems and azoospermia (ie, lack of sperm production) before successive semen collection attempts. For this purpose, collected seminal fluid can be submitted for determination of alkaline phosphatase levels. Because alkaline phosphatase concentrations are high in epididymal fluid, a value <100 U/L is consistent with blockage or ejaculation failure, whereas a value $>1,000$ U/L is consistent with collection of epididymal fluid and thus true azoospermia.

In a satisfactory potential breeding stallion, sperm numbers after >5 days of sexual rest should be ≥ 8 –10 billion in the first ejaculate and ≥ 4 billion in the second ejaculate. Total spermatozoal motility should be $\geq 65\%$, and progressive motility $\geq 50\%$. At least 50% of the sperm should be morphologically normal. A stallion is considered satisfactory if it produces at least 1 billion progressively motile and morphologically normal sperm in the second (or third) ejaculate of two (or three) collected 1 hr apart.

Stallions are classified as "satisfactory," "questionable," or "unsatisfactory" potential breeders based on the results of the above detailed examination. However, classification can be somewhat subjective, and an excellent finding in one category can balance a marginal finding in another. Satisfactory potential breeders should achieve a seasonal pregnancy rate of $>80\%$ when bred to 50 mares by natural breeding or to 120 mares by artificial insemination under normal management conditions. Questionable potential breeders may experience difficulty in doing the above. Typically, stallions are placed in this category if a problem is detected that might resolve over time with or without treatment; thus, a recheck is recommended within 6–12 mo. Unsatisfactory breeders have problems that may profoundly reduce their fertility or have undesirable heritable traits that may be transmissible to their offspring. Some stallions may be used to inseminate a percentage of mares with cooled-trans-

ported semen. Under these circumstances, longevity of spermatozoal motility should be tested using commercial semen containers before a decision is rendered regarding fertility potential.

BOARS

In postpubertal boars, testes should be symmetric (<1 cm difference), with each testis having a minimum length and width of 8 and 5 cm, respectively. Semen is collected with the boar mounted on a phantom or an estrous sow. As the penis is extruded, the tip (incorporating the coiled part) is grasped with a gloved hand and compressed; this stimulates full erection and ejaculation. The opening of the urethra is ~ 1 cm proximal to the tip of the glans, and care must be taken not to block it while applying digital pressure. The volume of semen is high, and ejaculation occurs over a long period, so semen is usually collected into an insulated container to maintain a relatively constant temperature. A filter or opened gauze sponge is fastened across the opening of the container to filter out gel and debris. Normal semen values for the boar are volume, 50–500 mL; sperm concentration, $>50 \times 10^6$ /mL; progressive motility, $>70\%$; total sperm per ejaculate, $>60 \times 10^9$; and percentage of morphologically normal sperm, $>80\%$.

DOGS

A complete breeding soundness examination (BSE) in dogs consists of a history, physical examination, semen evaluation, and testing for *Brucella canis*. If infertility is suggested from the history, it should be established that adequate breeding management was practiced and that bitches had normal fertility when bred to other dogs. The time sequence of litters sired and bitches that did not conceive should be recorded, as should any recent illness during or before the time the bitches were bred. These should be assessed to determine whether the infertility may be transient (eg, fever can adversely affect semen production for >60 days after the initial insult).

A general physical examination should be performed. Dogs with abnormalities such as severe joint disease or spinal problems may not be able to mount. Endocrinopathies such as hyperadrenocorticism or hypothyroidism may reduce fertility; these may be associated with abnormalities in weight or hair coat. The penis and prepuce should be examined; problems such as persistent frenulum, growths, or swelling due to

balanoposthitis may prevent normal intromission. Abrasions or lacerations on the penis may bleed during breeding, and blood may be seen in the semen.

The prostate should be digitally palpated per rectum. The most common prostatic problem in mature (>5 yr old) intact dogs is benign prostatic hyperplasia (BPH); the prostate appears uniformly enlarged and is not painful on palpation per rectum. Dogs with BPH might be asymptomatic or have a history of hematuria and/or hemospermia or rectal tenesmus. In dogs with clinical signs, the treatment of choice is castration, although breeding dogs can be treated medically with 5 α -reductase inhibitors, which prevent the conversion of testosterone to dihydrotestosterone. Treatment is important, because affected dogs are predisposed to developing prostatitis. Ultrasonography has become a common adjunctive tool for prostate evaluation in dogs, allowing for accurate measurements and assessment of the gland's echotexture for identification of potential pathologies, in which case a fine needle or biopsy instrument can be guided to sample a lesion.

The scrotum, testes, and epididymides should be palpated. Small, soft testes are usually associated with poor semen quality; greatly enlarged testes suggest orchitis or epididymitis. Lumps suggesting neoplasia may also be palpable. Scrotal abnormalities such as dermatitis may adversely affect semen quality by decreasing scrotal thermoregulation. Length, width, and height of testes should be measured with blunt calipers; these measurements are often of value for future comparison in cases of suspected testicular degeneration. Additionally, total scrotal width is highly correlated with body wt and an estimate of the dog's sperm production potential. Ultrasonographic examination of the scrotal contents is valuable not only to obtain more accurate measurements but also to evaluate for the presence of testicular or epididymal masses, which may not always be readily palpable in the early stages of a pathologic process.

Semen collection is performed with the dog on good footing (eg, a rug) rather than on a slippery surface or table. Care should be taken not to intimidate the dog; thus, any general examination procedures are best performed after semen collection. Semen may be collected in the absence of a bitch (although sperm numbers may be lower), but the presence of a bitch is preferable, especially for inexperienced dogs. The pheromone methyl paraben may be helpful for collection in the absence of a bitch; some

veterinarians freeze swabs of estrous bitch urine or vaginal secretions for this purpose, but the reaction of male dogs is variable.

A collecting cone such as the liner of a bull artificial vagina, lubricated with sterile nonspermicidal lubricant or petroleum jelly and attached to a test tube, can be used. The penile sheath is gently pulled back, and the cone is slipped over the penis. As soon as the bulbus glandis is exteriorized from the sheath and is within the cone, the penis is grasped through the cone, immediately caudal to the bulbus. Constant pressure is maintained caudal to the bulbus, and erection and eventually ejaculation should be achieved. Contact of the penis with the lubricated cone typically stimulates the dog to thrust into the cone, and the penis is compressed through the cone caudal to the bulbus as described above. Semen may also be collected with the gloved hand technique, by stimulating the dog's penis within the prepuce until a partial erection is achieved; the prepuce is then slid caudally, behind the bulbus glandis, and steady pressure is applied as with the cone technique until the dog ejaculates. A cup or tube fitted with a funnel is held over the tip of the penis to collect the ejaculate. Some breeders simply use a plastic bag held over the penis to collect semen.

The first (prostatic, clear) fraction and the second (sperm-rich, cloudy) fraction should be collected. After these fractions are ejaculated, close inspection of the collection tube should demonstrate that clear (prostatic) fluid is starting to layer on the cloudy second fraction; at this point, the collection may be stopped. The dog may continue to ejaculate prostatic fluid for up to 10 min before the erection subsides. The sheath should be examined after the penis is retracted to ensure that the penis is situated normally within the sheath and that no hair is caught within the sheath. Residual protrusion may occur if the sheath rolls inward as the penis retracts.

Semen evaluation consists of determination of appearance, volume, concentration, motility, and percent morphologically normal sperm. Yellow, brown, or red samples may indicate the presence of blood or urine in the ejaculate. The volume is variable, depending on how much prostatic fluid was collected and the size of the dog; it ranges from <2 to >20 mL but is typically ~5 mL. Sperm motility should be evaluated immediately using warmed equipment; this should yield >70% progressively motile spermatozoa. Sperm morphology is determined as for bulls (see p 2231). At least 80% of the sperm should be morphologically normal. The concentration is determined

using a hemocytometer. To do this, the sperm is diluted at 1:100, and the number of sperm in the large central square (made up of 25 smaller squares) on the hemocytometer is counted. The number of sperm counted $\times 10^6$ is the concentration of spermatozoa/mL. The total number of sperm in the ejaculate is calculated as volume $\times$ concentration. Total sperm number in the ejaculate ranges from 400×10^6 to $>1,000 \times 10^6$ and is correlated with body wt; as a general rule, a dog should produce $\sim 10 \times 10^6$ sperm/lb body wt.

Every dog investigated for infertility should be screened for *Brucella canis*. (See also BRUCELLOSIS IN DOGS, p 1402.)

Sperm quality may be normal or abnormal, or no sperm may be seen in the ejaculate. Infertility is rare in dogs with a normal sperm evaluation and, if seen, the history should be reviewed for mismanagement or bitch infertility. The presence of WBCs or RBCs in the ejaculate suggests inflammation of the tract, most commonly prostatitis; culture of prostatic fluid and appropriate treatment may help fertility. If sperm quality is abnormal, the history should again be reviewed to determine whether the dog has been sick recently or has received any drugs, especially anabolic steroids. Other recognized causes of abnormal sperm quality include inflammation of the scrotum or other factors that may be causing a high scrotal temperature, testicular neoplasia (ultrasonography of the testes is recommended because many neoplasms of the testes are not palpable), trauma to the area of the scrotum, or brucellosis. However, most cases of low sperm quality in dogs are idiopathic.

The dog's pituitary status can be investigated but is usually unrevealing. Luteinizing hormone and follicle-stimulating hormone are typically normal to high in dogs with abnormal semen quality, because the degenerating testes are not able to provide

the feedback mechanism to the pituitary. Because abnormal sperm quality may be induced by a recent transient disease or exposure to toxins, and spermatogenesis might resume, collections should be repeated about every 3 mo for ~ 1 yr before a definitive prognosis for breeding can be given.

Azoospermia is relatively common in dogs. It may be due to failure of the dog's testes to produce sperm, or to failure of the sperm to exit the testes because of epididymal blockage or incomplete ejaculation. As in stallions, the ejaculate may be tested for the presence of alkaline phosphatase, which is secreted by the epididymis. A high value ($5,000$ – $40,000$ IU/L) indicates fluid from the epididymis was collected and thus is consistent with true azoospermia. Low values ($<5,000$ IU/L) suggest epididymal blockage or ejaculation failure; semen collections should be repeated, using a strong stimulus such as a bitch in estrus. A cystocentesis should be performed after semen collection to determine whether retrograde ejaculation is occurring; swab samples of the vagina of a bitch after natural mating may also be performed to determine whether the dog is not ejaculating because of aversion to manual collection. Careful palpation and ultrasonographic examination should be performed to detect any abnormality of the epididymides or spermatic cords, such as absence (epididymal aplasia) or blockage of the epididymis.

A dog is considered "satisfactory" if all the above findings are within normal limits and the dog is seronegative for *B. canis*. Breeding dogs should be retested annually for *B. canis*. As in other species, "questionable" dogs are those with a condition that might resolve over time (eg, recent febrile episode with temporary testicular degeneration, BPH), whereas a dog with an untreatable condition or an inherited disorder is classified as "unsatisfactory" for breeding.

EMBRYO TRANSFER IN FARM ANIMALS

Embryo transfer has proved to be a powerful technology in genetic improvement of farm animals, primarily to propagate the genes of females of superior pedigree. In cattle, particularly in the dairy industry, breeding programs have been developed to promote genetic progress by

strategic use of elite females through multiple ovulation embryo transfer (MOET) programs. In addition to conventional methods to produce embryos available for transfer, new technologies that produce embryos after cloning by somatic cell transfer or transgenesis are

available but not widely used commercially.

Embryo transfer protocols have also been extensively used in research critical to understand several areas of biology and medicine, such as fetal-maternal interactions, models of human and animal diseases, production of transgenic animals to produce therapeutic proteins for people, etc. However, this discussion is restricted to the principles and methods currently used in commercial embryo transfer of farm animals. Except in horses, embryo transfer programs in most mammals include administration of drugs that superovulate females to allow the probability that multiple embryos are collected per procedure. Globally, it was reported in 2012 that 699,586 bovine embryos were collected from superovulated cows, and 443,533 bovine embryos were produced via in vitro fertilization procedures.

CATTLE

Although collection of a single embryo is occasionally done in cattle, the vast majority of embryo transfers in cattle are programmed after a hormonal treatment to superovulate donor cows and to maximize recovery of embryos during the collection procedure. In cattle, there are two generally accepted methods of superovulation. One method consists of administering a single IM injection (2,000–2,500 IU) of equine chorionic gonadotropin (eCG), typically on day 10 of the estrous cycle (in which day 0 is defined as the day cows are observed in estrus), followed 2–3 days later by two injections of prostaglandin $F_{2\alpha}$ (dinoprost or cloprostenol) 12–24 hr apart. The other commonly used method is to administer follicle-stimulating hormone (FSH). The superovulatory response induced by eCG treatment is often greater than that induced by FSH; however, more embryos of transferable (good) quality are produced on average after FSH treatment. For this reason, FSH has become the method of choice of superovulating cows for commercial use. The two most commonly used commercial FSH preparations are made from porcine pituitary extracts and contain some contamination with luteinizing hormone (LH). Whereas high amounts of LH in FSH preparations may interfere with optimal superovulatory response, it is believed that a low level of LH contamination does not interfere and may even be needed for superovulation.

Although some good results have been reported with a single administration, FSH

is typically administered (IM) over 4–5 consecutive days, twice daily in decreasing doses. Both commercial FSH preparations can be diluted into 20 mL of saline solution and given over 4–5 days. A typical 4-day FSH treatment protocol is as follows: day 1, 4 mL bid; day 2, 3 mL bid; day 3, 2 mL bid; day 4, 1 mL bid (total volume = 20 mL). FSH treatments typically begin on day 10 after estrus. On the third or fourth day of FSH treatment, a luteolytic injection of $PGF_{2\alpha}$ is given and repeated 12 hr later. Estrus can be expected 36–48 hr later, and the artificial insemination can be scheduled based on the observed heat (12 and 24 hr after onset of estrus) or by appointment (72, 84, and 96 hr after the administration of $PGF_{2\alpha}$) that is accompanied by administration of an agent to induce ovulation, human chorionic gonadotropin or gonadotropin releasing hormone (GnRH). Many variations of methods to increase the efficiency of superovulation programs in cattle exist. For example, the induction of a new follicle wave before gonadotropin treatments is desirable to increase the ovary response to superovulatory treatments. Injections of estradiol or GnRH, or transvaginal aspiration (follicle ablation) of the dominant follicle (known as dominant follicle removal [DFR]) are examples of approaches to induce a new follicle wave. A new follicle wave emerges 4, 2, or 1–2 days after treatments with estradiol, GnRH, or DFR, respectively. Responses to gonadotropin treatments to induce superovulation are best when treatments are started when the follicle wave emerges. These treatments aim to promote a more uniform follicle recruitment and growth that ultimately may result in more viable embryos per procedure. In the USA and many other countries, the use of estrogen preparations is not approved for use in reproduction.

Management of recipients can be done after observation of natural estrus or based on synchronization protocols. In either scenario, a luteolytic dose of $PGF_{2\alpha}$ is given ~12 hr before the first treatment of $PGF_{2\alpha}$ of donor cows. Recipient cows ovulating on the same day as donor cows are preferred for embryo transfer, but asynchrony of ± 1 day has produced pregnancy rates comparable to those of perfectly synchronized recipients. It is expected that 75%–90% will respond to the superovulation treatment, but 20%–30% of flushed cows do not produce embryos of transferable quality. Among those cows that successfully respond to the FSH treatment, the variability in producing good quality embryos is very good (from 0 to >20 per flush). On average,

a production of 5–7 embryos of good quality per embryo collection is considered a good commercial outcome.

Embryo collection is done on day 7 of the cycle when uterine stage embryos (morula and blastocysts) are expected to be recovered. Before the embryo collection, the donor cow is palpated and the ovarian response to the superovulation treatment assessed manually by determining the number of palpable corpora lutea in the ovaries. The procedure to collect the embryos from the uterus (flush) involves the following steps: 1) An epidural with 5–7 mL of lidocaine is given. 2) The perineum is carefully washed with hand soap or an antiseptic scrub (chlorhexidine or iodine); depending on the animal and cervical size, a 12–24 French Foley-type catheter placed over a metal rod (stylet) is introduced in the vagina as the palpating arm is placed in the rectum to manipulate it through the cervix. 3) Once inside the uterus, the catheter is advanced beyond the uterine body until it is located at the first third of one of the uterine horns; the rod inside the catheter is then withdrawn and the cuff is inflated with 15–20 mL of air, depending on the size of the uterine horn, which varies with breed, age, parity, etc. 4) Each uterine horn is then flushed with commercially available, complete, and ready-to-use flushing media; these embryo flushing solutions also contain antibiotics and bovine serum albumin as a source of protein. Some commercial preparations of complete flush media also contain surfactants to minimize the formation of foam and bubbles in the embryo search dish. In the past, the flush media had to be prepared for each collection and consisted primarily of Dulbecco's phosphate buffered saline with added antibiotics and 1% fetal/calf bovine serum (or alternatively, 0.1% bovine serum albumin); around the world, many flushes are still prepared in this manner. 5) The uterine horn may be lavaged by repeated small volume (25–50 mL) infusions of flush media that are allowed to drain into an embryo filter. Alternatively, the uterine horn may be flushed continuously; 1–2 L of flush media is used to flush a cow uterus. 6) After the flush is completed, the cuff is deflated and the contents of the catheter are carefully allowed to flow into the embryo filter located at the end of the outflow tubing. 7) The embryo filter is then taken to the laboratory, and its contents are dispensed into a search dish with grid and visualized using a stereoscope (dissecting microscope) at 10× magnification.

All embryos are transferred to a clean dish (with wells) containing holding media similar in composition to the flush media except for a higher concentration of bovine fetal/calf serum (10%–20%) or bovine serum albumin (0.4%). As with flush media, complete holding media are also available commercially. Embryos are then visualized at a higher magnification (40–60×) and classified according to their morphology, stage of development (unfertilized oocytes, early morula, tight morula, blastocyst, expanded blastocyst, hatched blastocyst, etc), and quality (excellent, good, fair, poor, degenerate). The quality score is based on morphologic assessment of the physical integrity of embryos and morphologic characteristics according to the stage of embryonic development, compaction status, color of cytoplasm, areas of cellular degeneration, number of extruded blastomeres, size of perivitelline space, and the size and sphericity of the embryo.

Only embryos classified as fair, good, or excellent should be transferred. Embryos are kept in holding media after being "washed" at least three times. Embryo washing is performed by transferring embryos into different, clean wells containing holding media. This procedure, recommended by the International Embryo Transfer Society, aids in removing cellular debris and potential pathogens adhered to the zona pellucida. Embryos are kept in holding media at room temperature until they are transferred to recipients or prepared for freezing, bisection ("splitting"), or determination of gender by embryo sexing. Alternatively, embryos can be refrigerated in transfer medium for up to 24 hr with no appreciable loss of viability. Splitting embryos into identical halves by microsurgery is practiced by a few commercial embryo transfer teams. The number of embryos to be transferred can be doubled with only a minor reduction in pregnancy rates. However, techniques to freeze manipulated embryos require improvement.

Since 1978, the current preferred and most common method to transfer cattle embryos into synchronized recipients is via nonsurgical techniques. The embryo is loaded into a small plastic straw (0.25 mL) fitted into a specialized (Cassou-type) insemination "gun." The embryo transfer gun is then placed into the vagina protected by a disposable sterile coversheath to prevent contamination of the tip of the gun with potential perineal and vaginal contaminants. The gun is passed through the cervix, aided by palpation per rectum, and advanced into the uterine horn ipsilateral to the corpus luteum. The contents of the straw are then

deposited as cranial as possible into the uterine horn with care to avoid prolonged and unnecessary manipulation. After direct transfer of single fresh embryos, 60%–70% of recipients are expected to become pregnant; transfer of two embryos may result in pregnancy rates as high as 90%. A significant proportion of bovine embryo transfers are made with frozen-thawed embryos (~46%) and, with good management, pregnancy rates routinely are >50%. Under the same management conditions and well-trained staff, the pregnancy rate of frozen-thawed embryos is expected to be 10% lower than that derived from transfers of fresh bovine embryos. Although increased pregnancy rates may be obtained with transfer of multiple embryos, the risk of dystocia and retention of fetal membranes associated with twin pregnancies and the increased probability of producing freemartin calves preclude widespread use of this approach. The use of sexed semen in embryo transfer programs is considered economically viable, especially if attention is given to inseminate donor cows with sperm numbers comparable to those used in artificial inseminations with conventional nonsorted semen.

SHEEP AND GOATS

The amount of embryo transfers done in small ruminants are a fraction of those recorded for cattle. Globally, almost 900,000 embryo transfers were reported for cattle in 2012, while only 12,458 were reported for sheep and 1,013 for goats. In addition to commercial and market factors limiting the production of embryos in small ruminants, current embryo transfer techniques in sheep and goats almost exclusively consist of surgical and/or laparoscopic methods for embryo collection and transfer.

Donor and recipients are synchronized using progestagens with an injection of PGF₂α given on the day the intravaginal progestagen device is inserted. Because of the additional superovulation hormonal treatment donor females receive, recipients come into estrus earlier than donor ewes and does; therefore, the progestagen source (typically an intravaginal device) in recipients is removed 12 hr before it is removed in donors.

FSH is commonly used to superovulate small ruminants. As in cattle, FSH is commonly administered twice daily in a series of decreasing doses administered over 3 days (eg, day 1 = 5 and 5 mg; day 2 = 3 and 3 mg; day 3 = 2 and 2 mg). On the last day of FSH treatment, the progestagen source is removed and a luteolytic injection of PGF₂α

given. Estrus is typically detected by vasectomized bucks/rams; artificial insemination should take place 12–24 hr after estrus is detected or 45–50 hr after progestagen removal. Intracervical or transcervical artificial insemination is difficult and requires advanced training and practice. Increased pregnancy rates are obtained by laparoscopic artificial insemination, because it allows the semen to be deposited in the cranial aspect of the uterine horns.

Surgical embryo collection is still very common, but laparoscopic and nonsurgical transcervical catheterization procedures are consistently improving and yielding good results, albeit still lower than those obtained with surgical methods. Embryos are collected 7–8 days after estrus.

PIGS

Embryo collection and transfer in pigs is not yet done commercially or as intensively as in ruminants. Until recently, embryo transfer in pigs was primarily performed for research purposes. In 2012, Canada, France, and Ireland were the only countries to report the commercial collection and transfer of 2,478 swine embryos. Owing to the high ovulatory rate in sows, superovulation treatment may or may not be used in embryo transfer procedures. Embryo collection can be done soon after a genetically valuable sow is slaughtered and the reproductive tract is collected for embryo retrieval. Surgical collection of embryos is also performed using ventral laparotomy of the caudal abdomen. Most embryo transfers are performed using surgical techniques (abdominal ventral laparotomy under general anesthesia). Recently, nonsurgical techniques to collect and transfer porcine embryos have been developed and proved successful, but they require specialized equipment and highly skilled individuals. Embryos are typically collected 4–7 days after ovulation. Current pregnancy rates with nonsurgical techniques remain lower than those obtained after surgical embryo transfers. Embryos should not be transferred to the uterine body, because this results in low pregnancy rates. The transfer of 16–22 embryos per recipient is recommended to achieve optimal pregnancy rates.

HORSES

Embryo transfer in the equine industry has been primarily used to obtain offspring from mares with restricted reproductive potential (mares with undiagnosed subfertility,

uterine pathologies, or simply older mares) or from performance mares that must remain nonpregnant to continue to compete. Most breed associations allow the registration of foals born by embryo transfer, and an increasing number now allow the registration of multiple foals born in the same year. Because of this recent increased acceptance by breed registries, many horse breeders have obtained several foals in one breeding season from a single donor mare.

Superovulating mares with a purified form of equine follicle-stimulating hormone extract preparation (eFSH) to increase ovulation and embryo recovery rates is no longer commonly done commercially. Difficulties with manufacturing suitable gonadotropins and the variable response of mares to FSH stimulation have precluded widespread commercial use of this approach to produce equine embryos. It was thought that the low embryo recovery rate in mares ovulating >4 follicles/ovary could be attributed to an inability of the ovarian fossa to accommodate multiple ovulations in that area, or alternatively, excessive response to the FSH stimulation could result in dysmatured oocytes.

A recent advance in embryo transfer technologies in commercial settings has been the possibility of producing in vitro equine embryos using intracytoplasmic sperm injection (ICSI). Frozen semen from deceased stallions can be efficiently used to produce in vitro embryos by using only a portion of a frozen semen straw to provide sperm for the ICSI procedure. The number of ICSI-derived equine embryos is expected to continue to increase sharply during the next few years.

The horse embryo is notoriously challenging to cryopreserve, probably owing to its relatively large diameter and the presence of an embryonic capsule that limits interaction between cryoprotectant agents and the embryo. Embryos of morula or early blastocyst stage (<6.5 days after ovulation) are preferable for cryopreserving, because after thawing, older embryos have invariably low morphologic quality that results in poor pregnancy rates. A vitrification media for horse embryos is commercially available, and acceptable pregnancy rates varying from 40%–60% have been reported. Successful cryopreservation of expanded equine blastocysts also has been reported for embryos that had their blastocoels collapsed after embryo biopsy procedures.

Because one of two embryos are typically recovered from the donor mare, it is important that breeding soundness evaluations are done for both donor and

recipients. Daily ultrasonography of the uterus and ovaries of donor and potential recipient mares during estrus provide critical information about the time of ovulation, which is essential for determining the day of ovulation and day of embryo collection and to assist in the selection of qualified recipient candidates for embryo transfer.

Nonsurgical techniques are currently used to collect and transfer horse embryos. Embryo collection is usually performed on day 7 or 8 (day 0 = ovulation). The use of good standard techniques generally yields a recovery rate of ~75%; this rate can be as high as 90% for young maiden or fertile mares or as low as 10%–20% in subfertile mares. Before embryo collection, palpation per rectum and ultrasonography are performed mainly to document the presence of the corpus luteum, the degree of cervical tone, and absence of any fluid in the uterus. Mild soap or povidone-iodine scrub can be used to wash the perineal region, followed by a thorough rinsing with clean water.

Sedation is not used in most cases, but it may be needed when working with uncooperative mares. Acepromazine should be avoided, because it may cause relaxation of the uterus and potentially impair fluid recovery or manipulation of the reproductive tract during flushing of the uterus; sedation with an α_2 -agonist (eg, xylazine, detomidine) is preferred. Embryo collection is performed using a routine transcervical uterine lavage procedure, using a silicone catheter with an inflatable cuff. Using sterile technique, the silicone catheter (28–34 in. long, French size 28–37, depending on the size of the reproductive tract of the mare) is introduced through the cervix into the uterus, and then the balloon is inflated (typically 60–80 mL) with air or collection medium; the catheter is then gently pulled back so the cuff seals the internal cervical os. Complete flush media with antibiotics, surfactant, and bovine serum albumin is available commercially and ready to use. Alternatively, as with cattle, flush media can be prepared with Dulbecco's phosphate-buffered saline and 1%–5% fetal bovine serum; 1–2 L are infused into the uterus and then allowed to flow back into a graduated cylinder or plastic bucket to measure the recovered volume. Once the uterus is filled, it can be gently manipulated per rectum to aid the recovery of fluid. An embryo filter equipped with a 75-micron mesh is usually connected to the end of the outflow tubing to yield ~40–60 mL of fluid. In some cases, an injection of oxytocin (10 IU) may be given to minimize the retention of a large amount of flush media in the uterus. The recovered fluid should be clear and free

of significant amount of debris and blood. Nearly 100% of the fluid used to lavage the uterus should be recovered. A total of 4–8 L of flush media is used to complete the embryo collection procedure (flush). If retention of fluid is suspected or if the outflow of media is interrupted, transrectal ultrasonography may be used to assess the presence of intraluminal fluid. A common cause of interrupted outflow drainage of flush media results from placing the tip of the catheter intracervically and not in the body of the uterus: the media easily flow into the uterus but not outward.

Once the flush is completed, the remaining fluid in the filter is searched in a sterile dish with grid under a magnification of 15× using a stereomicroscope. Once the embryo is found, it is transferred to a well in a sterile tissue culture dish containing holding media (commercial, ready-to-use with 0.4% albumin or made with Dulbecco's phosphate-buffered saline plus 10%–20% fetal bovine serum). The embryo should be washed at least 3 times by transferring into two other wells previously filled with holding media. Embryo manipulation is done with a 0.25-mL straw connected to a tuberculin syringe with a 16-gauge needle, a 0.5-mL straw directly connected to a tuberculin syringe, or a capillary pipette (20 μ L) attached to a tuberculin syringe. After being washed, the embryo should be transferred to a recipient mare (within 1 hr) or prepared for short storage and transportation. The stage of the embryo (morula, early, or expanded blastocyst) and quality (1, best; 5, dead) should be recorded.

Although surgical transfer of equine embryos was once thought to yield higher pregnancy rates than nonsurgical transfer techniques, the latter are now the preferred method to transfer horse embryos. Recipient mares should be reproductively sound and in good body condition and health. Synchronization of ovulation should be maximized by hormonal manipulation of

the estrous cycle and daily transrectal ultrasonography. Good pregnancy rates result from using recipients that have ovulated from 1 day before the donor to 3 days after the donor. In addition, progestagens such as altrenogest may be used until the day of pregnancy examination 4–5 days after the transfer (~12–13 days of gestation).

The nonsurgical embryo transfer is performed using transcervical catheterization. Plastic straws, 0.25 or 0.5 mL, are used to load the embryo; the column of medium containing the embryo should be surrounded by two small columns of air, which are in turn surrounded by two columns of medium. The straw loaded with the embryo is fitted into an embryo transfer “gun.” Embryo transfer sheaths with side delivery can minimize embryo damage during the transfer procedure.

Preparation for Short Storage and Transport:

Horse breeders without an adequate number of recipients and veterinarians with modest investment in equipment can collect embryos and prepare them for short storage and transport to a centralized embryo transfer facility. Pregnancy rates do not appear to differ from those obtained with fresh embryos, especially if embryos are shipped counter-to-counter on the same day they are collected. Embryos are routinely shipped in commercially available holding media that are ready-to-use preparations containing 0.4% bovine serum albumin and antibiotics. The embryo is placed into a 2-mL polypropylene cryotube vial or a 5-mL snap-cap tube that contains the holding media. The tube with the embryo is then placed into a semen shipping container designed to cool and transport horse semen. The container is preferably shipped to an embryo transfer facility on the same day the collection is performed using an airline carrier (counter-to-counter) or processed for overnight delivery using a commercial carrier.

HORMONAL CONTROL OF ESTRUS

Hormones are commonly used to manipulate the estrous cycle. The major indications for hormonal control of estrus are to induce luteolysis, induce ovulation of a mature follicle, suppress estrus, induce cyclicity in anestrus

animals, and superovulate cyclic animals. Effective treatments for these manipulations vary among species. A number of treatments currently lack regulatory approval; label instructions should be followed.

HORSES

Estrous behavior may be undesirable in performance horses and can be suppressed in mares by administration of progestagens, either progesterone in oil (150–300 mg/day, IM) or altrenogest (0.44 mg/kg/day, PO). In the past, oral progestagen was preferable because of muscle irritation from the injectable preparation. However, progesterone in a biorelease vehicle is available by prescription from a compounding pharmacy. This preparation (1.5 g, IM) is administered once every 7–10 days. Treatment with progestagens for 15 days during the late transition season can advance the first ovulation of the year by ~10 days. Although these preparations suppress estrous behavior, they may not effectively suppress follicle growth and ovulation in cyclic mares.

Ovulation may be synchronized in mares by administration of progesterone in oil (150 mg) and estradiol 17 β in oil (10 mg/day, IM, for 10 days) with prostaglandin F $_{2\alpha}$ (PGF $_{2\alpha}$; 10 mg, IM) administered on the tenth day. Progesterone plus estradiol in a biorelease vehicle is also available by prescription from a compounding pharmacy. Mares should come into estrus ~3 days after the end of treatment, and 85% of mares ovulate 9–13 days after the end of treatment.

Estrus may be induced in diestrous mares (having a corpus luteum that is 5 or more days postovulation) by treatment with PGF $_{2\alpha}$ (10 mg, IM) or cloprostenol (250 mcg, IM) to lyse the corpus luteum. Mares should return to estrus in ~3 days and ovulate an average of 9–10 days after prostaglandin treatment. The time to ovulation is variable, however, depending on the size of the largest follicle on the ovary at the time of prostaglandin administration. PGF $_{2\alpha}$ causes numerous transient adverse effects in horses, including sweating, colic, and trembling. Greatly reduced doses of cloprostenol (25 mcg) also effectively induce luteolysis in mares while virtually eliminating the unwanted adverse effects of PGF $_{2\alpha}$. However, although widely used in mares, cloprostenol is labeled only for use in cattle. Prostaglandin causes luteolysis of a mature corpus luteum and so does not induce estrus in anestrus mares.

Behavioral estrus may be induced in anestrus or ovariectomized mares by administration of estradiol 17 β in oil (1–10 mg, IM) or estradiol cypionate (0.5 mg, IM). Mares should show estrus 12–24 hr after injection. This estrus is not associated with follicular growth and is not fertile.

Treatment with estradiol cypionate is longlasting, but repeated or high doses may cause aggressive or defensive behavior when the mare is approached by a stallion. Treatment with estrogen in the presence of progesterone (eg, in a cyclic mare in diestrus) will not induce estrous behavior.

Ovulation may be induced in mares with mature preovulatory follicles (>33 mm diameter) by administration of human chorionic gonadotropin (hCG), 2,500 IU, IV; by administration of a deslorelin implant, 2.2 mg, SC; or by administration of deslorelin, 1–2 mg, IM, in a biorelease vehicle. Ovulation is seen in 85% of mares within 48 hr, typically 36–42 hr after hCG or injectable deslorelin treatment or 40–44 hr after treatment with a deslorelin implant. Repeated use of hCG over a long period is associated with antibody formation and may decrease response to treatment; this has not been seen with deslorelin. Use of deslorelin in implant form has been associated with periods of anestrus in treated mares, especially if the corpus luteum of ovulation is lysed with prostaglandin. For this reason, many veterinarians remove the implant after ovulation is seen; this is easily performed if the implant is placed in the vulvar mucosa.

Mares do not superovulate in response to equine chorionic gonadotropin (eCG), and they do not respond well to follicle-stimulating hormone (FSH) derived from other species, but they may be superovulated (average of three to four follicles ovulated) by treatment with equine FSH (no longer commercially available in the USA). GnRH given at 2–20 mcg/hr (by infusion pump) throughout ~10 days induced normal follicular growth and ovulation in anestrus mares; the larger dose induces superovulation (average of three follicles). Cyclicity has also been induced in anestrus mares by treatment with 200 mcg GnRH every 6 hr, 500 mcg GnRH every 12 hr, or by administration of a GnRH agonist, buserelin (10 mcg, SC), every 12 hr plus hCG (2,500 IU, IV) once a follicle has reached 35 mm in diameter. The dopamine receptor antagonist domperidone (1.1 mg/kg/day, PO) alone or in combination with GnRH (250 mcg, SC, qid) has also been used to stimulate follicular development in mares with quiescent ovaries.

CATTLE

In cows, ovulation may be synchronized with a progestagen and estrogen combination treatment, a two-dose prostaglandin regimen, or a GnRH and prostaglandin

combination. Administration of PGF₂α (25 mg, IM) or prostaglandin analogue (cloprostenol at 500 mcg, IM) to cows with a corpus luteum from 5 days after ovulation results in estrus in ~2–5 days. Two prostaglandin injections given 12–14 days apart synchronize estrus and ovulation in most cows. Time to estrus is more variable than with progesterone suppression, so insemination should be based on detection of estrus. Ovulation may also be synchronized by administration of GnRH, 100 mcg, IM (day 0), followed by prostaglandin treatment on day 7 and a second GnRH treatment on day 9. Cows should be inseminated 0–20 hr after the second GnRH treatment. This GnRH and PGF₂α protocol is termed “ovsynch.” There are many variations on this protocol, using additional steroids, prostaglandin, or GnRH treatments, that may increase the degree of synchrony or pregnancy rates after artificial insemination.

A progesterone-releasing intravaginal device (PRID) consists of micronized progesterone distributed homogeneously in an inert silicone rubber coated onto a cylindrical stainless spiral coil. The PRID is maintained in the vagina for 7 days, and a luteolytic dose of PGF₂α is administered 1 day before or at “pull-out” day. There are no milk or meat withdrawal requirements. In noncycling animals, an injection of equine chorionic gonadotropin (eCG) is administered when the PRID is removed.

A controlled intravaginal drug-release (CIDR) device may also be used for estrus synchronization. A CIDR is an intravaginal device constructed of a progesterone-impregnated medical silicone elastomere molded into a T-shape. It is labeled for estrus synchronization in beef and dairy cattle. Cows are administered GnRH, and concomitantly a CIDR is inserted and maintained for 7 days. At the time of removal, cows receive an injection of PGF₂α. Cows can be inseminated, with or without another GnRH injection, 48–72 hr after PGF₂α injection. The most effective synchronization treatment, an IM injection of a combination of 5 mg estradiol valerate and 3 mg norgestomet, with an ear implant of 3 mg norgestomet left in for 9 days, is no longer commercially available in the USA because of the ban on the use of estrogens in food animals. Note that all estrus synchronization protocols are less effective in *Bos indicus* cattle and *B. indicus* crossbreeds than in *Bos taurus* cattle.

Melengestrol acetate (MGA) is a steroidal progestagen used as a feed additive to promote growth and suppress estrus in heifers. MGA is used at a dosage of 0.5 mg/

head/day for 14 days for estrus synchronization. Fertility after this treatment is low, and females should not be bred. This protocol could be improved by administering PGF₂α 17 days after the last feed containing MGA. The fertility of this estrus is reestablished.

Ovulation may be induced in cows with mature follicles (10–15 mm diameter) by treatment with GnRH at 100–250 mcg, IM; luteinizing hormone (LH) at 25 mg, IM; or hCG at 5,000–10,000 IU, IM. Because the endogenous LH peak develops at the onset of estrus, this administration will not speed the time of ovulation in estrous cows but may be used to ensure luteinization in cows with histories of cystic ovarian disease or to induce ovulation in anestrus postpartum cows.

Superovulation may be achieved in cows by treatment with eCG (not currently commercially available in the USA) in mid-diestrus followed by prostaglandin-induced luteolysis 2–3 days later, or by treatment with FSH (potencies differ, refer to label instructions), typically IM, bid for 4–5 days, at a decreasing or constant dose with administration of prostaglandin (25–35 mg, IM) usually on day 3 or 4 of treatment. FSH treatment is discontinued at the onset of estrus.

GOATS AND SHEEP

In cycling goats, luteolysis may be induced by administration of PGF₂α (2.5–5 mg, IM) or cloprostenol (62.5–125 mcg, IM) as early as day 3. In sheep, PGF₂α (≥15 mg) or cloprostenol (125 mcg) is effective after day 5 of the cycle (estrus is day 0). Estrus may be synchronized by two doses of prostaglandin, 11–13 days apart in does or 7–9 days apart in ewes. Estrus may also be synchronized in cyclic or anestrus does and ewes by administration of progestagens; impregnated intravaginal sponges (medroxyprogesterone or flurogestone) have been the most widely used agents for control of ovulation but are not currently available for clinical use in the USA. In small ruminants, a controlled internal drug release (CIDR) intravaginal plastic device impregnated with progesterone (300 mg) can also be used. The CIDR is maintained in the vagina for 7 days, and a luteolytic dose of PGF₂α administered 1 day before or at device removal. The estrus response is high within 72–84 hr. A portion of a bovine norgestomet ear implant (1.5-mg/goat) or injection of progesterone in oil (10 mg/day, IM) has also been effective. In sheep and goats, the ear implant is placed subcutaneously near the base of the ear or the base of

the tail and then removed 7–9 days later. Progestagen treatment is administered for 10–14 days in sheep and for 14–21 days in goats. Ewes should be joined with rams the day after cessation of treatment; does return to heat on the second or third day after treatment ends. Injection of equine chorionic gonadotropin (eCG; 100–500 IU) at the end of treatment increases synchronization of ovulation or ovulation rate.
